You are going to come in contact with many patients who come to you in your office, in clinic or in hospital, complaining of various pains, discomforts and disorders in different parts of their bodies, where complete examinations and accurate laboratory test, disclose no organic pathology whatever. Many times you will meet confusion, doubt and despair in attempting to arrive at a proper evaluation of the situation at hand. Frequently, it will take every particle of honesty you possess to treat these cases. Even after a consideration of all the facts at your disposal, often, diagnosis will be impossible. If you have learned to include in your routine examinations and histories, not only an account of the frank physical symptomatology, but in addition, facts relative to the life situations and environmental influences in which the person lives, something about his usual emotional reactions, his desires, hopes and ambitions, his discontents, his defeats and his inner habit patterns of reaction to responsibility, disappointment, frustration and failure, frequently, you will be surprised to discover causes for what otherwise would seem bizarre and inconsistent physical symptoms. You will bring about occasionally, what seem to be miraculous cures if you will but include in your histories, and give full value to the facts or psychic insult, as well as of physical trauma, to psychopathology as well as to physical pathology.

working, suddenly appeared in the office with an engagement ring upon her finger, and with the news that our patient's fiancé had given it to her.

It was on the day following the above reported episode that the onset of the fatigues syndrome appeared. The threat to this woman's ego was simply too great for her to tolerate. Her unconscious instinctive mechanisms got to work, interrupted the smooth running of the autonomic system and produced the sensory symptoms, the real origin of which had not been discovered. The ultimate purpose of the whole movement was to get the young woman out of the intolerable emotional situation of being a daily witness to the happiness of her former fiancé and her more successful rival. The associations attached to her work, her office and her former relationships became too painful to accept, consciously. It was then that the unconscious mechanisms began to operate to remove her from the painful situation.

In an analysis of a thousand cases of so-called neurasthenia, it will be found that the outstanding symptom in at least eighty per cent of the cases, is an overwhelming sense of fatigue. Now this sense of fatigue is not real fatigue. Can we say that it is imagination? Not at all. What, then, justifies us in saying that it is not real fatigue? We all know that real fatigue is one of the most delicious sensations of the body. It produces a restful sense of relaxation, repose and peace. This sense of fatigue seen in the neuroses on the other hand does not produce rest and relaxation, it brings on a continual restlessness in which the person is tense and unable to rest, relax or sleep. In the former condition, rest results in a feeling of restoration of energy, in the latter, attempts at rest produce still greater sensations of fatigue and restlessness.

Neurasthenics are not suffering with real exhaustion, and they do not need rest or rest cures, as we ordinarily understand the term. Neither are they suffering with any organic changes within the nerve structures. In that state of mind known as the nervous breakdown, there is no actual structural breakdown in the nerves themselves. Rest only makes the individual even more sensitive to the sensory disturbances with which he is suffering. He needs change, perhaps, but he does not need rest. What he needs most is insight into the real, subjective dynamics of the symptoms, a better understanding of his personality and a better objective philosophy of life upon which to live.

This young woman for example, gradually recovered as she developed, over a period of several months, a real understanding of the subjective origin, nature and meaning of her symptoms and when she began to live upon a well planned intelligent scheme of objective living

Frank recognition of the dynamics of her unconscious habit patterns and her personality defects, and an honest attempt to eradicate or modify them through a direct, voluntary attempt to keep her thoughts and acts relevant to a new objective, brought to her finally a degree of health wholly unimagined in her former mode of living. But see the terrific price she paid for her new knowledge. What an indictment that this woman was permitted to go through the painful diagnostic surveys, the need less surgical explorations and the economic loss of time, simply because no one took the time or trouble to inquire into the emotional circumstances of her life and the habit patterns of her personality?

There is yet another interesting group of cases which falls into the class of sexual neuroses. The literature of modern medicine is filled with their descriptions. The following case taken from our own records illustrates certain of the polymorphic expressions of this type of difficulty.

A man of thirty-eight years, a graduate of one of the best eastern universities and of an excellent law school, comes for advice about a physical syndrome which invariably appears when he goes through a love affair. Three times in his life he had fallen in love and became engaged and each time when the engagement was announced or plans were made for marriage he was obliged to withdraw from the situation because of the development of a prolonged "nervous breakdown" in which the outstanding symptoms were anxiety, with muscular weakness, dizziness, lack of concentration, nocturnal emissions, indecisions, terrifying dreams, headaches and anorexia.

After the third affair of this nature he began to suspect that the physical symptoms might have some correlation with the emotional condition concurrent with the episodes. Investigation into the facts of the case proved him to be correct in his assumptions. This man's father was a judge of a high court and also sat as an elector in the House of Bishops of a prominent denomination. He boasted about his "ideas" on the correct methods of bringing up children. For years his three sons were not permitted to leave the house after the evening meal. They were allowed but few opportunities to come in contact with the normal activities of boys and girls of their own ages except in those forms of entertainment occurring within the church society and under the strict supervision of correct chaperonage. They were made exceptionally dependent upon their mother in all things, and especially in their human relationships. The father frequently lectured to them about the "social sins" as he called them, and painted his descriptions of the sexual diseases in lurid colors. He told them with great seri-

ousness that the young man who had carnal knowledge of woman before wedlock was eternally damned in the eyes of the moral world. He explained that no one but a moral leper would dare kiss or touch the person of a woman except she be his wife. He built up such a pure, moral picture of woman and such a disgusting immoral picture of sex that not one of the three sons could bring himself to break through the unconscious forbiddenness which this ignorant man built up in their immature minds, and go into marriage. I am not complaining so much of the fact that this man told his boys something of sex as I am of how he did it. His motives were sound, but his technique was unforgivably stupid and its consequences almost permanent.

In his adult difficulties this patient was unable to break away from the non-logical habit patterns of thought that had been made for him by the hyper-moral and overemotional attitudes of his father, because they had been pushed so far away into his unawareness by the pressure of time that they performed, automatically, the non-conscious function of prohibiting him from making any prolonged or close relationships with a person of the opposite sex.

In each love affair the sexual stimulation brought about by the contacts with a woman released these old associations from the unawareness and influenced his conduct in such a way as to prohibit him from continuing the relationship. The censorship implied in the father-made attitudes which had not been brought to full practical maturation in the adult conscious world of reality produced in him prohibitions, inhibitions and incapacities in his later life. His anxiety represented the old, immature fear of parental disapproval and disfavor, and the physical symptoms reproduced the picture which he had retained from his father's description of "the wages of sin." The practical results consisted of the development of an inability upon the part of the patient to continue his relationships with women beyond the point of formal social contacts.

We see also many cases in which the unresolved ideas relative to the auto-erotic practices of childhood and adolescence prevent both men and women from entering the marriage state because of the neurotic fear that they have injured their sexual organs. Many of these misinformed individuals feel that they would be unable to carry on a normal sex life implied in marriage, and become impotent or frigid, and never marry.

Finally, there is another group of cases the importance of which is rapidly growing in the minds of the medical profession. Ordinarily when we think of diseased processes we think in terms of disordered structure and function.

We have difficulty in thinking of one without the association of the other, and when situations arise in which both are involved, we have been in the habit of expecting the disorder in structure to precede the disorder in function. In the class which we are now considering it is known that the change in function precedes the change in morphology, and that long-continued excitation of the structures by anomalies in function ultimately produces serious pathological changes in structure. Moschcowitz, in the *New England Journal of Medicine* for April 4, 1935, lists these conditions as follows: (1) Essential hypertension, (2) "Graves' syndrome", (3) Gastric and duodenal ulcer, (4) Cardio-spasm, (5) Spastic or irritable colon and mucous colitis. Probably from the purely pathological aspect these five types are more or less related through changes in the blood and muscle supply caused by long-continued vasomotor malfunction.

Long ago Dr. Walter B. Cannon in his book, "Bodily Changes in Pain, Hunger, Fear and Rage", showed us the consistent visceral changes that accompany emotional reactions, and proved that affective states have a very definite effect upon the chemical balance of the blood and the endocrine glands. Pavlov's experiments with the conditioned reflexes have demonstrated beyond doubt that situations outside of the body touching upon the archaic autonomic mechanisms have definite influences upon the operation of the secretions and glandular structures. The work of Dr. Walter C. Alvarez at the Mayo Clinic gives ample evidence that life situations of certain types have definite effects upon the physiological functions. The work of Draper and McGraw has demonstrated that there may be psychic patterns of personality synchronous with the development of gall bladder disease and gastric ulcer. Maurice Fremont-Smith, Lawrence K. Lunt, Austen Riggs, Woodyatt, Nellis B. Foster, C. C. Wholey, Lauren Smith and many other writers of authority have given us undisputed evidence of their experiences in reporting cases wherein emotional conflicts, unresolved immature habit-patterns and blocked instinctive strivings have expressed themselves as obstruction of the bowel, sexual impotence, heart dysfunction, digestive interferences, muscular weakness, circulatory troubles, pain habits, high blood pressure, etc. The following case illustrates certain of these relationships.

Mr. I, aged fifty. Ten years ago suffered with what was diagnosed as gastric ulcer. Recovery was complete and the patient was free from symptoms for ten years. In 1929, at the time of the industrial and financial emergency, his South American export business failed and his holdings of stocks and bonds became depleted. He was obliged to discharge his large corps of servants, sell his palatial home, and move into a modest apartment, where his wife was obliged to do all the work. She did not take kindly to this great change in her life. She was suddenly

reduced from a position of great ease and luxury to one of hard labor, from a position of social prominence to one of almost total obscurity and her adaptive abilities failed her. As time went on she lost her equanimity and became irritable and intolerant. She nagged her husband to the point of exasperation, blamed him for the loss of his business and called him a fool and a knave. As time went on she became so unpleasant he spent most of his time away from home, and then she accused him of infidelity. After several months of this sort of thing he began to lose his appetite and sleep, and became unable to concentrate upon any matter of business. One day while at dinner, after a particularly disturbing scene with his wife he developed a sudden and sharp pain in the epigastrium, vomited his meal and went into a state of collapse. That night he had a large copious stool of clear mucus. The local physician made a diagnosis of gastric ulcer and acute colitis, and at once began to treat the patient for this condition. After several weeks of illness and without any appreciable improvement the man was sent to a hospital. Here no evidence of ulcer could be discovered in spite of the fact that all the subjective symptomatology continued. Finally he was turned over to a psychiatric group for study and recommendation. For days the gastric pain and mucous colitis continued. The patient was unable to retain much food and the mucous stools finally became filled with blood. Still no evidence of organic pathology could be discovered. Psychotherapy was continued and finally the man began to improve. As the causes for the emotional situation were gradually removed and as the patient gradually developed insight into the real nature of his troubles he slowly began to recover. After many weeks of continued treatment he left the hospital weighing some forty pounds more than upon admission and in an excellent condition of mental and physical health.

Cases of this type are exceedingly common. We believe that at least ninety per cent of all cases of mucous colitis are of psychogenic origin. Cannon was able to produce intestinal stasis in cats at will simply by throwing them into violent states of fear or anger. Many of us know the distressing feeling of precordial pain in situations calling forth the deep emotions of grief. The rise in blood pressure and the quickened pulse in fear are matters of universal experience.

The empty, "all gone" feeling in the pit of the stomach during violent anger is too common to need discussion. The sudden vertigo, with unconsciousness, in the hypersensitive person is an experience in the lives of many people. During the World War men frequently got up in the morning to find their thyroid glands enlarged to alarming proportions because of the fear aroused by the news of an impending advance or attack. We all know of the hysterical paralysis of the emotional conversions and the changes in the dermal circulation due to affective states. Those of you who read the unexpurgated edition of "All Quiet on The Western Front" will remember the example of uncontrolled howl movement in the new recruits.

Now all these conditions demonstrate the fact that it is the emotional conditions and situations that precede changes in function, and it is the long-continued, persistent changes in function that may, and often do, lead to changes in structure. In writing of certain difficulties in the knee joint Dr. Austen Fox Riggs says, "Furthermore, from the beginning the function is still further curtailed by the fear that anything but the gentlest use of the joint may cause damage. If this condition persists for any length of time, a secondary physical change takes place in the joint itself."

So, in your work as medical men, do not get into the demoralizing habit of depending entirely upon what your instruments of precision and the laboratory reports tell you. Remember that you are dealing with a total personality, all of whose factors cannot be measured with mathematical absolutism. One must develop the habit of feeling into the emotional and psychic factors as well as into the physiological facts. Treat the total man, not the disease. Learn to look upon man as more than simply a physical machine.

You will have many psychological points of view and various philosophical postulates upon which to make your interpretations, but do not put exclusive dependence upon any one school. Remember we have some ten or fifteen primary instinctive tendencies and any one of them may be at the bottom of the maladaptive conflicts. Bear in mind that there is one school of psychological thought that has no textbook and no exclusive leader. It is the school of meticulous care and common sense.

DIATHERMY IN LOBAR PNEUMONIA*

Preliminary Report

BY WINTHROP WETHERBEE, JR., M.D.,† JOHN A. FOLEY, M.D.,† AND JOSEPH RESNIK, M.D.†

INTRODUCTION

DURING the past decade or thereabouts there have been numerous reports in the literature dealing with the use of diathermy in the treatment of lobar pneumonia. The various observers have shown considerable difference of opinion as to the value of this measure, but are almost unanimous in their belief that it is valuable symptomatically, and that it is not harmful when properly used.

Stewart¹, perhaps the staunchest advocate of this method of treatment, has reported a series of over a thousand cases, with a mortality of 11.9 per cent as opposed to the 28 per cent mortality commonly observed in hospital cases of pneumonia treated by other methods. Harbin² mentions a series of sixty cases, with a 12 per cent mortality. Lihien³ believes that diathermy is sufficiently valuable to be indicated in all cases, except aspiration pneumonias, or lobar pneumonias with complicating pulmonary abscess, closed empyema, or cardiac decompensation.

Other workers have been only slightly less enthusiastic. Robinson⁴, while he does not find the duration of the illness shortened to any extent, observes relief of pain, increased tendency to rest and sleep, less need for sedatives, and a general improvement sufficient to justify its use. Simon⁵ finds no specific response to diathermy, but sufficient general increase in the comfort of the patient to make it a valuable symptomatic measure. All agree that under the direction of a competent physician it is an absolutely safe procedure.

Because of these favorable reports, it was decided to use diathermy in the treatment of lobar pneumonia on the Fifth Medical Service of the Boston City Hospital during the winter of 1934-35.

SELECTION OF PATIENTS

All of the patients with lobar pneumonia were given the standard treatment, including serum and/or oxygen when indicated. (With the exception of one case, the latter was given by means of the oxygen tent rather than by nasal catheter.) In addition, one half of the series were given diathermy. The candidates for diathermy were not selected, but were alternate

cases.† The stage of the disease, the extent of lung involvement, the type of organism, and the general condition of the patient were not considered, and an attempt was made to render the selection as nearly as possible one of strictly controlled cases. One or two patients who were moribund on admission and died within a few hours, were omitted from each of the groups in this report.

As soon as a patient was admitted and the diagnosis of lobar pneumonia made, the Department of Physiotherapy was notified, and if the patient was a candidate for diathermy it was started promptly, in some cases within a few minutes, and in every case within a few hours.

No patient was included in either group of this series, in whom the clinical diagnosis of lobar pneumonia was not corroborated by x-ray.‡

TECHNIQUE AND EFFECTS OF TREATMENT

Diathermy is a method of generating heat in deep-seated tissues by passing through them high frequency currents. The heat employed is not obtained, as such, from a source outside the body of the patient but is generated in the tissues proper, as a result of the electro-magnetic energy which oscillates through them at a very high rate of frequency.¹³

Of late, the terms short-wave diathermy and ultra-short-wave diathermy have come into prominence. The former refers to wave-lengths of approximately 30 to 12 meters while the latter comprises of the range, 12 to 2½ meters. In terms of frequency the present-day apparatus produces currents of ten million to one hundred million oscillations per second.¹⁴

For these currents Drs. Schliephake and Reiter have claimed selectivity and specificity. By selectivity is meant that high frequency currents of given wave-lengths will cause optimum heating effects of corresponding body tissues, while specificity implies that these currents produce, in addition to heat production, specific biologic effects on the tissues analogous to inflammation, combating sepsis.^{15 16}

†There were a few exceptions to this as for instance when a patient was admitted just before a week end or a holiday and it would not have been possible to start the diathermy as promptly as in the other cases. These patients were then used as controls and the next two or three in succession were included in the diathermy series until the two groups were even again. For all practical purposes however we may regard the selection as one of alternate cases.

‡A single exception to this was the patient E. L. In the control group who had her crisis on the second day in the hospital, the chest plate was not taken until three days after this time, and was read as negative. We felt that the history and physical signs in this case were sufficient to establish the diagnosis and that an x-ray taken earlier would have confirmed it.

In our series we employed orthodox diathermy with high frequency of one million oscillations per second, giving a wave-length of approximately three hundred meters. Under these circumstances whatever changes occurred in the conditions of the pneumonia patients, in all probability were brought about by the generation of heat resulting from the application of diathermy and not from selectivity or specificity.

That heat causes dilatation of blood vessels with resulting local hyperemia can be readily observed on the surface of the body when any form of heat is applied to it. It is, therefore, not unreasonable to expect similar changes in deep seated tissues which are heated by diathermy, namely, the consolidated portions of the lungs in pneumonia. By the same token expansion of the air spaces in the lungs occurs with resulting augmented oxygenation.

A portable high frequency machine was carried on a truck to the wards where treatment was administered. This truck was equipped with a rotary converter of one kilowatt to change the ward D C to A. C. The electrodes used were comprised of pliable block tin, about 20 gauge. They were covered with soap lather and applied anteroposteriorly with the smaller electrode nearest to the consolidated area. The dosage was sixty to one hundred milliamperes per square inch of contact area of the smaller electrode.^{17, 18} Thus in the average case one thousand to fifteen hundred milliamperes were used. The duration of the treatment was one-half hour and was repeated twice, daily. The average number of treatments per patient was eight, giving a total of four hours of diathermy. It is apparent that from the standpoint of time the sacrifice made is not exorbitant compared with the beneficial results derived from this measure.

In this discussion we are concerned neither with laboratory findings nor the underlying theories as much as we are interested in the actual clinical findings. The latter were gratifying.

In all but two cases of the diathermy group the treatment induced marked perspiration. Obviously this is a form of elimination, relieving the load of other organs concerned in this process. The patients while under treatment volunteered the information that the tension or pressure in the chest was lessened during the séance. The breathing was less labored and deeper, probably due to the relaxation and relief from pain brought about by the heat.

In general, comfort to a certain degree seems to have been secured.

When presence of fluid in the chest was detected pointing to empyema we did not deem it advisable to continue with diathermy.¹⁹ Instead

ultraviolet radiation was resorted to as a method of building up the resistance of the body to the infection.²⁰ The latter was given with a quartz mercury lamp in four exposures, namely, from waist-line up and waist line down anteriorly and posteriorly.

Although we discontinued the use of ordinary diathermy when empyema was encountered we are inclined to believe that it is worth trying the shorter wave-length diathermy for which, as explained, selectivity is claimed. Dr Schliephake¹⁵ reported that similar conditions, in his experience, responded favorably to short wave therapy.

ANALYSIS OF RESULTS

	Diathermy Group	Control Group
Occurrence of empyema	Three cases (16.6 per cent)	Four cases (22.2 per cent)
Number of patients who received serum	Seven (38.8 per cent)	Four (22.2 per cent)
Number of patients who received oxygen	Five (27.7 per cent)	Eight (44.4 per cent)
Number of patients who received both serum and oxygen	Four (22.2 per cent)	Three (16.6 per cent)
Termination by crisis	Eight (44.4 per cent)	Seven (38.8 per cent)
Termination by lysis*	Six (33.3 per cent)	One (5.5 per cent)
Average duration of fever in uncomplicated cases†	5.7 days	6.0 days
Number of deaths	Two	Six
Mortality	11.1 per cent	33.3 per cent

Although the effects of diathermy in our series agreed in the main with those noted by other observers a striking exception occurred, in that while Stewart¹ found that the fever terminated by lysis in 97 per cent of his patients, our percentage was very much lower (33.3).

*This does not include fever prior to admission, but its duration in the hospital.

Further data is supplied in tables 1 and 2

COMMENT

In a paper published thirty four years ago, Sears and Larrabee⁶ of this hospital reported the mortality of a series of over nine hundred consecutive cases of lobar pneumonia as 35.9 per cent. Excluding those patients who were moribund on admission the mortality was 29.1 per cent.

In 1934, Stewart¹ stated that the mortality from lobar pneumonia in a hospital practice is 28 per cent. With this approximate figure there is general agreement at the present time.^{21, 22}

Thus, despite the ever-increasing use of serum, and the advent of other newer methods of treatment, such as the oxygen tent, the death-rate from lobar pneumonia is essentially what it was a generation ago. Over a quarter of the patients admitted to a general hospital with this disease do not recover.

We come, therefore, more and more to the realization that in this disease symptomatic treatment is more important than specific treatment. In so doing, we go back to the conception of self-limited diseases voiced exactly one hundred years ago by Jacob Bigelow in a notable address delivered before the Massachusetts Medical Society¹¹.

Lobar pneumonia is a self-limited disease. If during its course we can promote rest and relaxation, if we can make the patient comfortable, ease the pain, relieve the dyspnea, lessen the apprehension, or if, in other words, we can help carry the patient along until such time as the illness has run its course, we shall have done the most valuable thing we can do in any self-limited disease. We feel that if the mortality of lobar pneumonia is ever lowered, it will be as a result of treatment directed along these lines rather than as a result of any more specific treatment.

We do not imply that serum, for instance, has no value, even in our present small series of cases, several patients seemed to improve markedly after receiving it. The fact remains, however, that in any large series of cases, the mortality is about what it was before serum was used. There is beyond question a growing feeling that specific therapy is not so valuable as it appeared to be at first¹².

From our present series it is hardly possible to draw any definite conclusions. The number of cases is so small that statistics especially must be regarded with suspicion, and we feel that our results are suggestive rather than conclusive.

The mortality for the entire series is 22.2 per cent, not far from the figure that to date has appeared to be an irreducible minimum. It so happens that the mortality in the diathermy group is one-third that of the control group. Because of this, and because of the very definite subjective improvement in the patients treated by this method, we feel justified in continuing with this form of treatment until a sufficiently large series of cases, with controls, has been accumulated, and more definite conclusions may be drawn.

SUMMARY

A series of thirty-six consecutive cases of lobar pneumonia were given the standard treat-

ment for this disease, including serum and/or oxygen when indicated. In addition, one half of the patients, alternately chosen, were given physiotherapy in the form of diathermy.

The mortality for the entire series was 22.2 per cent, that of the diathermy group 11.1 per cent, and that of the control group 33.3 per cent.

The cases are presented in some detail, and the effects of diathermy noted.

CONCLUSIONS

The use of diathermy is a valuable measure in the symptomatic treatment of lobar pneumonia.

It adds greatly to the comfort of the patient.

It appears to lower the mortality, although the present series of cases is too small to permit drawing any definite conclusions in this respect.

Further use of diathermy is indicated in this disease.

ACKNOWLEDGMENT We wish to express our thanks to Miss Ruth Holmes, R.N., and to other members of the technical staff of the Physiotherapy Department of the Boston City Hospital, whose cooperation did much to make this study possible.

SPECIFIC AND NONSPECIFIC ARTHRITIS*

(With Special Reference to Trauma)

BY BENJAMIN H. ARCHER, M.D.†

NUMEROUS attempts have been made to classify chronic arthritis. None have met with general acceptance. In part, this has been due to a lack of uniformity in nomenclature, and in part to gaps in our knowledge of the underlying cause.

For many years the pathologic condition and roentgenographic appearance of the joints have served as a basis for distinguishing the various types of arthritis. More recently the trend has been toward an etiologic classification.¹

Etiologically, chronic joint disease may be divided into two categories. In the first, the primary cause of the arthritis is known. In the second, the exciting agent of the disease is yet to be determined.

SPECIFIC ARTHRITIS

Exemplifying the first group are those cases of arthritis associated with specific infectious agents such as the gonococcus, the tubercle bacillus or the spirochaete pallidum. In addition there are certain specific diseases which produce a chronic arthritis in which infection is not the primary cause. Syringomyelia, hemophilia, ochronosis and gout are examples of this group.

In syringomyelia the arthritis is probably due to a neurotrophic disturbance of the joints. The arthritis of gout and ochronosis result from the deposition of metabolic irritants in the joint cartilages. The joint changes of hemophilia are caused by the effusion of blood into the articular cavities.

In brief, it is quite clear that there are certain infections and noninfectious diseases with known primary irritants that may result in chronic arthritis. To this type of case it seems proper to apply the term chronic specific arthritis. Furthermore, the group as a whole may be sharply defined, etiologically, from those instances of chronic arthritis in which the primary cause is unknown. The latter may be described as chronic nonspecific arthritis.²

NONSPECIFIC ARTHRITIS

This would seem to be a good generic term. It serves to focus our attention on the fact that the primary cause of this type of joint disease is unknown. What is more, as our knowledge increases, it may be possible to separate various

groups from this category and place them under the heading of chronic specific arthritis.

Pathologically, the joint lesions of nonspecific arthritis, like those of the specific form, fall into two groups. The terminology adopted by Nichols and Richardson³ has much to commend it, and will be used throughout this article.

These authors divide the joint lesions of all forms of chronic arthritis into proliferative and degenerative types.⁴ The first is characterized by primary proliferative changes in the synovial membrane and the perichondrium, the second by primary rarefaction and fibrillation of the central part of the articular cartilage.

It is important to remember that Nichols and Richardson in their classic monograph³ emphasized the fact that their classification was purely a pathologic one and did not correspond to different etiologic agents.

There is a striking similarity between the pathologic lesions of specific and nonspecific arthritis. This has led many investigators to suspect that both forms of chronic joint disease might be due to the same type of primary agents. With this in mind, intensive investigations have been carried out to find a specific bacterial agent, some neurotrophic disturbance or some abnormal concentration of metabolites in the blood, to explain the causation of nonspecific arthritis. As yet, there is no conclusive evidence at hand that any of these factors play a primary role in the etiology of this form of the disease.⁵

Within recent years trauma has been reemphasized as a primary cause of the degenerative type of nonspecific arthritis, and it is with this etiologic agent that we are specially concerned in this article.

TRAUMA

The relationship of trauma to chronic arthritis has been noted by many investigators. Nichols and Richardson³ state that trauma may be one of the causes of either proliferative or degenerative arthritis. Leriche⁶ describes "traumatic vasomotor synovitis." Leriche and Policard⁷ believe that many injuries of the joints are followed by serious vasomotor disturbances of the fibrous tissue which may induce a proliferative arthritis. Büdinger⁸, as early as 1908, reported splitting of the cartilage and thickening of the synovial membrane in cases of monarticular arthritis following trauma. He concluded that traumatic splitting of the cartilage is the most frequent injury of the knee joint, and

*From the Medical Division of Lincoln Hospital, New York City.
†Archer, Benjamin H.—Assistant Visiting Physician, Lincoln Hospital, New York City. For record and address of author see "This Week's Issue" page 823.

that while many cases heal spontaneously, in a certain percentage an arthritis develops Ludloff⁸, Axhausen⁹, Lawen¹⁰, Kulowski¹¹, König¹² and Key¹³ have substantiated Budinger's conclusions

All of these authors have discussed acute trauma of external origin, and have described the relationship of this irritant to the pathogenesis of the monarticular forms of arthritis

The relationship of repeated trauma of intrinsic origin to the monarticular and polyarticular forms of chronic arthritis has been studied by other observers

Miller¹⁴ and Keefer¹⁵ cite numerous examples of monarticular osteoarthritis due to repeated trauma Heiss¹⁶ has demonstrated the presence of this condition in Olympic athletes Radiographic evidence of osteoarthritis was found in twenty-three of 159 men examined In the football players the osteophytes were found principally in the knee, in boxers in the elbow or wrists, and in javelin and discus throwers in the elbow or shoulders The primary cause of the arthritis in all these cases would appear to be repeated intraarticular trauma due to the excessive use of one or more joints

Putti¹⁷ believes that regardless of what the primary cause of multiple osteoarthritis may be, there always enters into its pathogenesis the factor of trauma, not the direct type, but that of the chronic type of moderate degree of intensity which occurs under various circumstances Goldthwait, Painter and Osgood¹⁸ state it is certainly true that continued strain or injury lead to the development of the hypertrophic type of nontuberculous joint disease (osteoarthritis) Henderson and Hench¹⁹ are of the opinion that chronic forms of trauma result from the intrinsic causes of obesity and faulty posture and affect only the weight-bearing joints Keefer and Myers²⁰ believe that the anatomic changes of osteoarthritis can be explained on a basis of injury to the cartilage and bone which follows the "wear and tear" upon joint structures They stress the factors of senescence, occupational strain, and static abnormalities, as predisposing to the pathogenesis of the disease Bauer¹⁸ is in essential agreement with Keefer and Myers, and states, that degenerative osteoarthritis is the result of the "wear and tear" of increasing age and repeated trauma Smith-Petersen²¹, among others, has shown histologically the effect of multiple minimal traumata on joint surfaces It was found that the microscopic changes were those of a degenerative arthritis

From this brief review of the literature, one is apt to conclude that repeated trauma is a competent producing cause of the degenerative form of nonspecific arthritis I believe this to be true, but I also hold that repeated trauma may produce proliferative arthritis What is more, I believe that repeated trauma is not the sole

cause of degenerative arthritis, there may be other causes, such as infection, metabolic irritants, vascular and neurotrophic disturbances In the specific form of chronic arthritis this is quite obviously true, particularly in gout, syringomyelia, and congenital syphilis In the nonspecific group, further investigation may reveal such irritants

However, the importance of repeated intraarticular trauma as a factor in the causation of chronic arthritis of all types needs to be emphasized

Repeated intraarticular trauma may be defined as continual abnormal pressure or friction upon the articular surfaces or synovial membrane of a joint Normally there is pressure and friction upon these tissues Pressure is due to the apposition of articular surfaces when at rest, and friction arises on motion Under normal conditions, the cushioning effect of cartilage and the lubricating character of the synovial fluid seem to absorb the effect of friction on joint surfaces Abnormal pressure or friction may result from any cause which disturbs the anatomic relationship of the joint surfaces or its enveloping membrane It may also arise from excessive or abnormal use of a joint

The chief predisposing causes of intraarticular trauma may be enumerated as follows

- 1 Fractures of long bones near joints with faulty alignment of the fragments
- 2 Intraarticular fractures and unreduced dislocations
- 3 Foreign bodies in the joints
- 4 Occupational or athletic stress and strain
- 5 Constitutional causes, i.e., overweight, postural abnormalities, orthopedic disabilities and senescence

In view of the number of causes that may produce repeated intraarticular trauma, there seems to be no valid reason for stressing senescence²² Senescence, as such, is not the cause of degenerative arthritis It is repeated intraarticular trauma extending over a long period of years that is one of the primary agents of the joint changes seen in elderly people Senescence is only a predisposing cause like overweight, orthopedic disabilities or postural abnormalities The common denominator of all these constitutional causes of degenerative arthritis is repeated intraarticular trauma

The mechanical theory of the causation of degenerative changes in the central part of the articular cartilage can be based on the fact that when fractured at right angles to its surface, articular cartilage presents a very definite striation (Fisher) It is quite reasonable to believe that abnormal pressure or friction at one point of the articular surface may cause in time a solution of continuity at that point Repeated pressure or friction if prolonged at that point may result in a vertical splitting or cracking of the cartilage below the surface This produces

so-called fibrillation or crevassing of the cartilage. The same process may occur at various points of the joint surfaces. This solution in continuity of the normal contour of the articular cartilage can result from abnormal pressure suddenly applied, as in acute external trauma, or may follow repeated small traumata intra-articular in origin. Weight bearing and joint motion may then provide the force which eventually cracks the cartilage. The nature of hyaline cartilage with its semisolid consistency lends itself to this type of pathological reaction.

It is quite likely that any irritant which is able to disrupt the continuity of the surface of the central area of the articular cartilage may initiate degenerative pathological changes in this tissue. In addition to the mechanical causes which have already been enumerated it is highly probable that any factor which diminishes the lubrication of the joint surfaces through interference with the production of mucus may also lead to intra-articular trauma and erosion of joint surfaces.

It is important to remember that repeated intra-articular trauma may result in proliferative as well as degenerative changes in the joints. This is clearly evident in the action of foreign bodies on synovial membrane and articular cartilage. It is a well known fact that a ruptured semilunar cartilage of the knee, in time produces erosion of joint surfaces and degenerative osteoarthritis.²⁴ It needs to be emphasized that a foreign body in the same joint may result in a proliferative arthritis.

This has been demonstrated in osteochondritis dissecans.²⁴ In this disease, an aseptic necrosis of the articular cartilage results in the presence of a foreign osseocartilaginous body in the knee-joint. Because of repeated intra-articular trauma, the synovial membrane proliferates and a nonspecific arthritis follows.

Conway²⁵ operated upon six such cases and reported that the changes in the synovia varied from a simple edema of the synovial papillae to a pronounced hypertrophy of the whole membrane. In one case, of long duration, he noted in addition to the proliferative changes, evidence of a degenerative arthritis.

Quite definitely, then, it may be stated that the same primary agent, repeated intra-articular trauma, may result in either a proliferative or a degenerative arthritis depending upon whether the synovial membrane or the articular cartilage is principally affected by this irritant. What is more, if the irritation is sufficiently prolonged inspection of the lesion may disclose both types of pathologic change in the same joint.

A survey of the literature and my own observations lead me to the following conclusions in regard to intra-articular trauma.

- 1 Repeated intra-articular trauma is a common repeated producing cause of some cases of chronic nonspecific arthritis.

- 2 Repeated intra-articular trauma may result in proliferative or degenerative pathologic changes in a joint, depending upon whether the synovial membrane or the articular cartilage is primarily affected by this irritant.
- 3 This form of trauma helps to explain the pathogenesis of degenerative arthritis in gonorrhea, ochronosis and hemophilia. It also explains the evolution of proliferative arthritis in osteochondritis dissecans.
- 4 Constitutional conditions may predispose to intra-articular trauma.
- 5 Occupational or athletic activity in which a single joint is used to an abnormal extent, sets up intra-articular trauma, and the result may be a degenerative arthritis at any age.
- 6 Acute external trauma that injures a joint may be a predisposing cause of repeated intra-articular trauma. The initial injury, which acute trauma may cause to the central part of the cartilage or to the synovial membrane, may in turn produce repeated intra-articular trauma. The latter may then become the primary agent of a chronic arthritis of the joint affected.
- 7 Any factor which diminishes the lubricating power of the synovial fluid predisposes to intra-articular trauma, by increasing the friction and pressure of joint surfaces.
- 8 Repeated intra-articular trauma is a primary cause of some cases of chronic nonspecific arthritis. It is a secondary factor in all types of chronic arthritis specific and nonspecific.
- 9 No matter what the primary cause of an individual case of chronic arthritis may be, repeated intra-articular trauma tends to perpetuate the disease.
- 10 Even when the primary cause of a case of chronic arthritis is removed, the repeated intra-articular trauma which results from the derangement of the joint structure continues to act and may perpetuate the disease.

One cannot deny the importance of trauma in the causation and pathogenesis of chronic arthritis. Nevertheless, one must not overemphasize the rôle that this factor plays in the etiology of chronic joint disease.

Recently Baner²⁶ has stated that degenerative osteoarthritis is the result of repeated trauma and senility. Keefer²⁷ maintains that all instances of degenerative osteoarthritis are the result of repeated trauma.

One immediately thinks of the degenerative joint lesions of syringomyelia and syphilis osteochondritis as militating against this assumption.²⁸ What is more, degenerative osteoarthritis has been produced experimentally by the ligation of the blood supply to the patella.²⁹

It is difficult to reconcile such evidence with the view that repeated trauma is the sole cause of osteoarthritis. Then again, as already noted, repeated intraarticular trauma may result in a proliferative arthritis. This irritant is therefore not a specific cause for a specific type of pathologic change in the joints. Finally the characteristic lesion of degenerative osteoarthritis, the Heberden's node, cannot be explained on the basis of this theory.

It is quite obvious that the knuckle-joints and the proximal phalangeal joints are flexed and extended more frequently than the distal phalangeal joints. Indeed, it is well to recall, that because of the anatomic arrangement of the tendons of the fingers, most people cannot flex or extend the distal phalangeal joints without flexing and extending the proximal phalangeal joints.²⁷ It follows, then, that both of these joints are subjected to the same degree of repeated intraarticular trauma. Yet Heberden's nodes are a rarity in the proximal phalangeal joints and occur almost exclusively in the distal phalangeal joints.²⁸ Apparently some other factor or factors, besides trauma, must be operative, to explain the distribution of this lesion.

Though repeated intraarticular trauma is apparently not the sole factor in the etiology of all cases of degenerative arthritis, and indeed may be a primary cause of some instances of proliferative arthritis, the important fact which must be borne in mind is that this irritant may be a secondary factor in every case of chronic joint disease.

CONCLUSIONS

1 Etiologically chronic joint disease may be divided into the specific and nonspecific forms of arthritis.

2 Intraarticular trauma may result from a number of diverse mechanical causes, i.e., fractures and dislocations, occupational or athletic activity, foreign bodies in the joints, and constitutional conditions.

3 Repeated intraarticular trauma may be the primary cause of some cases of chronic arthritis. It is a secondary factor in every case of chronic joint disease.

4 No matter what the primary cause of a case of chronic arthritis may be, repeated intraarticular trauma through friction or pressure tends to perpetuate the disease.

GONADOTROPIC HORMONE (PROLAN) IN RELATION
TO CARCINOMA OF THE CERVIX*

BY JAMES A. HALSTED, M.D.†

THE discovery in 1926 by P. E. Smith and Zondek and Aschheim, independently that pituitary implants would activate the ovaries of immature rodents led to the demonstration of a substance in the urine of pregnant women which at first seemed to act similarly. This substance is the basis for the universally used test for pregnancy. Since this discovery the urine has been tested for it in a wide variety of conditions, among them cancer.^{1, 2}

Recently it has been clearly demonstrated by detailed biological tests that the pituitary hormone and pregnancy urine hormone are different substances.^{3, 4, 5} Since they are both ovary stimulators it is well to speak of them collectively as gonadotropic substances and to differentiate them as the anterior pituitary hormone and the anterior pituitary like hormone (A. P. L.—Collip). In all probability the hormone found in pregnancy urine (A. P. L.) is made by chorionic tissue. The same hormone is found in the urine of patients with hydatidiform mole and chorio-epithelioma.

In these three conditions large amounts of A. P. L. are excreted so that even if unconcentrated urine is injected into immature rodents ovarian changes will result, consisting of ripening of Graafian follicles (Prolan A effect Zondek) and corpus luteum formation (Prolan B effect). Zondek first found gonadotropic substance in the urine in teratoma of the testicle, an embryonic tumor, and Ferguson⁶ has shown that measurement of the hormone in the urine is of distinct aid in the management of these cases. Here the amount excreted is relatively small compared with the other conditions just mentioned, so that in many cases only by concentrating the hormone with alcohol can it be detected. This is Zondek's method for testing for gonadotropic substances in conditions other than pregnancy and chorio-epithelioma.

Anterior pituitary hormone is rarely found in this laboratory in the urine of "normal" women.⁷ A positive test by Zondek's method thus constitutes an increased amount. The commonest cause of increased excretion is ovarian deficiency. Thus it is the rule to find it after removal of the ovaries, after the natural menopause has begun⁸ and as Osterreicher⁹ has

shown, in many old women after the menopause is over. This is due to hyperfunction of the pituitary consequent to removal of the influence of the ovarian hormone. This explanation is supported by the experimental observations of Fichera¹⁰ who noted an enlargement of the pituitary gland of rats after gonadectomy, and of Engle¹¹ who demonstrated an increased content of gonadotropic hormone in the pituitaries of castrated rats.

Zondek has tested for anterior pituitary hormone in the urine by the alcohol precipitation method in a large number of patients with various kinds of tumors and in 1930 reported the results of tests in fifty five cases of genital carcinoma in women.¹ Forty of these cases were carcinoma of the cervix. He obtained positive tests in thirty three and thence stated that 82 per cent of cases of carcinoma of the cervix were associated with positive tests. Because of the implication occasioned by this report that a positive test might be of significance in the diagnosis of carcinoma of the cervix, it was thought worthwhile to attempt to repeat his work.

Inasmuch as a positive test is to be expected in women with ovarian deficiency, patients with carcinoma of the cervix were selected who were under the menopause age and who had not been treated with radium or x ray. Difficulty was experienced in finding a large number of such patients because most cases coming under observation had been treated previously or were beyond the menopause. Fifteen were studied during the course of the investigation, all of whom had normal menstrual histories prior to the onset of the disease. The diagnoses were all confirmed by histological section. One test for gonadotropic hormone was performed on each. The method used was essentially Zondek's method, mice being used as the test animals. Details of the test as performed in this laboratory are given by Albright, Halsted, and Cloney.⁷

RESULTS

(See table.) Of the fifteen patients studied four or 26.6 per cent had positive tests. Two of these were forty five and forty seven years old and may have had relative ovarian deficiency in spite of normal periods. Occasionally a positive test has been obtained in this laboratory at the approach of the menopause before the periods have ceased. Eleven patients had negative tests. The table gives the pertinent data on each patient.

*The biological tests reported in this investigation were performed in the Biological Laboratory of the Massachusetts General Hospital under the direction of Dr. Fuller Albright. The expense was defrayed by a grant from the De Lamar Mobile Research Fund.

Read before the Obstetrical Society of Boston, New York and Philadelphia, at Boston April 12, 1935.

†Halsted, James A.—Assistant in Medicine Massachusetts General Hospital. For record and address of author see "This Week's Issue" page 933.

RESULTS OF TESTS FOR GONADOTROPIC HORMONE (PROLAN)
IN 15 PATIENTS WITH CARCINOMA OF THE CERVIX

Case No	Age	Duration of Disease	Menstrual History Before Disease Began		Gonadotropic Hormone Test
1 C F	36	3 months	Regular and normal		Negative
2 L R	44	3 months	Regular until 2 years ago	Since then	Negative
			irregular and profuse		
3 L C	27	3 years	Regular and normal		Negative
4 M deL	34	6 months	Normal until 1 year ago	Since then	Negative
			frequent and profuse		
5 C C	27	4 months	Regular and normal		Negative
6 M S	49	?	Regular and normal		Negative
7 D C	27	?	Regular and normal		Negative
8 D C	34	?	Regular and normal		Negative
9 F B	39	1 year	Regular and normal		Negative
10 L C	39	6 months	Regular and normal		Negative
11 I L	44	? 2 years	Regular and normal		Negative
12 A D	34	18 months	Regular and normal		Positive
13 M W	35	5 months	Regular and normal		Positive
14 G P	45	10 months	Regular and normal		Positive
15 C R	47	1 month	Regular and normal		Positive

Tests were performed on a number of patients with gynecological disorders suspected of being cancer which after operation turned out not to be. The negative tests were in two cases of endocervicitis, one of metropathia hemorrhagica and one of leiomyosarcoma. The positive tests were in one case each of chorio-epithelioma, endocervicitis, and cystic corpus luteum.

DISCUSSION

Zondek obtained positive tests in 82 per cent of his cases, and Saphir² in 80 per cent of five malignant tumors and 50 per cent of six benign tumors studied, whereas in this investigation positive tests were obtained in 26 per cent. However, on analyzing the data given for Zondek's cases one finds that many of his patients had either had previous radiation therapy, Wertheim operations (panhysterectomy with removal of both ovaries) or were at least fifty years old. Exact analysis of his data is impossible from the information given, but it is apparent that he obtained positive tests in only about half of his cases not suffering from ovarian deficiency. Saphir, unfortunately, does not mention the ages or menstrual histories of his patients.

Although one does not obtain positive tests in 26 per cent of normal women this relatively small percentage cannot be said to be of any significance in the diagnosis of carcinoma of the female genital tract. Whether it has any significance at all remains to be seen. Kurzrok¹² has demonstrated an increase of anterior pituitary hormone in the urine of ten women at the time of ovulation and believes it may be possible to determine the ovulation date by application of this test. Riley, Brickner and Kurzrok¹³ obtained positive tests quite regularly before the headaches of patients with migraine. Smith and Rock¹⁴ obtained positive tests in 45 per cent of cases of functional uterine bleeding. With the development of more refined methods for meas-

uring the hormone in small amounts, it is probable that it will be found in more or less excess in a variety of conditions. It cannot be too strongly emphasized that methods for measuring gonadotropic hormone are most inadequate at the present time. The substance is apparently an unstable compound difficult to extract quantitatively and very divergent results have been obtained by equally competent workers. Only when very large amounts are being excreted, as in pregnancy and chorionic tumors, can much significance be attached to the result of a test.

SUMMARY

1 A brief account has been given of the various conditions which are known to be associated with an excess production of gonadotropic hormone (Prolan).

2 Although Zondek reported that 82 per cent of cases of carcinoma of the cervix had positive tests for gonadotropic hormone (meaning an increased amount) analysis of his cases shows that many of his patients had evidence of ovarian deficiency, in which condition a positive test is to be expected.

3 Twenty-six and six tenths per cent of fifteen patients studied in this clinic with carcinoma of the cervix and with normal menstrual periods prior to the onset of the disease had positive tests. This incidence which is, perhaps, greater than one would expect if there were not a relationship between cancer of the cervix and this hormone, still is not sufficient to be of diagnostic significance.

MEDICAL PROGRESS

PROGRESS IN HEMATOLOGY*

(Lato 1933 and 1934)

BY WILLIAM DAMESHEK, M.D.†

ADVANCE in hematology continues to be made along many fronts as interest in diseases of the blood forming organs continues unabated. Many more workers are busy in this field, and the harvest of interesting and often important findings continues to be a rich one. Stress continues to be placed upon the physiological aspects of the various disease syndromes rather than upon the more purely morphological criteria which were the concern of the older hematologists. The most important advances have been in the field of etiology. The causes of pernicious anemia, chronic hypochromic anemia, congenital hemolytic anemia, and of agranulocytosis have been more clearly defined. No outstanding advance in therapy has been made, but then one cannot expect a liver announcement every year. The award of the Nobel prize in medicine to three Americans G. H. Whipple, G. R. Minot, and W. P. Murphy for their epoch making work with liver emphasizes again the eminence of American hematology. The work of the Italian hematologists deserves more widespread attention than it has been given in this country, and the reviewer has been struck by the many comprehensive and excellently illustrated articles which have come out of the Italian clinics. The most notable text on hematology has appeared from Central Europe. It is the "Handbuch der allgemeinen Hämatologie" (Urban and Schwarzenberg, Berlin and Vienna, 1933) edited by Hans Hirschfeld and Anton Hittmair and written by a large corps of specialists. Like many other ponderous German tomes, it is made up of two volumes and each volume is further divided into two halves (each of about 800 pages).

From the Medical Service and Department of Pathology, Beth Israel Hospital, Boston. Much of this material has been utilized in a review article of Hematology for the Cyclopedia of Medicine and the author wishes to thank the publishers, V. A. Davis Co. Philadelphia, for permission to republish certain sections.

†Dameshek, William—Associate Physician, Beth Israel Hospital. For record and address of author see "This Week's Issue," page 823.

In last year's review (1929-1933), the approach was a general one with an attempt to present the subject of hematology in a broad way so that the reader might obtain a bird's-eye view of the field of hematology as it existed at the end of 1933. In the present review, more attention will be given to individual articles, although certain subjects will be stressed, i.e. anemia, agranulocytosis, glandular fever, and polycythemia.

THE BLOOD-FORMING ORGANS

The cells which circulate in the blood arise from three widely scattered centers of active cellular growth which have come to be called "organs." These are the bone-marrow, the lymphoid tissue and the reticulo-endothelial system.

A. The Bone Marrow. This, the most important of the blood forming organs, is receiving increased attention as the result of recent studies. The sternal bone marrow biopsy is receiving interested consideration. The sternum is easily entered by means of a hand trephine, a small plug of bone being obtained for sectioning and smears made on slides. Differential counts of the marrow in the sections have often proved of great diagnostic value. In the reviewer's hands, this procedure has proved of great value in the diagnosis of the often puzzling cases presenting chronic anemia, leukopenia, and thrombocytopenia, and has demonstrated that this triad of hematological signs is frequently due to aleukemic leukosis (q.v.).

B. The Lymphoid Tissue

C. The Reticulo-Endothelial System. Great numbers of articles continue to be written about this important group of phagocytic cells which is scattered throughout the body but is found principally in the liver, the spleen, the lymph nodes, and the bone-marrow. The reviewer has already cited the many activities of this "system" (New Eng. J. Med. 210 531, 1934) the phagocytosis of foreign particles, the

destruction of old red blood cells, the storage of fat, the formation of foreign body giant cells, the production of immune bodies, and the formation of the third type of white blood cells, the monocyte

THE BLOOD CELLS

Terminology For the red blood cells, terminology remains but little affected (cf *New Eng J Med* loc cit) The white blood cells have suffered some changes in terminology Generally agreed upon are the following

Bone-Marrow Cells Myeloblast, Myelocyte, Metamyelocyte, Mature Polymorphonuclear cell The metamyelocytes have been subdivided into "young" and "band" forms

Lymphoid Cells Lymphoblast, Lymphocytes, large and small The "plasma" cell is a form of lymphocyte

Reticulo-Endothelial Cells Histiocyte, Monocyte The word "monocyte" has come into general use and replaces the old term "transitional cell" as well as the ambiguous one of "large mononuclear cell"

The Polymorphonuclear Cells (Granulocytes) Schilling, following the lead of Arneith, subdivided the polymorphonuclear cells into myelocytes, young forms, band forms, and segmented (mature) forms The value of this subdivision in the study of infectious disease has been adequately demonstrated in hosts of papers As an example of carrying the method out to its logical conclusion may be cited the paper of Crocker and Valentine (*J Lab & Clin Med* 20 172, 1934) These authors have added a large number of new indices, the value of some of them being questionable The introduction of mathematics into such a variable tissue as the blood does not have strict scientific backing, and although it is possible to sit in a laboratory and prognosticate with a fair degree of accuracy what is going on in a given case of infectious disease, it is sometimes of infinitely greater value to examine the patient This should not detract, however, from any serious attempt to tabulate frequently exact findings in a given case of infectious disease and to interpret progress from them The reviewer merely cautions against too literal an interpretation of hematological data in infectious disease since these data should simply be regarded as symptoms or signs in a complex which, in its entirety, represents a diagnostic or prognostic interpretation

The Lymphocytes Wiseman (*J A M A* 103 1524, 1934) discusses the origin, physiology, and morphology of the lymphocyte He states that the lymphocyte has a "definitive" life cycle similar in all respects to that of the polymorphonuclear cell and the erythrocyte (This is not new, hematological treatises for many years have differentiated primitive lymphocytes, large or immature lymphocytes often with dark blue cytoplasm, and small

lymphocytes with pyknotic nuclei) Wiseman points out that increased activity of lymphoid tissue is accompanied in the blood stream by increased numbers of lymphocytes with increased concentration of basophilic substance in the cytoplasm (Cf the findings in "glandular fever" q v) It is axiomatic that hyperplasia of any of the three blood-forming organs is reflected to greater or less degree in the peripheral blood Arneith and now Wiseman suggest studying the lymphocytes for variations in immaturity, the reviewer has found careful studies of this type of value in glandular fever and lymphatic leukemia

The Monocytes The importance of the monocyte has loomed large in recent literature, chiefly because of its association with the reticulo-endothelial system, from which it is derived

Wiseman in the above cited paper discusses the origin of the monocyte and its relationship to the "clasmatoocyte" and demonstrates how knowledge regarding this cell has gradually been built up, particularly from the study of monocytic leukemia The monocyte and the clasmatoocyte are in all probability related cells, says Wiseman, since they appear together in experimental tuberculosis, and in the blood stream in monocytic leukemia Levi and Penati in an extremely careful and complete piece of work (*Arch per le Sc med*, 58 773, 1934) discuss the fundamental experimental and clinical data bearing on the origin of the monocytes They produced experimental reticulo-endothelial reactions by the injection in animals of electro-negative colloids and studied the resultant blood-picture Experimental monocytosis was also produced with the bacterium monocytogenes, various vaccines, and experimental tuberculosis These authors point out that a reticulo-endothelial reaction in the tissues and monocytosis in the blood are not always correlated, and that it is possible to obtain a high grade of monocytosis without any hyperplasia of this system They feel it is less difficult to derive the monocytes from the bone-marrow hemocytoblasts In their second paper, Penati and Levi discuss clinical monocytosis and monocytopenia, infectious "mononucleosis", and monocytic leukemia in great detail, together with the bearing of these conditions upon the various theories regarding the origin of the monocytes They conclude that the monocytes are derived from hemocytoblasts (usually myeloid, at times lymphoid in origin), and that the doctrine which derives these cells from the reticulo-endothelial system is not sufficiently documented (Hemocytoblasts of the Ferrata type and histiocytes are in all probability synonymous terms The sum-total of hemocytoblasts [histiocytes] found in the bone-marrow, spleen, liver, and lymph-nodes may be called the "reticulo-endothelial system"

There is in reality no strict divergence in views between the theory that the monocytes are derived from the cells of the reticulo-endothelial system and that which states that they originate from hemocytoblasts.)

Red Blood Cells The *reticulocytes*, immature red blood cells, have continued to be of first importance in the study of the anemias particularly from the therapeutic standpoint. Osgood and Wilhelm (*J Lab & Clin Med* 19 1129, 1934) state that the reticulocyte method ordinarily in use gives results which are too low. These investigators mix a small quantity of blood with brilliant cresyl blue in a test tube and then make smears. The normal percentage of reticulocytes by this method is frequently 2.4 per cent. Dameshek (*W Virginia M J* 30 193, 1934) showed that the reticulocyte response in hypochromic anemia following the use of inorganic iron varied directly with the extent of reduction in hemoglobin. At a hemoglobin level of 20 per cent, the maximal reticulocyte response with the use of an optimal dose of iron was 10.15 per cent. Minot (*Tr Am Physicians* 49 287, 1934) indicated the value of the "double reticulocyte response" in the study of the therapeutic potency of various extracts of liver. Dameshek and Castle (*J Am M A* 103 802, 1934) used this method in as saying the potency of various commercial extracts of liver for parenteral use in pernicious anemia. First one extract was injected and daily reticulocyte counts obtained, after a ten day period of observation, another extract was given in the same dosage. If a second reticulocyte response occurred the second extract was considered to be definitely more potent than the first.

The sedimentation rate of the red blood cells continues to be widely utilized. Cherry (*J Lab & Clin Med* 20 257, 1934) after a careful analysis of the various factors which influence the sedimentation rate, comes to some very sensible conclusions, to which the reviewer subscribes. Cherry states that "to rely upon this test, without other laboratory data, is unwise."

From a clinical point of view the sedimentation test alone is confusing because individuals react biochemically to disease in different ways, thereby producing variations in rate in the same pathologic state. As a prognostic aid it is of slight help. The leukocyte count or filament—non filament study in conjunction with the clinical picture is of much greater aid than the sedimentation rate. "So many articles are written which are enthusiastic about the outstanding value of the test in this field or that, that it is refreshing to read a critical article which places the test in its proper category—simply another symptom or sign (often misleading like other symptoms and signs) indicating an abnormal bodily state."

Stainsby (*M Clin N Amer* 18 911, 1934) in writing of the value of the sedimentation test discusses its value in the neuroses. It is some times difficult to make up one's mind whether the patient's complaints are on a "functional" basis or composed of more solid stuff. With an elevated rate, considerable effort should be made to determine the underlying morbid process. Stainsby adds, however, that a normal rate does not rule out organic disease. He points out the value of the procedure in following the course of rheumatoid arthritis and in indicating the end of the active process in rheumatic fever and pulmonary tuberculosis.

ANEMIA

Etiology Some of the most important advances in our knowledge of anemia have been made in the understanding of the underlying etiological factors which are concerned. The bone-marrow, in which are formed all of the red blood cells, must be provided with a sufficient quantity of "liver substance" as Castle (*Ann Int Med* 7 2, 1933) has pointed out. This depends upon (1) a diet adequate in vitamin B₂, protein, and iron, (2) a well functioning gastric mucosa in which protein-splitting and iron dissolving enzymes are present, and (3) a normally absorbing bowel.

The Diet. The importance of the diet, particularly its vitamin B content, previously stressed by Castle and Rhoads, was confirmed by Lucy Wills (*Lancet* 1 1172, 1934) in her studies of the "tropical macrocytic anemia" and the "pernicious anemia of pregnancy" seen in India. The most striking work indicating the correlation of the diet, particularly that containing vitamin B₂ with development of macrocytic anemia has been performed by Rhoads and Miller (*J Exper Med* 58 585, 1933) on dogs. These investigators by feeding dogs a diet inadequate in vitamin B₂ were able to produce glossitis, stomatitis, gastrointestinal disturbances such as diarrhea, severe macrocytic anemia, and a megaloblastic hyperplasia of the bone marrow typical of that of human pernicious anemia. This disorder, if not too severe, responded to vitamin B₂ containing preparations but not to parenteral liver extract, indicating a different type of absorption mechanism in the dog as compared with the human being.

Davidson and Leitch (*Nutrition Abstr & Rev* 3 901, 1934) take up in great detail the importance of a sufficient quantity of iron in the dietary, not only in human beings but in animals as well. They determined that "first-class animal protein" and green vegetables are deficient in the diets of the poorer classes and that these inadequacies may result in an iron deficient anemia. The same mechanism holds

true in the nutritional or milk anemia of infancy, as pointed out by Josephs (*Bull Johns Hopkins Hosp* 55 259, 1934) This author demonstrated by careful metabolic studies that the "birth-stores" of iron derived from the mother were probably sufficient to last to the end of the sixth month under normal conditions. However, with a continued low iron diet, such as is found in an exclusive milk diet and possibly on account of other factors, microcytic hypochromic anemia due to iron deficiency would develop.

The Stomach Castle's epoch-making contributions which indicated so strikingly how intimately the condition of the gastric mucosa was related to the normal hematopoietic function have been abundantly confirmed. Strauss (*J A M A* 103 1, 1934) reviewed the entire concept in an article on the rôle of the gastrointestinal tract in conditioning deficiency disease. Deficiency diseases, he brings out, are not only those in which a substance like vitamin B₂ is lacking from the dietary, but may develop when the substance enters the body but fails to reach the essential organs concerned. Pernicious anemia is a "conditioned" deficiency disease because the deficiency is caused not by a defective diet but usually by the absence from the gastric juice of a specific heat-labile factor (Castle's enzyme or "intrinsic substance") (It must be remembered that many cases of pernicious anemia have a strong dietary factor as well as a gastric factor and the disease probably does not develop in these instances until the diet becomes poor). Usually the cause for this loss of the specific enzyme from the stomach in a case of pernicious anemia is not clear but some cases develop following gastrectomy, polyposis of the stomach, and diffuse gastric carcinoma. Madelaine R. Brown (*New Eng J Med* 210 473, 1934) investigated 151 autopsies of cases of undoubted pernicious anemia and found that eighty-two had gross lesions affecting the gastrointestinal tract. Forty-one of forty-two histological studies of the stomach showed chronic gastritis with or without a loss of glandular epithelium, and in thirty-seven the acidophilic cells had disappeared. She therefore concluded that achylia gastrica in pernicious anemia is due to a loss of acidophilic cells. Fouts, Helmer, and Zerfas (*Am J M Sc* 187 36, 1934) investigated the concept enunciated by Morris and his associates that pernicious anemia was due to the absence of a "hormone" from the gastric juice. They concluded on the basis of experiments with gastric juice kept at different temperatures for varying lengths of time, and from other experiments in which the various gastric enzymes were separated by ultrafiltration (*Am J M Sc* 188 184, 1934) that the reason for the ability of Morris's gastric juice concentrate to induce a remission in cases of pernicious anemia was on account of the inter-

action which took place between Castle's enzyme and the globulin of the gastric juice (Castle has previously shown that normal gastric juice alone is not sufficient to stimulate hematopoiesis, but that an interaction between gastric juice and protein or vitamin B₂ was necessary). It has thus been adequately demonstrated that the normal gastric juice contains an enzyme, which is not rennin or pepsin, the function of which is to interact with protein or vitamin B₂ containing foods. The resultant substance after absorption by the bowel stimulates or nourishes the bone-marrow so that normal red blood cell formation takes place.

It must not be supposed that the "intrinsic substance" of Castle is the only factor of importance in the gastric juice. The reviewer has suggested that the lack of hydrochloric acid in cases of chronic "primary" hypochromic anemia might be of causal importance in the disease. Mettler, Kellogg and Rinehart (*Am J M Sc* 186 694, 1933) in their study of ten cases came to the same conclusions, i.e., that the gastric dysfunction leads to failure in utilization of organic iron. This is also well brought out by the Italian investigators Allodi, Penati, and Quaglia (*Minerva Med* 25 489, 1934). It is likely that the hydrochloric acid of the gastric juice aids in the preliminary solution and digestion of organic iron. Its continued absence, possibly in the presence of other factors (dietary, hemorrhagic, etc.) leads gradually to an iron deficient state, i.e., hypochromic anemia.

The Intestines That a normally functioning bowel is essential in the absorption of the hematopoietic stimulants formed in the stomach had already been postulated by Castle (*Ann Int Med* 7 2, 1933). Strauss points out (*J A M A* 103 1, 1934) that macrocytic anemia is distinguishable from pernicious anemia may develop in the presence of various types of intestinal lesions such as celiac disease, idiopathic steatorrhea, and chronic stricture of the bowel. Hare (*Brit M J* 2 162, 1934) concluded that ulcerative colitis may bring about various types of anemia, whether macrocytic, microcytic, or a combination of both. That the gastric lesion in pernicious anemia may not be the only one present was commented upon by Madelaine Brown (*New Eng J Med* 210 473, 1934) who found that lesions of the intestines with enteritis were frequently present. It may thus be seen that anemia may develop (1) as the result of a diet deficient in (a) protein, (b) iron, (c) vitamin B, (2) as the result of some gastric defect, (3) as the result of some intestinal lesion. The latter two mechanisms are important in the development of the "conditioned" deficiency diseases among which pernicious anemia, primary hypochromic anemia, and pellagra are prominent.

OTHER FACTORS

The Liver Recent investigations have demonstrated that the liver is important in normal

hematopoiesis. This had been suspected since Whipple, Minot and Murphy's epoch making investigations of the efficacy of liver in the treatment of anemia. Wintrobe and Shumacker (*Bull Johns Hopkins Hosp* 52 387, 1933) on the basis of three cases of macrocytic anemia associated with disease of the liver suggested that the liver stores and possibly elaborates to some extent the hematopoietic principle produced by the interaction of the intrinsic and extrinsic factors of Castle. Other authors such as Van Deyn (*Arch Int Med* 52 839 1933) and Heath (*Folia Haemat* 51 391, 1934) have taken up this attractive hypothesis. Heath states that the anemia in cases of hepatic cirrhosis is probably explainable on the basis of a loss on the part of the liver of the capacity of providing sufficient of the needed material for normal red cell formation. Goldhamer, Isaacs, and Sturgis (*Am. J. M. Sc* 183 193 1934) make an important contribution to this problem. By making extracts of human liver derived respectively from a fetus, an inadequately treated case of pernicious anemia, an adequately treated case, a case of cirrhosis of the liver and a case of acute yellow atrophy of the liver and then giving them parenterally to patients with pernicious anemia, these investigators were able to demonstrate that the liver is probably a storage reservoir for "active principle." The anemia of cirrhosis of the liver may be due these authors state, to failure of normal hematopoiesis to take place. These speculations, although attractive, probably do not give the entire explanation. It is likely that severe liver damage may be a factor in certain cases of anemia, but it is also probable that other factors must be present as well, such as an inadequate diet and an impaired gastrointestinal tract.

The importance of pregnancy as a factor in the development of anemia has been studied by Strauss (*J. A. M. A* 102 281 1934) who postulates that the fetus removes from the mother a definite store of "active principle" and of iron. In the presence of achlorhydria, the mother may be said to be vulnerable and unable to keep pace with this continued loss of substance to the fetus, and anemia may develop. Dieckmann and Wegner (*Arch Int Med* 53 188 345, 1934) have studied the blood of a group of normal pregnant women with great care and have demonstrated that anemia of a mild type develops in most of them, the anemia being most marked between the twenty sixth and the thirty fifth week.

The constitutional or hereditary factor probably plays some part, principally in pernicious anemia, possibly as well in primary hypochromic anemia. This was recently emphasized by Friedlander (*Am. J. M. Sc* 187 634, 1934) who studied 500 cases of pernicious anemia. This disease, which is largely confined to the white race in temperate zones, is present particularly in "those

individuals endowed with a diathesis characterized by a fair complexion, light hair, blue eyes, and achlorhydria."

METHODS OF STUDY

Hemoglobin The reviewer has already noted the tendency in recent years to record hemoglobin in grams per 100 cc of blood rather than in per cent of normal. What is supposed to be normal has varied from method to method, it may be 13.8 by one method and 17.2 Gm per 100 cc by another. The Tallqvist and Dare methods have been found unacceptable by the reviewer and by Dieckmann and Wagner (*Arch Int Med* 53 188 1934), the latter investigators also found the Sahli method unreliable, although if it is done with due care and if the tubes and standards are calibrated against the Van Slyke oxygen capacity method, it will be found to be satisfactory for clinical use. The Newcomer method although seemingly more accurate may be unreliable at low readings. Dieckmann and Wagner have found the Haldane-Palmer carboxyhemoglobin method most satisfactory. The reviewer is becoming more and more convinced that determination of the hemoglobin indirectly by determination of the blood iron should have far wider use (cf Peters and Van Slyke, the Wong iron method). Sachs, Levine and Appellus (*Arch Int Med* 52 366, 1933) found that the average iron content of whole blood of 100 normal men was 50.01 mgs per 100 cc., that of women definitely less. The iron content is roughly 0.3 per cent of the total hemoglobin.

Mean Corpuscular Volume. Wintrobe (*Am. J. M. Sc* 185 58 1933 and *Arch. Int. Med* 54 256, 1934), Heath (*New Eng. J. Med* 209 173 1933) and many others have demonstrated that determination of the average volume of the red blood cell is an important diagnostic procedure, particularly in the diagnosis of the macrocytic anemias. The mean corpuscular volume is determined by first obtaining the volume of packed red blood cells per unit of blood. This may conveniently be done by centrifuging the blood in a Wintrobe 1 cc. hematocrit tube (the blood is prevented from clotting by the use of dry sodium oxalate) and observing the volume of packed red blood cells. This figure per 1,000 cc of blood (normally 460) is divided by the erythrocyte count in millions, the resultant figure being the mean or average corpuscular volume in cubic micra. Examples (1) Hematocrit (volume of packed red cells per 100 cc. of blood) 46, R.B.C 5.0 millions,

$$M.C.V. = \frac{46 \times 10}{5.0} = 92$$
 (2) Hematocrit 40 R.B.C 3.0 millions,

$$M.C.V. = \frac{40 \times 10}{3.0} = 133$$
 Wintrobe gives the following figures normal or normocytic 84-92 macrocytic, greater than 94, microcytic, less than 80 cubic micra

Red Blood Cell Diameter Janet M. Vaughan and Helen M. Goddard (*Lancet* 1 513, 1934) compared the results obtained by mean corpuscular determinations with those obtained by determining the average cell diameters and concluded that volume can be regarded as a measure of cell size in pernicious anemia and in primary hypochromic anemia but that there were occasional discrepancies as in congenital hemolytic anemia when the red cells are unusually thick and in certain other cases. The reviewer has found both methods to be of value, although the determination of the corpuscular volume is less time-consuming and laborious. The occasional discrepancies should be checked by careful examination of the stained blood smear.

CLASSIFICATION

The tendency in recent years has been to escape from the greatly involved often meaningless classifications of the past and to substitute for them a simple classification based on cell size or volume. Wintrobe (*Arch Int Med* 54 256, 1934) is one of the foremost exponents of this view, to which the reviewer heartily subscribes. Roughly, all cases of anemia may be classified as macrocytic, normocytic, and microcytic. The macrocytic (large cell) anemias Wintrobe brings out, are characterized by an increase in the average red blood cell diameter to 8.0-8.5 micra and an increase in the mean corpuscular volume to above 94 cubic micra. The normocytic anemias have a normal red cell diameter (7.0-7.5 micra) and a normal average red cell volume (80-94). The microcytic anemias, which are usually hypochromic as well, are characterized by small average cell diameter (6.0-6.5 micra) and a low average red cell diameter (less than 80 cubic micra). The most common of the macrocytic anemias is "pernicious anemia", but many other types are present associated usually with a deficiency in Castle's antianemic principle (see Etiology). Normocytic anemia is usually associated with decreased bone marrow function (aplasia, hypoplasia). Microcytic anemia is associated with a deficiency in iron from the body and is seen particularly in chronic blood loss and in the chronic hypochromic anemia of middle-aged women with achlorhydria.

The above terms should be qualified by indicating the possible etiological factors present thus:

Macrocytic anemia poor dietary, achlorhydria, diarrhea

Normocytic anemia benzol

Microcytic anemia achlorhydria, pregnancy

PERNICIOUS ANEMIA

Some of the most important advances in the past few years have been made from the stand-

point of etiology (qv). The concept is gradually becoming established, as enunciated by Castle (*Ann Int Med* 7 2, 1933) that pernicious anemia is not in reality a separate disease, but rather the end-result of many diverse factors, whether dietary, gastric, intestinal, or hepatic in origin. The end-result is a megaloblastic marrow with the resultant presence in the peripheral blood of macrocytes. It is important therefore in every case of suspected pernicious anemia to study very carefully the gastrointestinal tract and the diet.

Diagnosis It has struck many students of the disease that outspoken cases are on the decrease and that most instances are relatively mild so far as the anemia goes, although the neurological symptoms may dominate the picture. McGhie (*Canad M A J* 30 274, 1934) makes a plea for early diagnosis and stresses such symptoms as anorexia, sore tongue, paresthesias, and difficulty in locomotion, together with such signs as glossitis, diminished vibratory sensation, and increased reflexes. Neuromyasthenia, arthritis, some gastrointestinal disorder are all apt to be diagnosed unless one takes pains to do very careful hematological work in these patients. Early examples of "combined system disease", which is in reality part and parcel of the greater syndrome of pernicious anemia, are often associated with what at first glance is an almost normal blood picture. However, careful investigation will usually show the following: slight reduction in red blood cells (3.5 to 4.0 millions), high color and volume index, increased mean corpuscular volume, low white blood cell count, macrocytes with an increase in the average diameter of the red cells, presence of "pernicious anemia neutrophils", slight increase in icterus index and in bilirubin content of the blood, and complete achlorhydria. Wintrobe has pointed out (*Arch Int Med* 54 256, 1934) that the mean corpuscular volume is of utmost importance in diagnosis. The color index, depending as it does upon an accurate hemoglobin determination and an accurate erythrocyte count, is very frequently in error, but the corpuscular volume is easily obtained when the hematocrit determination and the red cell count are known. In making a diagnosis it is futile to wait until severe anemia is present and nucleated red blood cells are present in the smear. In the presence of (1) the findings indicating macrocytosis, (2) glossitis, (3) achlorhydria after histamine, and (4) neurological changes usually of posterior and lateral column involvement, the diagnosis of pernicious anemia is justified. The reviewer has frequently pointed out that certain cases of aleukemic leukosis will simulate very closely all of the hematological features of pernicious anemia. With the presence of splenomegaly, and particularly when therapeutic response to liver extract does not take place, this possibility

should be suspected. It is important above all else in any case presenting neurological lesions particularly those of the extremities to rule out pernicious anemia, since treatment in the latter event may be so effective.

Treatment. Advance in the therapy of pernicious anemia continues unabated. Dameshek and Castle (*J A M A* 103 802, 1934) state that liver from the cow, the pig, the horse, even the codfish has been utilized and has been given in the form of a powder for oral use and in solution for parenteral administration. These authors state that parenterally given (intramuscular) solution of liver extract has been demonstrated to be 30 to 100 times as effective as orally administered extract. Thus the material derived from 100 Gm of liver (if fully potent) when given intramuscularly is equivalent to 3,000 to 10,000 Gm of material given orally. There is, to be sure, some loss in potency in too great a "refinement" of extract, particularly when it is "concentrated" in small bulk. However, even with this loss of potency a large amount of effective material is introduced when 3 cc of solution containing the material derived from 100 Gm. of liver extract is given intramuscularly. This is particularly valuable when the central nervous system is involved, and has completely modified the prognosis for these cases. Striking responses are often obtained with the persistent and extremely frequent use of the "concentrated" products of liver extract. When faced with a case of this type, it is the custom of the reviewer to inject daily doses of the material derived from 100 cc. of extract in the deltoid or gluteal muscles until definite improvement begins. This is followed by doses given every two days, then every three days, and when the patient is ambulatory, once weekly or even every two weeks. Some patients require weekly doses, others bi weekly doses in order to continue hematologically normal (50 million rbc) and neurologically relatively free of symptoms. Complete cure of the neurological symptoms is to be expected only in the mild cases showing paresthesias and slight to moderate loss in vibratory sense. In those patients presenting spasticity and ataxia 50 to 75 per cent improvement in gait and in strength can be expected, although the reflex changes will persist almost unchanged. Those cases with posterior column involvement alone usually do better than those with lateral column involvement as well. Striking, even unbelievable improvement sometimes occurs and is indeed a contrast even to the results obtained with oral liver therapy. Goldhamer, Bethel Isaacs and Sturgis (*J A M A* 103 1668, 1934) and Grinker and Kandel (*Arch Int Med* 54 861, 1934) are, however, pessimistic regarding the effects of therapy.

The exact therapeutic effect of vitamin B containing products is still uncertain. Davidson (*Brit M J* 2 481, 1933) reviewed the therapeutic effects of yeast products in different types

of anemia and concluded that some hematopoietic principle was present, although in small concentration. Lassen and Lassen (*Am J M Sc* 188 461, 1934) cite the conclusion of Strauss and Castle that the extrinsic factor "may now be defined as a substance closely related to vitamin B₂ if not vitamin B₂ itself" (Castle, in an editorial note in the same article, states that he is fully prepared, however, to relinquish this suggestion.) These authors concluded on the basis of careful experimental work that the extrinsic factor searched for by Castle is not identical with vitamin B₂ nor with B₁ and presumably not with any other fraction of the vitamin B complex." It is difficult to explain the often striking results obtained in cases of pernicious anemia with "marmite" (an autolyzed yeast product), unless other substances, as Lucy Wills and Nasseb state (*Lancet* 1 1286, 1933), are present in this crude commercial product. Miller and Rhoads (*New Eng J Med* 211 921, 1934) state that "conclusive proof of the identity or lack of identity of the dietary anti-anemia factor and vitamin B₂(G) clearly must be deferred until isolation of the vitamin in a pure form has been effected." This is a rather conservative conclusion since these authors demonstrated that a rice-polishings concentrate after incubation with normal gastric juice gave a clear-cut reticulocyte and erythrocyte response in a case of pernicious anemia.

PRIMARY HYPOCHROMIC ANEMIA (IDIOPATHIC HYPOCHROMIC ANEMIA, ACHYLIC CHLORANEMIA, ACHLOREHYDRIC ANEMIA, HYPOFERRIC ANEMIA, CHRONIC HYPOFERRISM)

Various authors have confirmed the original findings of Kesselson, Reimann, and Weiner, Dameshek, Witts, Davies, and others regarding the presence of a so-called "primary" anemia with a "secondary" type of blood picture (i.e., low color index, achromia of the red cells etc.) Mettler, Kellogg, and Rinehart (*Am J M Sc* 186 694, 1933) found that the food intake was frequently deficient in iron and that the gastric contents were almost always completely achlorhydric. Dameshek (*J A M A* 100 540 1933) pointed out that the disease was in all probability a chronic iron deficiency state and that these symptoms of early greying of the hair, wrinkling of the skin, sores about the mouth, atrophy of the tongue, brittleness and flattening of the finger nails were probably "trophic" disturbances dependent upon a lack of iron in the bodily cells. A careful study of the disease was made by the Italian investigators Allodi Penati and Quaglia (*Minerva Med* 25 499 1934) who confirmed the above clinical findings and also expressed the view that the pathogenesis of the disorder was in great part linked up with a deficient function of the stomach. Recent studies have convinced the reviewer that most cases are associated with multiple etiological factors (as noted in chapter on Etiology). The diet is fre

quently deficient, the gastric juice is defective, and often an added factor of bleeding (menorrhagia, from hemorrhoids, etc.) is present. Multiple pregnancies are also important in the pathogenesis of the disorder.

Treatment The treatment of the condition, whatever the cause, is relatively simple. The body may be said to be in a state of iron starvation and large quantities of iron are necessary. Dameshek (*W Virginia M J* 30 193, 1934) determined the optimal dosages of iron for various preparations to be as follows: *ferric ammonium citrate* 3.0 to 6.0 Gm daily (given either in the form of 0.5 Gm capsules, in 25 per cent solution or as the scale salt itself in 2 Gm dosage dissolved in milk), *reduced iron* 3.0 Gm daily (given in 0.5 to 1.0 Gm capsules), *ferrous chloride-ferrous glutamate* 4 Gm daily. In using these large doses of iron, it is wise to begin with a relatively small dose and accustom the patient's gastrointestinal tract to its presence, when this is done, the dose can gradually be raised to the optimal dosage. Recently, *ferrous salts* have been advocated as being superior in absorptive power and necessitating smaller doses of material. The reviewer has compared a ferrous compound with reduced iron and ferric and ammonium citrate and has found it to be at least as effective (*ibid*). Fullerton (*Edinburgh M J* 41 99, 1934) used ferrous sulphate and found that a small dose of the dried salt (0.8 Gm) was as effective in hemoglobin regeneration as 6.0 Gm of ferric ammonium citrate. The reviewer has pointed out in the above publications that most cases of hypochromic anemia will respond when adequate dosage of iron is given, but that an occasional case which is refractory responds when copper in the form of copper sulphate 0.006 Gm is added to the daily iron ration. It is probably inadvisable to use copper except in the occasional refractory case, since chronic copper poisoning with possible hemochromatosis may result.

Organic compounds of iron are probably of little or no value, certainly as compared with the inorganic preparations. This is brought out in the experiments of Elvehjem, Hart, and Sherman (*J Biol Chem* 103 61, 1933). Patek and Minot (*Am J M Sc* 188 206, 1934) made the interesting observation that concentrated bile pigment alone might increase the hemoglobin or might facilitate the absorption or utilization of iron. One patient, unable to obtain a normal hemoglobin level with large doses of iron, showed an increase in hemoglobin concentration when bile pigment was administered in addition to the iron.

OTHER TYPES OF ANEMIA

Aplastic Anemia Thompson, Richter and Edsall (*Am J M Sc* 187 77, 1934) found, on analyzing a group of cases of aplastic anemia

that many discrepancies were present between the textbook description of the classical case and their cases as observed at the bedside. (This is probably true for many conditions.) They found that evidences of regeneration were frequently present. (On the other hand, careful analysis of their cases will show that certain of them were in all likelihood examples of aleukemic leukosis [qv]). The reviewer (*New Eng J Med* 210 687, 1934) stated that although certain idiopathic cases of aplastic anemia are still encountered, the great majority present a more or less well-defined history of contact with a chemical such as benzol, arsenic, arsphenamine, neo-arsphenamine, radium, radioactive substances, mesothorium in watch-dial workers, x-rays, and gold. He reported a case following the use of large amounts of gold sodium thiosulphate in the treatment of lupus erythematosus. There has been no advance in therapy in this disease, the custom being to give numerous transfusions until further evidence of blood regeneration appears lacking. Gottheb (*Ann Int Med* 7 895, 1934) recommends trial of splenectomy and cites a case in which a remission occurred lasting for two months.

Congenital Hemolytic Anemia The most striking advance in this disease has been the discovery that the fundamental abnormality is an increased tendency of the red blood cells to assume a spherical shape. Naegeli, in the last (1931) edition of his textbook and Haden (*Am J M Sc* 188 441, 1934) designate this tendency as spherocytosis. This abnormality was discovered by comparing the average red blood cell diameter which is always less than normal (microcytosis) with the average corpuscular volume, which may be normal or even increased. This can only be due to an increased thickness of the red cells, which Haden and Naegeli feel is an inborn error in the disease, as much of an anatomical variation as the "tower" skull and other physical abnormalities often present. Haden found that the increased fragility (the amount of dilution necessary to produce hemolysis) varied directly with the degree of spherocytosis or altered shape of the cells, and stated that "the cells in this disease may be regarded as nearer the hemolysis point by reason of their shape." He concludes that "the one fundamental variation from normal is the microspherocytosis. The anemia, jaundice, splenomegaly, reticulocytosis, and increased fragility are all secondary to the globular form of the erythrocyte."

As regards treatment, Reifenshtein and Allen (*J A M A* 103. 1668, 1934) recommend, on the basis of three cases, the use of parenteral liver extract, particularly in the mild case of the disorder. Their three cases all showed definite clinical improvement. Other observers dis-

agree with this concept, however, maintaining that not only may hemoclastic crises appear but that the gall bladder and liver may become irretrievably damaged before splenectomy is finally done.

Ovalocytosis, Sicklemia, Sick Cell Anemia. Pollock and Dameshek (*Am J M Sc* 188 822, 1934) in describing elongation of the red blood cells in a Jewish family, review the often confusing terms which have arisen about this curious disorder. "Ovalocytosis" is said to be present when 10 per cent or more of the red cells are oval in shape. Elongation is the next degree of abnormality. When sickled red cells are present without anemia "sicklemia" is said to be present. An anemia in which sickled cells predominate is called "sickle cell anemia". Oval shaped and elongated red blood cells have now been frequently reported in members of the white race, although sickle-cell anemia has so far been described only in the colored. Pollock and Dameshek state that "it is probable that oval elongated, and sickled red cells and sickle-cell anemia represent various gradations in the same general abnormality of red blood cells". The disorder is fundamentally an hereditary one, and probably of no significance unless severe anemia is present. Diggs, Ahmann and Bibb (*Ann Int Med* 7 769, 1933-34) demonstrated that a tendency of the red cells to sickle was observed in 83 per cent of 239 Negroes when sealed moist preparations of blood were examined. These authors found that the ratio of sickle-cell anemia to the sickle cell trait is about one to forty and that the trait itself has no significance. Corrigan and Schuller (*New Eng J Med* 210 410, 1934) noted the presence in their autopsied cases of sickle-cell anemia, the ineffectiveness of liver, liver extract both by mouth and parenterally, desiccated hog's stomach, bone-marrow extract, iron and transfusions.

"SPLENIC ANEMIA", BANTI'S DISEASE, ETC

In most cases of continued enlargement of the spleen, leukopenia is a prominent feature and there is usually a distinct anemia together with some reduction in the blood platelets. Larabee (*Am J M Sc* 188 745 1934) suggested the term "chronic congestive splenomegaly" for this group of cases and pointed out their similarities despite the wide difference in etiological agents. Cirrhosis of the liver, syphilitic splenomegaly, chronic malaria, residual splenomegaly following various infections all may produce the same clinical state which, by the uncritical, is often called "splenic anemia" or Banti's disease. Whether there is such an entity as Banti's disease is open to question (Most cases of alleged Banti's disease have in the reviewer's experience been finally diagnosed as chronic myelosis.) Increase in the pressure

in any part of the portal circuit may result in splenomegaly, gastrointestinal hemorrhages, etc. The mechanisms of the leukopenia and slight anemia have not been worked out, although Larabee suggested a possible diminution in "active principle" because of involvement of the liver. Splenectomy will reduce the pressure in the portal circulation and thus reduce the dangers of hematemeses and ascites. Storti (*Haematologica* 15 107, 1934) and other Italian workers have recently advocated the use of ligation of the splenic artery as a simple and easier technique than splenectomy.

POLYCYTHEMIA

Etiology. Two main types are recognized the idiopathic (polycythemia vera) and the secondary. The mechanisms involved in the secondary type are well brought out in a case reported by Waring and Yegge (*Ann Int Med* 7 190, 1933). This patient had long standing bronchial asthma and emphysema which undoubtedly produced anoxemia and cyanosis and was followed by polycythemia. The patient was working at a high altitude and this factor alone was sufficient to cause some degree of polycythemia. Possibly the pulmonary artery might have become sclerosed as the result of increase in the pressure within the lesser circuit. All of these factors tended to cause a greatly increased burden upon the heart. These authors discuss "Ayerza's disease", the conception of which has greatly changed since Ayerza described his "black cardiacs" in 1901. Caster, Capdehourat, and Repetto (*Arch méd chir de l'app respir* 8 385, 1933) discuss the mechanisms in the development of this disease entity of chronic severe cyanosis and polycythemia. Although they do not minimize the importance of pulmonary artery arteriosclerosis as a factor, they stress the more fundamental factor of various types of chronic bronchopulmonary disorders which produce cyanosis. The individual affected, if his marrow is normal, reacts with polycythemia, a compensatory mechanism. Arteriosclerosis of the pulmonary artery, they feel, is secondary to the chronic bronchopulmonary disease. Heart disease need not necessarily be present. These authors feel that the reason the syndrome is not seen more frequently is that many older individuals with bronchopulmonary disease do not have a sufficiently reactive marrow.

The cause or causes of the so-called true polycythemia have not yet been discovered. Morris (*J A. M. A* 101 200, 1933) came out with an attractively simple hypothesis that the erythremia might be the result of hypersecretion of "addisin" (the so-called gastric hormone) or of hypersusceptibility of the marrow to it. He attempted to contrast pernicious anemia (due to a deficiency in "addisin") with polycythemia ("hyperaddisinism"). Unfortunately, these hypotheses have not stood the test of even a single year of investigation (cf.

also under Etiology of Anemia) Reznikoff, Foot, Bethea, and DuBois (*Tr Amer Physicians* 49 273, 1934) demonstrated that the blood-vessels of the marrow in cases of the idiopathic type of polycythemia showed unusual changes of the intima and media. These circulatory changes might be the initial factor which caused a great increase in the anoxemia of the marrow with resultant polycythemia. This author also pointed out that the disease was much more common among the Jewish population of New York City than in other groups and suggested an hereditary factor. Spodara and Forkner (*Arch Int Med* 52 593, 1933) brought out the hereditary factor in their study of a large family of polycythemic individuals. The reviewer discovered this family trait in the affected family when one of the authors of the above paper was a medical student making classroom red blood cell counts. Boyd (*Am J M Sc* 187 589, 1934) describes a case characterized by polycythemia, duodenal ulcer, coronary thrombosis, and ascites and discusses the possibility that the ulcer might have had some bearing on the production of polycythemia, he feels, however, that the polycythemia was probably instrumental in causing the duodenal ulceration. Baserga (*Polichinco* 41 17, 1934) pointed out that polycythemia is occasionally associated with primary disease of the central nervous system particularly in the diencephalo-hypophyseal region (acromegaly, encephalitis lethargica) and reported a case in which polycythemia was present in a case of pituitary neoplasm. It is possible that a red cell regulating mechanism is situated in the hypothalamic-pituitary portion of the brain.

Diagnosis Most cases of polycythemia vera probably go unrecognized and are diagnosed as heart disease, angina pectoris, cerebral disease, peripheral vascular disease, etc. The reviewer has had occasion many times to comment on this fact. The infrequency with which routine erythrocyte counts are done and the inaccuracy of the Tallqvist hemoglobin test account to great extent for this state of affairs, which cannot be corrected unless one thinks of the possibility that the disease might be present and does a red cell count. One should consider the possibility in a patient with a dusky cyanotic appearance presenting vague symptoms which are frequently cerebral in type, at times circulatory. Sloan (*Arch Neurol & Psychiat* 30 154, 1933) states that the disease has predominantly a nervous and mental symptomatology. This may be easily understood since the blood volume is increased, the cerebral vessels distended, the circulation slowed, and the viscosity of the blood increased. Schiff and Simon (*Ann méd psychol* 91 616, 1933) describe a case characterized by cataplexia chorea, and mental confusion. Bieling (*Med Klin* 29 1410, 1933) describes a severe case of Ménière's syndrome due to polycythemia.

It is important for the practicing physician to be on the lookout for these cases, because much may be done with appropriate treatment.

Treatment There has been no improvement in the fundamental treatment of polycythemia. Falconer (*Ann Int Med* 7 172, 1933-34) suggests the use of venesection as an adjuvant to the use of phenylhydrazine hydrochloride. The reviewer has repeatedly used this method and finds it of value. If the erythrocyte count is eight to ten million per cu mm, it is probably best to begin by removing from 500 to 1,000 cc of blood and to begin phenylhydrazine therapy only when the red cell count is about 6.5 million. This procedure avoids excessive hemolysis and possible thrombotic complications which might ensue if large doses of phenylhydrazine were given immediately. Phenylhydrazine hydrochloride may be given either in capsules of 0.030 Gm ($\frac{1}{2}$ grain) or dissolved in aqueous solution (1 dram = $\frac{1}{2}$ grain). The original dosage is usually 0.090 to 150 Gm daily, which is diminished to a maintenance dose of about 0.030 Gm daily depending upon the individual patient. It is difficult to gauge the exact dosage, which must be individually adjusted. Vaguez and Mouquin (*Presse méd* 42 1065, 1934) discuss the treatment of the disease with phenylhydrazine. They begin with a dosage of 0.050 to 100 Gm and suspend medication in any event when the patient has taken a total of three Gm. They discuss the possible complications such as thrombosis and the rare examples of permanent cure. Falconer (*J A M A* 101 1633, 1933) report a case in which a remission has been present for eleven years following treatment with phenylhydrazine. Stone, Harris, and Bodansky (*J A M A* 101 495, 1933) are convinced that acetylphenylhydrazine is less toxic and provides a greater margin of safety in cases of overdosage, in two cases these authors were able to maintain a normal red cell count with only 100 mgs weekly. The status of the various methods of treatment, including that by x-ray treatment over the bones, is discussed in a review of the subject in the *American Journal of the Medical Sciences* (187 716, 1934). Phenylhydrazine easily holds first rank.

LEUKOSIS (LEUKEMIA)

Classification There are three types of white blood cells (1) the granulocytes, (2) the lymphocytes, and (3) the monocytes. These owe their presence in the blood stream to three separate sources (1) the bone-marrow, (2) the lymphoid tissue, and (3) the reticulo-endothelial system. Leukemia might be better termed "leukosis" since it represents pathologically a generalized proliferation of the various types of white blood cells. Since three types of white blood cells and three separate blood-forming organs are present, three types of leukosis are possible: myelosis, lymphadenosis, and reticulosis.

The existence of monocytic leukemia, a third type of leukosis originating in the reticulo-endothelial system, has been abundantly confirmed. V Levine (*Folia Haemat* 52 305, 1934) who reports nine cases, found that the disease was relatively common. The disease is called reticulo-endotheliosis by several authors. Gittins (*Arch Dis Childhood* 8 367, 1933) gives an excellent review of the subject together with a classification of the various types of reticulo-endothelial proliferations. He groups them as (A) Reactive (to blood destruction, sepsis, chemical abnormalities), (B) Focal Neoplasia (Reticuloma, etc.), and (C) Leukemic (Reticulo-endothelial leukosis or monocytic leukemia, leukemic and aleukemic). Foord, Parsons, and Butt (*J A M A* 101 1859, 1933) who report four cases of "leukemic reticulo-endotheliosis" also follow much the same type of classification. Calender (*Am J Path* 10 443, 1934) in his review of the classification of the various types of leukocytic proliferation uses the term "Reticulocytoma, Leukemia". Most of these classifications, particularly those relating to reticulo-endothelial proliferations, are similar to those which have been published in European articles. The most comprehensive of these is that of Baserga.

The leukoses may be considered to be generalized proliferations of one of the white cell forming tissues. This proliferation may be associated with large numbers of circulating leukocytes or even with great diminution in their number. "Aleukemic leukemia", being a paradoxical term, is best replaced by using the terms aleukemic myelosis, lymphadenosis, and reticulosis. The fundamental pathological process is identical in both the aleukemic and the leukemic forms.

Etiology The great majority of observers have finally agreed, after years of hickering, that the leukoses represent generalized neoplastic proliferations of one of the white blood cell forming tissues. This concept has recently received confirmation in the experimental laboratory at the hands of Furth, Seibold, and Rathbone (*Am J Cancer* 19 521, 1933) and of Büngeler (Editorial *J A M A* 102 1086, 1934). Both of these groups of investigators were able to induce leukosis in mice. The leukemic and sarcomatous lesions were frequently present together in the same mouse and transitions between one and the other state could often be seen. These lesions leukemic or sarcomatous, corresponded chemically and biologically to those of malignant tumors. Furth (*J Exper Med* 58 253, 1934) was also able to induce leukosis in chickens by means of the injection of material free from viable cells. The "acute" leukoses, although resembling so closely severe infectious processes, should be re-

garded as highly malignant lesions composed of exceedingly primitive mesenchymal cells.

Diagnosis Among the most frequently misdiagnosed conditions in hematologic practice are the aleukemic leukoses. Balbridge and Fowler (*Arch Int Med* 52 852, 1933) state that five per cent of their cases of diffuse myelosis were peremptorily aleukemic. Their statement that "most physicians seem to regard aleukemic myelosis as an obscure form of hematopoietic disease which can be diagnosed only at necropsy" is heartily endorsed by the reviewer.

The acute leukoses when aleukemic are peculiarly enough to be differentiated from agranulocytosis. Many cases of so-called agranulocytosis are in all probability examples of acute leukosis. This view was stated by Dameshek (*J A M A* 102 950, 1934) who cited some of the diagnostic features, chief among which was the progressive anemia and reduction in platelets present in the leukotic process. Jackson (*Am J M Sc* 188 604, 1934) also cites these features and makes thus epigrammatic statement: "Leukemia is still leukemia whether the white count be 50 or 50 000 per cu mm." He stresses the value of the bone-marrow biopsy. Strumia (*Am J M Sc* 187 826, 1934) points out the transitions which may develop from extreme leukopenia to extreme leukemia in cases of leukosis. He goes too far it appears, in attempting to link up the two conditions as being pathogenetically similar. The elevation in basal metabolic rate which frequently occurs in the chronic types of leukosis may be so striking at times as to suggest the possibility of hyperthyroidism. Dameshek, Berlin, and Blumgart (*New Eng J Med* 210 723 1934) comment upon this possibility and its possible implications. (See under Treatment.)

The diagnosis of the type of leukemia is relatively simple in the chronic varieties of the disease, but becomes difficult in the fulminating acute varieties when a primitive type of blood cell formation is taking place and extremely young cells are present in the circulation. Forkner (*Arch Int Med* 53 1, 1934) takes up the diagnostic points by which the primitive cells (myeloblasts, lymphoblasts, monoblasts) may be diagnosed in a given case. In common with other authors, he states that the supravital technic is of particular value in the differentiation of the monocytic strain of cells, although in certain cases it is only by a combination of all the available methods of study (including that of oxidase staining) that an acceptable opinion concerning the cell type may be established. It is his opinion that the clinical picture of diffuse marked swelling of the mucous membranes, particularly of the gingivae usually associated with ulceration and necrosis is characteristic of acute monocytic leukemia.

and usually absent in the other types. To this opinion the reviewer can only partially subscribe since the lymphatic type frequently gives very striking gingival and buccal lesions.

The heterophile antibody test, introduced in the diagnosis of benign lymphadenosis ("infectious mononucleosis") q v, has been utilized by Bernstein (*J Clin Investigation* 13 677, 1934) in the diagnosis of leukemia. This author found that heterophile agglutinins in the blood sera of twenty-one patients with leukemia were confined to low titers (less than 1 to 4) in twenty instances, whereas in most of the conditions simulating leukemia, heterophile agglutinins were found over a wider distribution of titer, up to one to sixteen. Bernstein brings out that the mechanism whereby antibodies are formed is disturbed in leukemia.

Treatment The treatment of the leukoses continues to be unsatisfactory, although a patient with the chronic form may frequently be tided along for a number of years. Craver (*M Clin North America* 18 703, 1934) gives in detail the plan of treatment for chronic myelosis in use at the Memorial Hospital, New York. Equal daily doses of x-rays are given over the spleen to total a mild erythema dose (about 600 roentgens). The cycle of treatment is finished in about a week and no further treatment for from three months to a year is necessary. The bones are also irradiated, the proximal ends of the long bones, the spine and the sternum being selected. Craver also cites his experience with arsenic (Fowler's solution) and believes it to be of value between cycles of x-ray treatment. (It is also of value when proper x-ray treatment is not readily obtainable.) He uses more guarded doses than those suggested by Forkner in 1930 and begins with three minims three times daily, raising the dosage by one minim per dose daily until the patient is taking about ten minims three times daily. (When x-rays are not being used, this dosage may be inadequate. It should be controlled by frequent leukocyte counts.) Portmann (*J A M A* 102 178, 1934) states that chronic myelosis is ultimately a generalized disease, and that certain organs are affected in greater degree than others. Treatment by x-rays should therefore be individualized and should always be administered to the vertebrae, the ribs, and the sternum, at times the long bones. In the treatment of chronic lymphadenosis (lymphatic leukemia) Craver discusses very carefully the procedure of treatment by x-ray, depending in great part upon the regions involved, the leukocyte count, the patient's condition, and the metabolic rate. Cycles of treatment are given over the affected lymph-nodes and possibly over the mediastinal and retroperitoneal areas, if the patient's condition permits.

Because of the extreme elevation in basal metabolic rate which is so striking a manifestation of certain cases of chronic leukosis, particularly of the lymphoid type, Dameshek, Berlin, and Blumgart (*New Eng J Med* 210 723, 1934) conceived the idea that thyroidectomy might be of benefit. These authors point out that many of the symptoms of the disease (increased sweating, tachycardia, reaction to cold, etc.) may be part of the hypermetabolism rather than due directly to the leukotic process. In one case of aleukemic lymphadenosis with a metabolic rate of +65 per cent, there was striking relief of all the symptoms followed by complete regression of all the lymph-nodes and the spleen. The blood-picture became normal. This remission has persisted for one and a half years. These authors state that the procedure is worthy of further trial in similar cases.

There has been no advance in the treatment of the acute leukoses.

TUMORS OF WHITE BLOOD CELLS

Classification Callender (*Am J Path* 10 443, 1934), the Registrar of the American Registry of Pathology, gives the following "semi-official" classification of tumors of the white blood cells: lymphosarcoma, myelosarcoma, and reticulum cell sarcoma. These may be leukemic and aleukemic. Hodgkin's disease is grouped among the reticulum cell proliferations. The reviewer has used much the same classification although he has subdivided the neoplasms a little further, chiefly according to the degree of cellular maturity. Thus, the generic terms for tumors of the lymphoid, myeloid, and reticulum cells (histiocytes) are myeloblastoma, lymphoblastoma, and histiocytoma. Lymphoblastoma is subdivided into lymphosarcoma (highly malignant) and lymphoma (relatively benign). Myeloblastoma (commonly called chloroma) is subdivided into myelosarcoma and myeloma ("Multiple myeloma" is a lymphoid tumor composed of plasma cells and should be called plasmoma). Histiocytoma is subdivided into reticulum cell sarcoma and reticulo(endothelio)ma. Any of these forms, particularly of the more malignant types may, by metastasizing into the blood stream, produce the picture of leukosis.

Diagnosis The differential diagnosis of enlarged lymph-nodes is frequently very difficult. Held and Goldbloom (*M Clin North America* 18 633, 1934) discuss a few of the differentiating points, but the reviewer has often found it difficult to distinguish between a pyogenic, tuberculous, carcinomatous, and lymphosarcomatous process by inspection and palpation. The diagnostic procedures which should be done in a given case are, besides physical examination, leukocyte counts, differential count of the white cells, tuberculin test, x-ray of the chest, possibly basal metabolic rate determination. In a

questionable instance, and even when the diagnosis appears obvious it is imperative to perform a biopsy of one of the affected nodes. This procedure is of more value than all the possible physical examinations and laboratory tests one may do.

Treatment. Craver (*M. Clin. North America* 18: 703, 1934) reviews very carefully and very sanely the therapy of the malignant tumors of the white cells. He states that the fundamental plan of treatment is determined by asking the question as to whether the disease is localized and therefore offers some hope of cure, or whether it has spread so far beyond its source that treatment must be only palliative. Leucemia (*Am. J. M. Sc.* 188: 612, 1934) says that radiation therapy must be considered the method *par excellence* in the treatment of lymphosarcoma. Thorough radiation therapy increases the expectation of life in all forms of lymphosarcoma from two and one-half to three and one-half years and leads to cure in at least ten per cent to fifteen per cent of the cases. (This is not the reviewer's experience, he is much more pessimistic.) Leucemia believes that it is essential to radiate the entire lymphatic system, regardless of whether the disease is localized or generalized. This causes "depletion of the blood" and requires careful management. He states that this drastic procedure leads at times to complete eradication of the disease, the outlook for the individual patient varying with the primitiveness of the cell and the extent of involvement at the time of treatment. Anomia, cachexia, and fever usually render prognosis unfavorable.

HODGKIN'S DISEASE

The tendency in recent years has been to group Hodgkin's disease among the proliferative lesions arising from the reticulo endothelial (monocytic) cells. Callender (*ibid.*) follows this grouping and it has been used by the reviewer (*Folia. Haemat.* 49: 64, 1933). The disorder may be localized or generalized. If generalized involving the lymph nodes, spleen, liver and bone marrow, it may be said to be leukotic, and the reviewer described a case of this sort as "aleukemic reticulosis" (*Folia. Haemat.* loc. cit.). The most comprehensive review of the disease which has appeared in recent years is that of Wallhauser (*Arch. Path.* 16: 522 and 672, 1933). This author takes up in great detail the many investigations which have been made in the attempt to show that the disease is of infectious (particularly tuberculous) origin. He does not appear to be enthusiastic about this possibility, and this feeling is shared by most investigators, namely that Hodgkin's disease is not of infectious origin, but definitely neoplastic in type. Diagnosis cannot be made by the blood picture, which varies tremendously according to the stage and type of the disease. It is true that

the blood picture shows more or less characteristic changes (providing one knows the diagnosis beforehand). Biopsy must be resorted to and its importance cannot be overemphasized. Ogilvie and van Rooyen (*J. A. M. A.* 102: 1842, 1934) report on the Gordon test which consists in injecting into the brains of rabbits some of the lymphoid material suspended in saline (after it has remained in the ice box for about a week). If the test is positive for Hodgkin's disease, the rabbits develop severe ataxia, incoordination, paralysis of the hind legs, and death. These authors found the test of value in two clinical cases. It needs further trial before its exact value can be demonstrated. The treatment of Hodgkin's disease is by persistent x-ray therapy, and this is commended upon by Craver, Lenczka and Wallhauser (all cited above). Leucemia (*Am. J. M. Sc.* 188: 612, 1934) states that radiation therapy increases the expectancy of life, and produces five and ten year survivals in about one third of the cases. This author uses very drastic treatment covering the entire lymphoid system.

BENIGN INFECTIOUS LYMPHADENOSIS (INFECTIOUS MONONUCLEOSIS, GLANDULAR FEVER)

Nomenclature. The term "infectious mononucleosis", suggested in 1922 by Sprunt and Evans and Longcope, is an unfortunate one since the cells concerned are not monocytes but lymphocytes, again how can a mononucleosis be infectious? Pfeiffer in 1885 described a group of cases in children which he called glandular fever, and this seems by far the better term since it is non-committal and clinically descriptive. Benign infectious lymphadenosis, although rather unwieldy, describes accurately the pathological process which is that of intense proliferation of lymphoid cells, a proliferation, however, which is benign (i.e., not leukemic or sarcomatous) and infectious in origin.

Etiology. The infectious nature of the disease is well known. Penati (*Minerva Med.* 25: 414, 1934) in his comprehensive article analyzes the various experiments which have been performed in an attempt to determine a specific etiological agent. The most promising results, he states, are those of Aage Nyfeldt who isolated a bacterium from the blood stream identical morphologically and culturally with that isolated by Murray, Webb and Swann from a highly contagious disease of rabbits associated with monocytosis. Nyfeldt called this organism *Bacterium monocytogenes hominis*.

Many authors have commented upon the frequency of the disorder in medical students, nurses, physicians, and members of physicians' families. Schulz (*München med. Wchnschr.* 80: 1809, 1933) had the unusual opportunity of observing an epidemic of the disease and was thus able to draw some inference regarding the incubation period, which he concluded was one week or less.

Pathology The pathology of the disease has been but little studied since it is so benign a disorder and complications are so few. Penati (loc cit) describes the intense lymphoblastic hyperplasia which is exceedingly difficult to differentiate from the lymphoblastic proliferation of lymphosarcoma or of malignant lymphadenosis (leukemia).

Symptoms Schultz (loc cit) was able to study thirty-five cases in an epidemic of the disease. Great fatigue and moodiness, particularly in children, usher in the disease and are soon followed by conjunctivitis, at times epistaxis, at times vomiting. Headache develops and becomes quite severe at times. The lymph nodes become enlarged and are the characteristic feature of the disorder. Schultz states they are frequently overlooked by the physician, and to this the reviewer emphatically subscribes. The nodes are frequently tender. The spleen is usually enlarged.

Blood Picture All recent observers are agreed that the blood picture is that of a well-marked lymphocytosis with the presence of all types of abnormal lymphocytes. Stuart, Burgess, Lawson, and Wellman (*Arch Int Med* 54 199, 1934) describe carefully the cytologic changes and state that all gradations in type between the small normal lymphocyte and the lymphoblast are seen. Most striking features are the vacuolated cytoplasm, often with irregular projections from the surface of the cell, the nucleus is frequently indented. The presence of all types of immature lymphocytes is properly stressed by these authors who were also able to observe amitotic division of the lymphocytes in the peripheral blood. Penati (loc cit) describes the lymphocytes and their many types very carefully, in other papers this author together with Levi (*Haematologica* 16 261, 1935) describes the lymphocytes and monocytes in the experimental infectious lymphadenosis of rabbits. It is the reviewer's opinion that the large lymphocytes of glandular fever may easily be differentiated from monocytes if the various characteristics of cytoplasm, granules in the cytoplasm, types of nucleus, character of nuclear chromatin, etc., are all kept in mind. The large lymphocyte has a sky-blue, pale-blue, or deep blue cytoplasm which is clear with only a few large granules, if any, the nucleus is only about one-half the size of the cell, round usually, and is made up of heavy chromatin blocks. The monocyte is gray-blue in color with many fine granules in the cytoplasm, the nucleus is large in comparison to the size of the cell, usually indented, and composed of a fine chromatin mesh. Further differentiation may be made from supravital studies (q v).

Diagnosis Most of the cases, being mild, escape recognition through failure of the attending physician to palpate carefully for enlarged

lymph nodes. The recognition of the disease among physicians and their associates is possibly due to the fact that a blood smear is frequently made. The blood picture is the most important diagnostic feature. The extreme lymphocytosis with so many immature lymphocytes suggests acute lymphatic leukemia, but this is ruled out by the course, the absence of anemia and reduction in blood platelets. Recently a new and interesting diagnostic test has been introduced. Described originally by Paul and Bunnell in 1932, the heterophile agglutination test has received abundant confirmation. Bernstein (*J Clin Investigation* 13 419, 1934) describes the technique and points out the diagnostic importance of agglutination of sheep's cells by the patient's serum in high titers. The details of the technique from an immunologist's standpoint have been investigated by Stuart in a paper by Stuart, Burgess, Lawson, and Wellman (*Arch Int Med* 54 199, 1934). Stuart states that the presence of agglutinins for sheep erythrocytes in human blood was until recently of only academic interest. In glandular fever, these agglutinins become greatly increased so that positive agglutination may occur in as high a dilution as one to 5120.

A suspension of sheep's cells is added to successive dilutions of the patient's blood serum and after incubation for a few hours or after standing in the ice box overnight, the results are read. Stuart states that "with substantiating clinical and cytologic pictures, serums agglutinating in dilutions of 1-320 or more may well be considered positive." Van Ravenswaay (*New Eng J Med* 211 1001, 1934) considers the test positive when complete agglutination occurs at a dilution of 1/32, but other authors (Bunnell, Bernstein) consider even 1/8 and 1/16 as positive results. Rosenthal and Wenkebach (*Klin Wchnsch* 12 499, 1933) state that those cases showing the clinical and hematological features of "infectious mononucleosis" but with a negative agglutination test are examples of "glandular fever" and to be differentiated from true "infectious mononucleosis." To this view the reviewer does not subscribe, possibly the agglutination test does not always give the correct information. It must be remembered, as van Ravenswaay points out, that the test is non-specific like the Weil-Felix test in typhus fever, which too may frequently be negative despite the typical features of the disease being present. It is comforting in a case which suggests acute lymphatic leukemia to obtain a positive agglutination test in high titer. Bernstein (*J Clin Investigation* 13 677, 1934) points out that in leukemia the titers are exceedingly low. The cause for the increased tendency on the part of the blood serum in the disease to agglutinate sheep's red cells has not as yet been worked out.

AGRANULOCYTOSIS (GRANULOCYTOPENIA, GRANULOPENIA, MALIGNANT NEUTROPENIA)

Etiology Much speculation has taken place regarding the sudden prominence of agranulocytosis as a clinical entity. Until recently its etiology was a mystery. Kracke and Parker (*J Lab & Clin Med* 19 799, 1934) list the following agents which had been at one time or another suspected: live bacteria, dead bacteria, hormonal products, radiation, and chemicals. None of these agents had been consistently implicated. Almost simultaneously, however, a group of articles appeared in which the etiology of the disease could be quite clearly traced to the use of a drug or drugs. Watkins in a short note (*Proc Staff Meet Mayo Clin* 8 713, 1933) implicated the barbiturates. Madison and Squier (*J A. M. A.* 102 755, 1934) were able to show quite conclusively in fourteen cases that amidopyrine and drugs containing amidopyrine had been used prior to the attack of agranulocytosis in all of their cases; they were able to reproduce the disease in two instances by giving the drug experimentally. Hoffman, Butt, and Hickey (*J A. M. A.* 102 1213, 1934) in re-investigating their fourteen cases of agranulocytosis demonstrated that all of them but one had taken amidopyrine prior to development of the disease, one had taken dimethylphenol. Rawls (*Am J M Sc* 187 837, 1934) Holten, Nielsen, and Transbol (*Ugeskr f læger* 96 155, 1934), Benjamin and Biederman (*J A. M. A.* 103 161, 1934) and others reported clear-cut instances of the disease following the ingestion of amidopyrine. Aspirin and the barbiturates appeared to be of no etiological importance, although Dameshek and Gargill (*New Eng J Med* 10 440, 1934), Bohn (*J A. M. A.* 103 249, 1934) and Silver (*J A. M. A.* 103 1058, 1934) showed that dimethylphenol—the drug so widely heralded in the treatment of obesity—had almost certainly brought about the disease in their cases. Kracke and Parker (*J Lab & Clin Med* 19 799, 1934) in analyzing chemically the various drugs which had been implicated (neoarsphenamine, arsphenamine, acetanilid, phenacetine, and amidopyrine) showed that they were all distinguished by the presence of a benzene ring with an NH_2 (amino) linkage, they therefore called the offending chemicals the "benzamine drugs". These authors postulated that the oxidation products of these drugs affected the bone marrow causing the disease (*Am J Clin Path* 4 453, 1934). The rapid onset of granulocytopenia following a small dose of amidopyrine suggested to Benjamin and Biederman (*J A. M. A.* 103 161, 1934) that a hypersensitivity to the drug was present. This is of course borne out by the small number of actual cases of the disease in contrast to the millions of adminis-

trations of amidopyrine and other drugs, as noted by Reznikoff in the Special Report of the Council on Pharmacy and Chemistry (*J A. M. A.* 102 2183, 1934). The exact mechanism of this possible hypersensitivity has not yet been worked out. It can be stated definitely at present that amidopyrine is a potentially dangerous drug and that a certain few patients are unusually sensitive to even small doses of the drug. The unusually large number of sedatives containing amidopyrine in combination should make one exceedingly cautious in their use. Jackson (*Am J M Sc* 188 482, 1934) points out that the evidence for the incrimination of the above drugs is not altogether conclusive and multiple factors may be present.

Pathology There is as yet no unanimity of opinion regarding the essential bone marrow pathology of the disease despite the number of autopsies which have been performed. The most careful of recent studies have been made by Jaffé (*Arch Path* 16 611, 1933) who agrees with Fitz Hugh and Krumbhaar (1932) that the most probable condition which exists is that of "maturation arrest", i.e., a condition in which mature polymorphonuclear cells in the marrow are not formed, although large numbers of primitive cells (myeloblasts and myelocytes) are present. Struma (*Am J M Sc* 187 826, 1934) points out the same thing, although he appears to go too far in attempting to bring leukemia into the same essential disease pattern as agranulocytosis, the difference he says being "a release which occurs in acute leukemias but not in agranulocytosis."

Diagnosis Many uncritical observers diagnose as agranulocytosis almost any condition in which severe leukopenia is present. Doan (*J A. M. A.* 101 2075, 1933) brings out that only twenty per cent of the cases referred to his clinic with leukopenia are instances of true agranulocytosis. Dameshek (*J A. M. A. Correspondence* 102 950, 1934) points out many cases of so-called agranulocytosis are in all probability examples of leukemic leukosis. This has been voiced by Jackson (*Am J M Sc* 188 604, 1934). The disease may be considered to be a "selective" one involving only the bone marrow leukocytes, the red cells and the platelets not being affected. In any case in which anemia is striking or the hemorrhagic tendency pronounced the likelihood that one is dealing with agranulocytosis is remote. Pronounced constitutional symptoms in the presence of slight mucous membrane or throat signs together with severe leukopenia (the red cells and platelets being essentially normal), are enough to make one suspect the presence of agranulocytosis. In most cases the count is below 2,000 per cu. mm. (usually below 1,000 per cu. mm.) and the polymorphonuclear cells are conspicuous by their absence.

Treatment Up to the present time the following methods of treatment for the disease

have been advocated nonspecific therapy, transfusion of blood, "stimulating" doses of x-ray, nucleic acid derivatives (pentose nucleotides, adenine sulphate), "leukocytic cream", and liver extract Reznikoff (*J. Clin Investigation* 12: 45, 1933) obtained good results with the use of adenine sulphate in eleven of fifteen cases. The drug is obtained from the Eastman Kodak Company in 5 Gm lots. It is dissolved in 1 Gm doses in 50 to 100 cc of sterile salt solution with the use of heat (even boiling) and given slowly intravenously in daily or twice daily injections, reactions are rare. Dameshek (*New Eng J Med* 209: 1054, 1933 and *J A M A* 102: 950, 1934) reports on its successful use without reactions in seven successive cases. Jackson's pentose nucleotides ("Pentnucleotide NNR") have been used by many authors with good success. It is given in 10-20 cc doses intramuscularly twice daily, 40 cc may be given, and the intravenous route may be used. Dameshek (*New Eng J Med* 209: 1054, 1933) reports severe reactions with this drug and many authors are skeptical of the possible beneficial results. Reich and Reich (*Am J M Sc* 187: 71, 1934) because they failed to produce bone marrow stimulation or increased maturation in rats with the drug concluded that the "results cast some doubt on the value of pentnucleotide in the treatment of agranulocytosis". It may be remarked that it is not always possible to carry over in toto to human beings results obtained from rats. Strumia (*Am J M Sc* 187: 527, 1934) introduced "leukocytic cream" which represents the disintegration products of leukocytes obtained by centrifuging 150 cc of whole citrated blood in cream separating bottles. The leukocytic "cream" thus obtained under aseptic precautions is injected intramuscularly daily in divided doses. Whether this method has any advantage over those of Reznikoff or Jackson remains to be seen. Brugsch and Lantsch (*München med Wchnsch* 80: 1014, 1933) and v Bonsdorff (*Klin Wchnschr* 13: 1079, 1934) have used liver extract intramuscularly with good results. It is thus seen that the nucleic acid derivatives and liver extract given parenterally are probably of value, although because of poor results obtained some observers doubt this. The question of transfusion is a moot one, the reviewer has failed to note any benefit from its use. The outlook for recovery appears to vary with the observers. In the reviewer's own recent series of cases (unpublished) nine of twelve recovered. Early diagnosis and massive dosage with the above nucleic acid derivatives appear to be of greatest importance.

THE HEMORRHAGIC DISORDERS

Classification Most observers are agreed that in the main there are two types of hemorrhagic disorders: purpura and hemophilia. Various types of purpura, however, are present, differing greatly in the essential mechanisms con-

cerned. Some types of purpura are associated with a low blood platelet count (thrombocytopenic) and others with normal counts, the blood-vessel wall being presumably affected (non-thrombocytopenic).

Kugelmass (*J A M A* 102: 204, 287, 1934) in a comprehensive paper on the hemorrhagic states in childhood proposes a classification based upon differentiating those cases presenting inherent defects in the blood-clotting mechanism itself and those in which the vascular endothelium is defective. He further subdivides the cases as follows:

- A Cases with defective blood-clotting mechanism
 - 1 Deficient prothrombin in new born → hemorrhagic disease of the new born
 - 2 Diminished platelets → thrombocytopenic purpura
 - 3 Deficiency of fibrinogen as in severe disease of the liver → increased clotting time
 - 4 Congenital defects of platelets, etc → hereditary diseases such as hemophilia, thrombasthenia, etc

- B Cases with defective vascular endothelium
 - Malnutrition, scurvy
 - Allergy
 - Chronic infections—chemical poisons
 - Hereditary defects of capillary structures

Farber (*Am J M Sc* 188: 815, 1934) classifies the hereditary hemorrhagic disorders as follows:

- Hemophilia—prolonged clotting time, platelet count normal
- Thrombopenic purpura—prolonged bleeding time, platelet count low
- Thrombasthenic purpura—prolonged bleeding time, platelet count normal
- Hereditary hemorrhagic telangiectasis (a vascular defect)—normal bleeding and clotting time, normal platelet count

Farber was unable to put into this group a family of bleeders which he observed in which certain features in common with hemophilia, certain with purpura, were present.

The reviewer is inclined to agree with Kugelmass in dividing the hemorrhagic disorders into two main types: (1) those with an inherent defect of one of the blood-clotting factors, and (2) those in which the blood-clotting factors are normal but the vascular endothelium is defective. Clinically, however, two types of hemorrhagic manifestations are present: (1) the purpuric, and (2) the type distinguished by poor clotting of blood.

Etiology Kugelmass (loc cit.) lists the following etiological factors which may be present in a given case showing a hemorrhagic tendency: inadequate dietary (particularly in fats and vitamin C), use of various drugs, irradiation, in-

fections, diseases of the liver, diseases of the spleen, trauma and congestion, and diseases of the bone marrow. The hereditary factor is of course all important.

In hemophilia the blood platelets although normal in number, are probably unable to form a normal clot, this defect is "genotypic", i.e., carried in the germ plasma. Purpura of the thrombocytopenic form is present in "destructive" conditions of the marrow (aplasia due to benzol, etc., tumor metastases, leukoses, etc.) and in the "selective" disorder of the marrow known as purpura hemorrhagica (Werlhof's disease) in which some defect in the bone marrow megakaryocytes is probably present. It is interesting in this connection to note that Lawrence and Knuth (*Am J M Sc* 188 37 1934) found that a diminution in megakaryocytes was present in only two of six cases of purpura hemorrhagica in which bone marrow biopsy was done. On this account these authors felt that there are at least two different types of the condition in so far as the bone marrow is concerned and that the types in which megakaryocytes were present in the marrow would be more likely to profit by splenectomy.

The non thrombocytopenic form of purpura is by far the most common type of hemorrhagic disorder encountered in practice, and in the reviewer's experience is frequently symptomatic of latent infection, a "toxic" process, senility, uremia, rheumatic fever, allergic processes, scurvy, etc.

Diagnostic Methods Kugelmass (loc. cit.) lists the following procedures which are of diagnostic value: (1) A complete blood study (hemoglobin, red and white cell counts, examination of the stained smear). This rules out the presence of leukemic processes and various other hematologic abnormalities. (2) Determination of the clotting time, clot retraction, bleeding time, platelet count to indicate the type of change in the clotting mechanism which is involved. (3) In rare cases when the above factors are normal, the content of fibrinogen, prothrombin, and antithrombin. (4) Application of the tourniquet test (for capillary resistance), occasional use of the microscope for study of the nail bed (of value in hereditary hemorrhagic telangiectasis). Nygaard (*Proc Staff Meet., Mayo Clin* 9 492, 1934) has devised a test of the coagulability of the plasma which he finds is of value in the diagnosis of purpura hemorrhagica. In this condition, the coagulability of the plasma is greatly reduced, despite the fact that the coagulability of the whole blood is normal (test-tube method). Nygaard concludes that the test tube method can not detect finer changes in the coagulability of the blood. Pemberton (*Am J Surg* 24 793, 1934) points out the value of study of the morphology of the platelets from a stained smear by a competent hematologist. With this state-

ment the reviewer heartily agrees, one can frequently obtain as much information from the single examination of a well stained smear as from all the diagnostic procedures outlined above.

Because of a low platelet count and hemorrhagic manifestations, one should not immediately make the diagnosis of purpura hemorrhagica, but should remember that the same phenomena are present whenever megakaryocytes are destroyed (as in aplastic anemia, leukemia, etc.). Neither is every case presenting ecchymotic spots an example of purpura hemorrhagica, usually the reverse is true and platelets are abundant. Search should then be made for some underlying condition: infectious, toxic, etc.

Treatment. For hemophilia, no acceptable method of treatment has been found despite the enthusiasm which was engendered by Birch's reports in 1931 and 1932 of the striking therapeutic responses to ovarian extracts. Stetson, Forkner, Chew, and Rich (*J A. M. A* 102: 1122, 1934) in a carefully conceived study, were able to demonstrate that theelol orally, soluble ovarian substance intramuscularly, ovarian substance orally, fresh whole beef ovary orally, aqueous extract of fresh whole beef ovary orally, solid residue of ovarian tissue orally, and theelin subcutaneously all were completely without effect on the coagulation time in seven cases of hemophilia. Several other authors have confirmed these results. Jones and Tocantins (*J A. M. A* 103 1671 1934) review the entire field of hemophilia and conclude that transfusion of blood constitutes the best method for the prevention and treatment of acute attacks of bleeding. They also found that intramuscular injection of whole blood has seemed to benefit some patients and that fresh serum was a satisfactory local hemostatic agent.

In the treatment of purpura hemorrhagica, splenectomy still holds first place as the method most likely to bring about remission. Pemberton (*Am J Surg* 24 793, 1934) states the problem from the surgeon's standpoint. He says that the procedure is often life-saving, and that remissions permanent in degree are present in sixty three per cent of the cases. The operative hazard in the chronic type is "minimal." He does agree, however, that in cases which are incipient or mild, splenectomy is rarely indicated. The reviewer would even go farther. It seems best to attempt all forms of palliative therapy in this disease which is so subject to remissions and relapses. We are now seeing more and more cases of recurrent bleeding following splenectomy. Among palliative methods to be used Kugelmass (loc. cit.) cites high protein and high fat diets, elimination of infectious foci, regulation of ovarian dysfunction by the use of the various pituitary and ovarian hor-

mones, injection of whole milk intramuscularly, transfusion of blood, etc. It is also wise, in the reviewer's experience, to use various vitamins in large concentration (A, B, C, D) and possibly to give liver extract and iron. When bleeding manifestations are numerous, it may be worth while to try some of the newer methods of therapy: the use of ascorbic acid (Meick) (vitamin C) given in solution intravenously as suggested by Boger and Schroder (*Munch med Wchnschr* 81 1335, 1934). These authors found that the daily intravenous administration of 100 mgs of ascorbic acid was effective in controlling capillary bleeding even though the blood platelets might be diminished. The capillary wall is an important factor even when the platelets are reduced. Landau and Hejman (*Presse méd* 42 174, 1934) observed that there might be no correlation between the signs of bleeding and the platelet count and bleeding time and suggested that variations in the contractility of the blood vessels might occur. Vitamin C probably acts on the capillary endothelium and thus may be the rationale for its action. Similar reasoning is behind the recent use of moccasin snake venom therapy in the hemorrhagic states, as suggested by Peck in 1932 (Peck and Goldberger, *Am J Obst & Gynec* 25 887, 1933). The venom (obtainable from the Lederle Co.) is used in dilutions of 1:3000 in physiological saline and injected subcutaneously in gradually increasing doses usually twice weekly and for a length of time depending upon the type of case concerned. Peck was able to control bleeding in purpura hemorrhagica even though the platelet count did not rise, again suggesting that the venom has a direct action in capillaries.

An antivenom preparation (antivenin) has been in use for several years in the control of the hemorrhagic states. Taylor (*Am J Surg* 21 285, 1933) reports on several cases which have been treated in this fashion. (Antivenin may be obtained in 10 cc vials from certain drug houses and is injected intramuscularly after a preliminary test for sensitivity.) Taylor states that the antivenin of certain South

American snakes has greater efficacy than that obtained from the moccasin snake. The reviewer, in a limited experience, feels that it is worthy of further trial, in two cases bleeding stopped after injection of the antivenin. Whether this was coincidental is debatable. Savagnone (*Policlinico* 41 763, 1934) found that calcium gluconate given intravenously increased the platelet count somewhat, but his results are not at all conclusive. Jones and Rathmell (*Tr A. Am Physicians* 49 277, 1934) in a carefully controlled study found that large doses of viosterol had no real effect on the platelet count either in normal subjects or those in whom purpura was present.

With respect to transfusion, debate still continues regarding the relative merits of the direct versus the indirect methods. There can be no doubt, as Lundy (*Minnesota Med* 17 699, 1934) states, that the indirect method with the use of sodium citrate is simply and readily performed and no more formidable than any intravenous procedure. Lundy suggests administering the blood slowly, about fifteen cc per minute. When many transfusions are done, a direct method (the reviewer uses the Scannel) is preferable because the blood is unmodified, there is less handling, etc. From Soviet Russia has recently come an interesting suggestion: the use of stored blood obtained either from professional donors or even from cadavers shortly after death. Irger and collaborators (*Novy Khir Arkhiv* 32 53, 1934) report on this method and on their studies with experimental conservation of dog's blood. They conclude that because of various morphologic and biologic alterations which occur, the value of conserved blood for purpose of transfusion is much less than that of fresh blood.

In the non-thrombocytopenic forms of purpura, a vigorous search should be conducted for latent infections, even lues. Calcium in large doses is frequently of value. The reviewer uses calcium gluconate 1.5 Gm every three hours by mouth together with milk, and at times gives the same drug intramuscularly.

CASE 21431

PRESENTATION OF CASE

A seventy year old Hebrew potato merchant entered complaining of cough productive of yellow material.

Four months prior to admission he had pneumonia involving the left lung. At this time there was a high leukocyte count and a negative blood culture. The sputum contained typical pneumococcus. He convalesced slowly and one month after the onset of his acute illness suffered a relapse which confined him to bed for two weeks. Subsequently he recovered and returned to his business. He continued working for six weeks although he felt weak and markedly short winded. His breathing became wheezing in character. A productive cough which had been present with varying intensity for thirty three or more years continued with somewhat increased severity. About two weeks before admission following undue exertion he felt "grippy and feverish." The following day he was found by his physician to have paroxysms of auricular fibrillation. Rales were audible at both bases and at the right top anteriorly and posteriorly. There was no leukocytosis at this time. Following this his temperature began to rise to 103° or 104° each night. His sputum increased and became purulent but had no foul odor. He slept poorly and was often irrational at night. His leukocyte count rose to 37,000 two days before admission.

At the age of forty thirty years before entry, he had been sent to Colorado because of cough and "germs" in his sputum. He remained there for five years but had a very active existence following his return East. At an examination eleven years before admission, when fifty nine years of age, rales were found over the right apex. Five years later definite medium crepitant rales were heard at both bases, more on the left. In the following year a prostatectomy was performed. Three years before admission, following physical strain he first coughed up blood. At this time medium crepitant rales were heard at the left base and axilla. There was no fever. No tubercle bacilli were found in his sputum.

Physical examination revealed a well-developed and nourished old man who was suffering from considerable respiratory distress. Except for slight pallor the skin and mucous membranes were normal. There was slight cyanosis of the nailbed and a suggestion of parrot beaking of the nails. The right pupil was slightly smaller than the left and both were contracted, presumably as a result of administered morphine. The teeth were in only fair condition. The tonsils were red and lumpy. The heart was not enlarged to percussion nor were there any auscultatory abnormalities noted. The blood pressure was 110/60. The brachial vessels were soft. The lungs were examined with the patient lying on the left side. There was dullness on the right side extending with increased intensity from the second rib to the upper border of the liver dullness. Posteriorly there was only slight impairment of resonance of the right chest from the upper border of the scapula to the base. On the left side there was some hyperresonance. The breath sounds were generally diminished in intensity, except for an area inferior to the right clavicle where bronchial breath sounds were obtained. Constant sibilant rales were audible throughout both sides and there were coarse crackling inspiratory rales at the left bottom posteriorly. Vocal resonance was diminished in the area of dullness. A lipoma in the region of the left costovertebral angle precluded examination here. The abdomen was slightly distended and tympanic. The liver and spleen were not palpable. Neurological examination was negative except for absent knee jerks.

The temperature was 102.5° , the pulse 100. The respirations were 24.

Examination of the urine revealed normal specific gravity and a slight trace of albumin. The sediment contained 3 to 100 white blood cells. The blood showed a red cell count of 4,700,000 with a hemoglobin of 65 per cent. The white cell count was 42,800, 83 per cent polymorphonuclears. Four sputum examinations revealed thick mucopurulent material which was negative for tubercle bacilli and elastic tissue. The stools were negative. The non protein nitrogen of the blood was 20 milligrams per 100 cubic centimeters. A Hinton test was negative. The icteric index was 4. A blood culture exhibited no growth.

X ray examination showed dullness in the region occupying the greater portion of the right upper lobe. The inferior margin of this dull area ended in a sharp horizontal line laterally. There was a lobulated shadow in its medial aspect which appeared to lie in the region of the lung root and was about two inches in diameter. The diaphragm, heart and mediastinum were normal.

On the day of admission an exploring needle introduced in the third right interspace in the midaxillary line elicited definite resistance which

increased after passing the pleura. A small amount of bloody fluid was withdrawn. On the fifth day a thick, creamy, odorless pus was removed from the third right interspace posteriorly. Microscopic examination of this exhibited pus cells and gram-positive organisms resembling pneumococci. X-ray at this time showed a small quantity of fluid in the posterior aspect of the right pleural cavity. On the following day under local anesthesia a resection of the third right rib was done. At the end of the second week the only significant change in the physical findings was a return of resonance at the right bottom anteriorly. Flatness was present in the infraclavicular region on this side. By the end of the third week the entire right side was dull. An x-ray film showed the small area of dullness in the right side of the chest to be increased. The operative wound was cleaned of granulation tissue and a half ounce of creamy pus was extruded. At this time the patient's chief discomfort was a constant hacking cough with inability to raise sputum. During the entire hospital stay the temperature remained between 100° and 104°, with an evening rise which averaged about two degrees. His pulse, despite the fact that he received 36 grains of digitalis within one week and a grain and a half daily thereafter, remained elevated, ranging between 100 and 160. The respirations varied, being from time to time between 30 and 60. The leukocyte count ranged from 26,000 to 37,000. During the fourth week the patient seemed to be improving. Shortly afterward, needle taps into the right second, fourth and seventh interspaces medial and lateral to the midclavicular line revealed resistance but no pus, air or blood. X-rays at this time showed an increase in the dullness of the right upper chest with some increase in the amount of fluid. The outline of the right side of the diaphragm was obliterated in its lateral half. The trachea was displaced toward the left in the region of the aortic arch. The right lower lobe contained only a small quantity of air. During the fifth week the patient developed considerable difficulty in coughing and his respiratory passages seemed filled with secretion. He died on the forty-eighth hospital day.

DIFFERENTIAL DIAGNOSIS

DR JAMES H MEANS I do not know of any occupational hazard pertaining to potato merchandising so I think we must pass that over.

I think it is easiest to get a lucid and simple impression of this case by beginning with the past history rather than the present illness because I suspect that they are related.

We note above in the present illness that he had had a productive cough for thirty-three or more years. Indeed he had had a productive cough for about half of his life, and it is of

interest that it began some few years before he was sent to Colorado. That is all we know about this illness forty years ago. If he was told that he had germs in his sputum he was undoubtedly told he had tubercle bacilli. I cannot conceive of a doctor telling him about any other germs or sending him to Colorado for any other reason, so he either had or was thought to have pulmonary tuberculosis at that time. He remained there for five years and apparently made a good recovery because he was able to lead an active existence after his return East.

"At an examination eleven years before admission râles were heard at both bases, more on the right." I do not know where the examination was made. I should like to know what else was present at that time but that single finding is perhaps of interest. Our attention is directed toward the right apex. It certainly could have been a chronic tuberculous process which was lingering on. It may not have been active because one may have râles without actual tuberculous activity. One can also have a non-tuberculous infectious process in an old tuberculous cavity. This basal process, however, which is bilateral and was found some years later, interests me a good deal and when I am told that a man of seventy who has had a productive cough for half of his life has râles at both bases I am led to suspect that among other things he has some degree of chronic bronchiectasis, or something on that order.

In the following year a prostatectomy was performed. We do not know why. There is no mention of symptoms connected with that part of his body.

Three years before admission he coughed up blood. We do not know how much. He might have coughed it up because of an old tuberculous process, of course, or because he had bronchiectasis.

"At this time medium crepitant râles were heard at the left base and axilla." They had been heard at both bases prior to this.

"No tubercle bacilli were found in his sputum." Of course that does not mean he did not have tuberculosis before. Now going back to the first paragraph we are told that four months prior to admission he had pneumonia involving the left lung. We do not know anything about it, we are simply told he did have pneumonia. At this time he had a high leukocyte count and negative blood culture, and the sputum contained a type IV pneumococcus. I would feel that he either had pneumonia or something else. He convalesced slowly and one month later suffered a relapse which confined him to bed for two weeks. He subsequently recovered and returned to business, continuing work for six weeks although he felt weak and shortwinded. In other words, he did not recover completely.

I am interested in the wheeze probably as

pointing to something involving the bronchial tract.

This productive cough which he had apparently for thirty three years became intensified at this time.

"The following day he was found by his physician to have paroxysms of auricular fibrillation." That is not really significant. Any one of seventy may have paroxysms of auricular fibrillation, particularly when an infection has persisted. It might be present in a patient with arteriosclerotic change in the heart.

It seems to me we can draw certain inferences from the history. I think in all probability he did have tuberculosis and I think very likely he had in addition a chronic pulmonary disease, bronchiectasis which was not tuberculous. It is entirely possible for an individual to have both. The present condition suggests that he had a purulent process in the chest because he was developing a fever and running a high leucocyte count and was getting up some purulent sputum, so that the history points to his chest and to this lung and suggests that he has a chronic suppurative process of some kind, a suppurative process in the pleura communicating with the bronchus.

The fact that he is well developed and nourished on physical examination is of interest in a man suffering from a chronic disease. It shows good resistance to it. It had not caused any state of cachexia. Of course people with tuberculosis will go on for many years with lungs filled with cavities and remain fairly well and in a good state of nutrition. I have seen such cases, and I am sure we all have.

It appears that the heart is not the seat of his trouble.

"The lungs were examined with the patient lying on his left side." I do not know why they were examined in that position and it does not state whether they were examined in any other position. I do not know whether that was the only position he was able to assume or whether there was any special virtue in that position.

"There was dullness on the right side extending with increased intensity from the second rib to the upper border of the liver dullness." That area of dullness is more in the region of the middle lobe than of the other lobes. It makes us wonder if perhaps the seat of this difficulty is not in the middle lobe either wholly or in part. The signs are chiefly in front which would fit with a middle lobe lesion. On the left side where he may have had pneumonia there was some hyperresonance.

"Constant sibilant râles were audible throughout both sides and there were coarse crackling inspiratory râles at the left bottom posteriorly." That would fit with our conception of an initial process in both bases of a bronchiectatic nature. I should like to know

something more about the physical signs in the region of the right middle lobe. I do not see any mention of the tactile fremitus. I should interpret these signs at least as being consistent with a process in the lung field, one of consolidation and very likely in parts of it at least with plugging of the bronchus bringing about a diminution in the breath sounds.

I infer from the history that he had a suppurative condition in his lung, probably of a fairly recent origin, because I should be rather more inclined to explain the chronic symptoms on the basis of either an old tuberculous process of the right apex or this bronchiectasis, which I suspect he may have at both bases, and that the recent lesion is a suppurative one somewhere in the middle of his right chest. I think the physical findings are consistent with such an interpretation of the history and indicate that the lesion is in the anterior part of the right chest in the region of the middle lobe. I fancy that there must be a good deal of induration of the lung about the suppurative lesion and very likely some atelectasis.

The blood shows a moderate hypochromic type of anemia which anyone with chronic infection might have. He has a high leucocytosis which would go with a purulent condition and would suggest that the pus was not draining well, also with a high fever.

I went as far as I could with these x rays and I was not certain that the lesion clearly was in the upper lobe. I still think it could be middle lobe. It is unwise to disagree with the radiologist and I do it only in a sporting sort of fashion. There are a lot of dense spots in the left side that could be miliary tuberculosis, I suppose, and down at the bases some thickening that I think might go with my theory of an old bronchiectasis. Then there is a lesion in the middle of the right chest which is very peculiar. It has a flat bottom, on here is a straight line which could be I suppose, the margin of the middle lobe with perhaps some fluid encapsulated in the interlobar space, and a most remarkable lesion toward the hilus which is dense and seems to be nodular. There are several parts to it. In the next picture it appears as though a cavity had been emptied.

There are some other interesting features. I was impressed that the ribs were close together on the right. The right chest is smaller than the left.

To go on with the story—"On the day of admission an exploring needle introduced in the third right interspace in the midaxillary line elicited definite resistance which increased after passing the pleura." Apparently they plunged their needle into something solid. On the second attempt they struck a hole, apparently, and obtained thick, creamy odorless pus. The fact that it was odorless might indicate that it was not of very long duration.

There was fluid at times in the base and I suspect it had been released from the lung in the process of paracentesis and thus was found at the bottom of the pleural cavity

Whatever happened, the fluid disappeared. Of course, it might be simply an accumulation of serous fluid of an irritative sort that was rapidly taken up. One sees it in the chest for example in connection with abscess of the liver. It could have been due to something like that.

Of course the pulse would not be slowed much by digitals because its rapidity is due to toxemia.

I should say at this point that they had attempted to drain a cavity, indeed they had drained a cavity, but he still presented the picture of undrained pus from which I would infer that there was more than one cavity.

Those in charge evidently thought the same and tried to find other pus pockets but did not succeed.

"The trachea was displaced toward the left in the region of the aortic arch." I should like to ask the radiologist about that. I cannot understand why it should be displaced toward the left if the right chest is smaller and there is atelectasis.

To summarize and interpret the findings in this case then, I would say that here was a man who had had three episodes related to his lungs over a period of four months, the first of which he was told was pneumonia on the left side.

During his stay in the hospital he presented evidence of a suppurative process in the right lung, which I believe to have been multiple abscess with a good deal of induration and atelectasis. I also believe that he had empyema probably resulting from the spilling of pus during paracentesis.

I believe that he has old pulmonary tuberculosis, and an old bilateral bronchiectasis. I am puzzled about what relation these old processes bear to the more acute terminal one.

I raise the question of an old healed milary tuberculosis.

I think of malignant disease of the lung with secondary suppuration, but I cannot feel that we have the evidence to assert its presence.

That is as far as I can go.

X-RAY INTERPRETATION

DR AUBREY O HAMPTON We had as much difficulty with this patient as Dr Means has had, and in fact Dr Lord and I had quite a discussion over him. He had this complete consolidation of the lower aspect of the upper lobe and, as Dr Means says, it does extend down forward here to the diaphragm and the middle lobe might well have been involved. We could not see the top of the middle lobe, so we did not know for certain. The thing that interested us most was this round shadow here, and this irregular nodular shadow here at the lower as-

pect of the right lung root. The question was whether that was a tumor or not, whether that produced the whole picture certainly it looks like a tumor. The complication is this, which is probably bronchiectasis at the left base and perhaps bronchiectasis of the right middle lobe, or you could say that this was bronchiectasis and this was bronchiectasis, and all we have in addition is a consolidated right upper lobe.

DR MEANS Is that a cavity with fluid level?

DR HAMPTON We could not find a cavity that we were sure of. We took this Bucky film in an effort to show cavities. If this is tumor, why should not the heart shift toward the right? Apparently the trachea shifted in the opposite direction. We tried to explain that without much success. We did not find anything except calcified old tubercles in the left lung and these few dilated bronchi at the left base.

CLINICAL DISCUSSION

DR FREDERICK T LORD Our conclusions were in accord with those of Dr Means with respect to the probability of an old pulmonary tuberculosis and also of bronchiectasis at the left base. The complex of physical signs over the right upper part of the chest as presented in the case history is incomplete. Dr Means was, in consequence, at a disadvantage in interpreting the significance of the signs. They varied somewhat from time to time. In the right upper front there was dullness, diminished breathing, voice, whisper and tactile fremitus. At times, bronchial breathing was heard over the inner upper part of the dull area. These findings, with the roentgenologic evidence of a dense mass in the region of the right root, suggested obstruction of the right upper lobe bronchus due to malignant disease. The clinical aspects and the x-ray also suggested the possibility of encapsulated pleural fluid in this region. The tapping on the fifth day was done in the third interspace in the right upper axillary region and between one and two cubic centimeters of pus containing pneumococci (later shown to be type VIII) were obtained at what seemed to be the level of the pleura. It was, in consequence, thought that he had an encapsulated empyema, but at operation by Dr Churchill the pus was found to come from multiple small areas in the lung and not from the pleura. The finding of pneumonitis and cavity formation due to pneumococcus infection is of some interest because of its rarity. In explanation, it may be suggested that the usual factors leading to resolution of pneumococcus pneumonia could not operate under the pathologic conditions and that the absence of access of blood with its antienzyme permitted the unrestrained digestive action of enzyme on the lung framework.

CLINICAL DIAGNOSES

Carcinoma of the lung?
Bronchiectasis.
Old tuberculosis
Empyema, right.
Bronchopneumonia.

DR. JAMES H. MEANS'S DIAGNOSES

Multiple abscesses, right lung
Pulmonary atelectasis, right.
Empyema, right.
Old tuberculosis, right top
Chronic bronchiectasis, both bases
Cancer of the lung with secondary suppuration?

ANATOMIC DIAGNOSES

Oat-cell carcinoma of the lung, right upper, with metastases to the regional glands
Bronchopneumonia, right upper
Empyema, encapsulated, right.
Compression atelectasis, right middle and lower
Bronchiectasis, left lower
Pulmonary tuberculosis, healed, left upper
Pulmonary emphysema, left.
Pulmonary osteoarthropathy, slight.
Arteriosclerosis, slight, aortic

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY The autopsy findings are in part confirmatory and in part rather surprising. The most immediate finding on opening the thoracic cavity was that we broke into a very large empyema cavity on the right side which lay between the diaphragm and the base of the lung. It contained about a liter of pus and had thick walls. It was difficult to estimate how long it had been present but it certainly must have been there a couple of weeks. The lower lobe and middle lobe were completely atelectatic, probably from compression between the empyema cavity and the consolidated upper lobe. The bronchus to the right upper lobe was completely occluded by a mass of tumor which was infiltrating in rather fan shaped fashion the entire lobe. The lung abscess found by Dr. Churchill had been adequately drained and had nearly healed. On the left side there was a localized area of bronchiectasis at the left base and the other lobes were essentially normal, with slight compensatory emphysema.

A PHYSICIAN Was there any tuberculosis at the right apex?

DR. MALLORY The left apex had a small tuberculous scar. That was all the evidence of tuberculosis that we found. The right upper lobe beyond the obstruction of the bronchi was largely atelectatic, to a certain extent chronic

ly infected. There were no obvious cavities at the time of autopsy.

A PHYSICIAN What was the tumor?

DR. MALLORY It appears to be an oat-cell carcinoma, quite typical.

DR. EDWARD D. CHURCHILL The empyema that was found at autopsy probably came in the last two weeks in this illness and at that time we had practically decided he had an advancing malignant disease because of the operative findings and the physical signs of bronchial obstruction.

CASE 21432

PRESENTATION OF CASE

A fifty seven year old white American widow was admitted to the surgical service complaining of increasing weakness and bleeding from the rectum and vagina.

She had been well until three years previously. At this time her menses, which had always recurred regularly at monthly intervals and lasted for three to four days, suddenly became irregular. The intervals varied from three to ten weeks and the duration extended to one week. The flow was quite profuse and contained many large clots. There was no associated distress. She considered this the result of her menopause and continued with her normal activity until one year prior to entry. At this time she began to lose her appetite and her diet was gradually limited to fruits, soft foods and milk. She lost thirty pounds during the year before entry to the hospital and became progressively more readily fatigued so that she was compelled to discontinue her housework and spend most of the day in bed. About one month before admission she first noted fresh blood and clots in her stools associated occasionally with tenesmus and cramplike "gas pains." She had always been constipated and took a laxative each day. For three days before admission she had frequent desire to go to stool with the passage of blood and clots.

At the age of forty-eight she had complete amenorrhea for a period of ten months. Subsequently the previous cycle returned. She had typhoid fever at the age of fourteen.

Her mother died of gastric hemorrhage resulting from an ulcer at the age of forty seven. Her father died of a stroke at the age of seventy five.

Although married for twenty five years the patient had no children. There was a questionable miscarriage after one month of amenorrhea.

Physical examination showed a well developed, rather obese woman in no apparent distress. There was slight exophthalmos but the eyes were otherwise negative. The heart was enlarged to the left. There was a loud blowing systolic murmur audible over the precordium.

The blood pressure was 174/84. Palpation of the abdomen demonstrated a firm slightly tender rounded mass in the right lower quadrant, extending from within the pelvis halfway to the umbilicus. Vaginal examination showed that the mass was connected with the uterus. Rectal examination elicited a sphincter so spastic as to preclude demonstration of further details.

The temperature was 100°, the pulse 88. The respirations were 20.

Examination of the urine showed a slight trace of albumin with a specific gravity of 1.002 to 1.012. There was no sugar present. The sediment contained on one occasion many red blood cells but in other specimens there were few or none. It was, however, loaded with white blood cells and contained an occasional cast. The blood showed a red cell count of 2,030,000, with a hemoglobin of 40 per cent. The white cell count was 12,350, 81 per cent polymorphonuclears. The platelets were normal. The blood Hinton and Wassermann tests were strongly positive. The nonprotein nitrogen of the blood was 57 milligrams.

On the second day a proctoscopy was done. The proctoscope passed for a distance of eight and a half inches. The bowel was not dilatable beyond this point and a slot-like opening with considerable bleeding was observed. A biopsy was done. That night the patient's temperature suddenly rose to 103.8°. She became somewhat drowsy but talked coherently. On the next morning she was comatose, cyanotic, incontinent and had Cheyne-Stokes respiration. The pupils were constricted and fixed. There was a bilateral Babinski sign. The temperature remained elevated but the pulse dropped to 70. The blood pressure was 90/40. A lumbar puncture showed an initial pressure of 200 millimeters. The fluid was clear and negative. She improved gradually, became less comatose and on the fifth hospital day was transferred to the neurological service. Examination there demonstrated a definite exophthalmos. The pupils were constricted, equal and reacted to light and distance. The heart findings were unchanged. The blood pressure had risen to 156/54. There was dullness and diminished tactile fremitus at both lung bases posteriorly. Breath sounds were present and appeared to be coarsened. The bladder was found to be halfway to the umbilicus. The patient was fairly well oriented but remained semistuporous for the greater portion of the examination. The right knee jerk and ankle jerk were slightly greater than the left. The Babinski sign was absent. The remainder of the neurological examination was negative. Subsequently there was definite mental improvement. A portable x-ray of the chest on the eighth day showed a mottled area of dullness in the right upper lung field and another below the right hilus. Four days later the consolidation in the right upper lobe had

decreased. There was no great change in the patient's general condition until the beginning of the third week. At this time echolalia, increasing distention of the abdomen, and enlargement of the tumor mass in the right lower quadrant were noted. A positive Babinski sign appeared on the left side. On the twenty-third hospital day the temperature rose rapidly to 105°, the pulse was 100 with many dropped beats, and the respirations became shallow with the rate of 50 per minute. There was dullness at both bases posteriorly with bubbling râles on the right. Her breathing became Cheyne-Stokes in character and the temperature rose to 107°. The patient became comatose and expired that day.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN. This is a rather complicated story of a woman who has lues and who comes in at the age of fifty-seven bleeding from the vagina and rectum. We have certain evidence that there is a tumor in the pelvis which probably is quite significant. The omission of any note as to whether this tumor was expansile I think in this instance, even in a luetic, is not important. With the story as presented, one thinks in this type of case of a carcinoma of the body of the uterus which has now become quite widespread and has involved the lower large bowel, so that you have not only bleeding from the vagina but bleeding from the rectum as well.

The important thing that is omitted from the history that we should like to know is the character of this discharge that she had from the vagina. It simply mentions blood and clots, nothing about the odor. In carcinoma of the fundus of the uterus you frequently get a very foul discharge which is quite characteristic.

In the sequence of events one wonders what happened in the proctoscopy to cause the temperature to rise so rapidly. Perhaps there was no connection between this examination and the definite increase in the patient's illness. Also, there was a biopsy taken which is withheld from us.

DR. TRACY B. MALLORY. We will be glad to tell you that, Dr. Allen. It showed adenocarcinoma.

DR. ALLEN. That is extremely helpful because we now know that the patient not only had lues but adenocarcinoma as well. Of course the thing that interests us is whether this could be a primary bowel lesion. Could this uterine condition have been a fibroid or an ovarian cyst in the pelvis and the real lesion be in the bowel itself? I think we probably can feel pretty sure that the right sided mass does not mean primary carcinoma in the cecum. She comes in with enough anemia to fit such a diagnosis, but I would question whether she would go three

years with symptoms of this sort with a primary lesion in the cecum.

One wonders about the cerebral accident that happened in the hospital. Was it due to metastatic malignant disease, lues, hemorrhage or anemia of the brain. The spinal puncture would help somewhat if we could be sure that the fluid was clear and negative. I suppose that means negative for a Wassermann as well as other things. Therefore I suppose we can say that the cerebral symptoms were not due to lues. If it were due to metastatic malignant disease it would surprise me a little to have her improve rather than continue to get more confused. I should be inclined to think that the cerebral accident was due to hemorrhage or thrombosis rather than to malignant metastases, although she may have had malignant metastases to the brain. She probably did have malignant metastases to the lung.

I should be inclined to favor the diagnosis of primary adenocarcinoma of the fundus of the uterus with secondary involvement of the sigmoid or high rectum, and a generalized carcinomatosis otherwise and burnt-out lues.

CLINICAL DISCUSSION

DR. ERNEST M. DALAND. I examined the patient an hour or two after she came into the hospital and at that time she said nothing about any rectal symptoms but spoke only of her vaginal bleeding. I did a pelvic and rectal examination on her at that time. She had this large mass slightly to the right. It was freely movable and smooth and it seemed like a large fibroid although the possibility of an ovarian cyst was considered. It did not feel like carcinoma of the fundus. It was too large and not firmly fixed. That afternoon when the history was more carefully taken the rectal bleeding was brought out. The next morning I did a proctoscopy. This was done without any difficulty in the knee-chest position. The proctoscope passed eight and a half inches. I could not inflate the bowel above that, and, as the history says, she showed a narrow slit with bleeding coming from the slit. The specimen was taken with a curet through the slit. I could not see any definite growth through the edge of the slit. It looked granular. We got a poor specimen which grossly we could not diagnose. The appearance was not that of carcinoma arising in the sigmoid.

DR. CHARLES S. KUBIK. I saw the patient a short time after the cerebral accident. Some improvement had already taken place and so I thought it was vascular occlusion that is thrombosis or embolism, rather than hemorrhage, and because it was stated that at the onset the pupils were constricted and both plantar reflexes were extensor in type I was inclined to think that the trouble was in the basilar artery.

CLINICAL DIAGNOSES

Adenocarcinoma of the sigmoid.
Tertiary lues.
Cerebral thrombosis
Brouchopneumonia.
Arteriosclerosis.

DR. ARTHUR W. ALLEN'S DIAGNOSES

Adenocarcinoma of the uterus
Secondary involvement of the sigmoid
Metastatic carcinoma, possibly of the lung and brain
Cerebral thrombosis
Tertiary lues

ANATOMIC DIAGNOSES

Adenocarcinoma of the uterus with infiltration of the rectal wall
Peritonitis, acute localized
Atrophy of the right kidney
Compensatory hypertrophy of the left kidney
Hydronephrosis, left
Hydroureter, left.
Pulmonary edema, slight.
Arteriosclerosis, marked, aortic

PATHOLOGIC DISCUSSION

DR. MALLORY. The biopsy which was taken, as Dr. Daland has described, showed a superficially normal mucosa underlying which in the submucosa islands of definite adenocarcinoma could be seen. One might be tempted to conclude from such findings that the gut was invaded from without but that would be very dangerous since often rectal biopsies are taken not from the center of the tumor but from the edge, and we frequently find normal mucosa overlying cancer which is infiltrating laterally. So that our suspicions were not aroused at all and knowing nothing of the story at that time we assumed that it was a primary carcinoma of the bowel.

The autopsy showed that it was not that but a primary uterine cancer which had grown upward and laterally to involve nearly sixteen centimeters of the upper rectum and sigmoid. The tumor mass seemed at first very hard and firm but as we cut into it we found there was simply a shell of tumor on the outside and the center was composed of gelatinous, necrotic material. The terminal ileum also had become involved in the tumor and two or three loops were firmly adherent to it. Between these loops we found a small abscess about eight centimeters in diameter filled with pus. It is not very clear that that played any part in the symptomatology. We found as is so common in carcinoma of the uterus practically no metastases. In other words all the tumor present was direct extension from the uterus. The lungs, liver, brain were all free from metastases.

The brain lesion turned out to be localized infarct in the left globus pallidus

One other rather striking feature at the autopsy table, but of no importance whatever in the clinical course of the disease, was a completely atrophic right kidney with an imperforate ureter on that side. On the other side we of course found compensatory hypertrophy, and there was also a moderate degree of hydronephrosis and dilatation of the upper part of the ureter with obstruction lower down where it passed beneath the tumor mass.

A PHYSICIAN: Were there any syphilitic lesions anywhere?

DR. MALLORY: No anatomical trace of them.

The heart was entirely negative except for very slight hypertrophy.

DR. JAMES H. MEANS: What was the exophthalmos?

DR. MALLORY: I am not clear about that, Dr. Means. It was not very evident on the autopsy table. It may have been a transitory affair. Have you any explanation, Dr. Kubik?

DR. KUBIK: No, I do not recall that as being a striking feature. She may have had simply a myopia.

THE IMPORTANCE OF RECOGNIZING CHRONIC CONSTRICTIVE PERICAR- DITIS (PICK'S DISEASE)

It has become of far more than academic interest to recognize chronic constrictive pericarditis, for it has been proved recently that a considerable percentage of the cases, formerly incurable, can now be completely relieved by surgery consisting of pericardial resection. It is not a common disease but neither is it excessively rare for in three clinics alone in this country (one in Boston, one in Cleveland, and one in Nashville) in the last few years at least forty cases have been recognized at the last count (spring of 1935) and fourteen have been cured. Others throughout this country and in Germany have also been relieved by pericardial resection.

Three essentials for a successful operation have recently been outlined by White in the St. Gyre's Lecture of the National Hospital for Diseases of the Heart at the Royal Society of Medicine in London. They are first, a correct diagnosis, secondly, selection of a patient who is seriously crippled by the disease and yet a

satisfactory risk for operation, and thirdly, an experienced thoracic surgeon. In the series of fifteen cases presented by White, Dr. E. D. Churchill of the Massachusetts General Hospital effected cures in six and a large measure of improvement in one other out of ten cases on whom he operated.

The following definition and diagnostic clues have been offered by White. "Chronic constrictive pericarditis consists of a chronic fibrous or callous thickening of the wall of the pericardial sac which is so contracted that the normal diastolic filling of the heart is prevented." The points for diagnosis are (1) the insidious development of dropsy in a young or middle-aged person without previous disease of heart or kidneys, (2) preponderant liver enlargement and ascites, (3) the presence of little or no cardiac enlargement, (4) increased prominence of the neck veins—a very important sign, (5) small pulse pressure, often with "paradoxical" (Griesinger-Kussmaul) pulse, (6) x-ray evidence (poor pulsation of entire heart or of right heart border alone, calcification, chronic pleuritis), (7) abnormal electrocardiogram (low voltage or low or inverted "coronary" T waves in chronic disease in early youth), and (8) a previous history of acute pericarditis. The first, third, fourth, and seventh of these clues are the most important and consistent ones.

The three conditions with which chronic constrictive pericarditis has been usually confused are the ordinary portal cirrhosis of the liver, chronic heart disease (in particular, mitral stenosis) with congestive failure, and acute or subacute polyserositis (which is Concato's, not Pick's disease). From portal cirrhosis of the liver chronic constrictive pericarditis is to be distinguished chiefly by two signs (in the absence of complicating heart disease): (1) engorgement of the neck veins, and (2) abnormal electrocardiogram. From heart disease chronic constrictive pericarditis is to be distinguished by the absence of characteristic murmurs, especially the diastolic murmur of mitral stenosis, and of much cardiac enlargement. Actually heart disease itself is found with only the greatest rarity complicating chronic constrictive pericarditis. And finally, from acute or subacute polyserositis chronic constrictive pericarditis is to be distinguished by the absence of evidences of infection (fever and leukocytosis) and of friction rubs (of acute pleuritis or acute pericarditis), and by the presence of increased systemic venous pressure (except when there is a pericardial effusion as a part of the acute polyserositis). In this connection it is important also to call attention to a frequent error, namely that of considering perihepatitis or Zuckergussleber (frosted liver) and perisplenitis as a necessary part of the clinical entity of chronic constrictive pericarditis. There may or may not be a chronic peritonitis involving capsule of liver

or spleen, as a part of a chronic polyserositis which may accompany Pick's disease, the pericardium may be the only serous sac involved in this disease and the liver capsule may be clear and glistening even though the liver is enlarged. The degree of hepatic cirrhosis in cases of chronic constrictive pericarditis as a rule is relatively slight. Conversely there are cases of chronic peritonitis with the liver not enlarged but closely encased in a thick capsule with no evidence of chronic constrictive pericarditis.

PROGRESS IN MEDICAL EDUCATION

THE statistical review of medical education in the United States for the past year, recently published in the *Journal of the American Medical Association*¹ presents material which deserves consideration by every person interested in that fascinating subject, but especially by every physician. In the comment accompanying the review are suggested some trends the importance of which one can only guess.

The problem of relieving suffering and of overcoming disease confronts the physician daily, in fact many times a day, and in an important sense schools of medicine are springs which supply the rivers of healing. Physicians must be interested in every fact pertinent to the question of how this primary problem concerning the springs is being solved, or at least is being attacked.

Excellent reviews of recent progress in the various branches of medicine have been issued in the literature, notable among them being the articles on medical progress in the past twenty-five years which appeared in the *British Medical Journal*².

The time is ripe for a study of the progress in medical education which has been made in the twentieth century. A superficial survey has been presented by the statistical studies, to one of which reference has already been made, but what is needed is a more penetrating analysis which will note the new ideas, their introduction, their spread, their influence, perhaps advancing, perhaps receding, their results, possibly their relatively permanent contribution to education.

There is, for example, the idea of a university. This was relatively slight in its influence in American medical education in 1900, yet of all ideas now working themselves out, it has wrought, perhaps, the greatest transformation. Most medical schools are associated with universities. To what extent are they dominated by the idea of university education? It is reported that educational methods appropriate

for secondary school have been hyper-extended into the medical departments of some so-called universities. There is still much opportunity for improvement.

Another idea growing in importance of influence of late is that the patient, the concrete person who is sick, is the focus of interest for the medical student as well as for the physician and should be recognized as such. Then the old idea of learning by doing, applied especially in the internship, is receiving more widespread attention.

A fourth idea, vague, threatening, portentous, is the socialization of medicine. Few of us, if any, know just what this means. Its manifold connotations bewilder us. We are sure all is not well with the world of the practice of medicine. Some say it is the "individualization" of medicine that is the matter. Others say that medicine is essentially individualistic, and physicians are in their nature individualists. Then there is the retort discourteous that individualism is a cloak for selfishness.

It is too soon to record the influence of this fourth idea, it has hardly begun its course in its modern form and certainly it demands study. But those ideas mentioned first and others which might be noted have obviously been at work for years and of their effect too little has been said.

What we want to know is what progress has been made in this, the latest, of the centuries, in educating physicians. It is not merely what increase has there been in the information which every physician or any physician, must have as part of his armamentarium, but what progress in method has been achieved so that with a given expenditure of time and effort, and if one may say so, of brains, there comes to the individual student more power as a physician. Here is a challenge indeed to the medical educator.

SIGNING THE PLEDGE

MANY readers of the *Journal* who hold teaching appointments at the various universities have doubtlessly within the last few weeks been asked to take an oath of allegiance to the Constitution of the United States. This oath, made mandatory by an Act of the Great and General Court of Massachusetts, was the subject of considerable controversy a few months ago. It is now required of teachers in private institutions, and of school children.

There is no reason why any good citizen of the Commonwealth should stickle over his rights and his principles and refuse to take this oath, objectionable as the coercive method may be to him. True such coercion may be opposed to the spirit of the Constitution which it professes

to uphold, but the oath itself will do no harm, nor will it serve any useful purpose

Surely there can be no advantage in denying to our political guides an opportunity of rendering lip service to the ideals of robust Americanism and, by twisting the American eagle's tail a little harder, make it scream a little more loudly

THIS WEEK'S ISSUE

SECTION OF OBSTETRICS AND GYNECOLOGY*

C. J. KICKHAM, M.D., Chairman	R. S. TITUS, M.D., Secretary
524 Commonwealth Ave., Boston, Mass	472 Commonwealth Ave., Boston, Mass

WHAT IS YOUR OPINION AS TO THE DANGER OF BARBITURATES IN OBSTETRICAL ANALGESIA?

During the past five years, the use of the barbiturates in obstetrical analgesia has increased tremendously. The drugs in popular usage are sodium amylal and sodium pentobarbital (nembutal), the latter has been rapidly replacing sodium amylal. The employment of these medications has become so universal that they have often been given indiscriminately.

One of the pronounced disadvantages of the barbiturates is the extreme restlessness of the patient. Sodium pentobarbital has a more depressing effect upon the higher brain centers with a decreasing amount of excitement. Consequently any patient who has been given these medications must be watched by a trained attendant, and it is therefore most unwise to administer these drugs to a patient who is having the baby at home. In the hospital, a nurse should be at the patient's bedside throughout the entire labor and also during the postpartum period until the patient has fully awakened. Many a patient after delivery has gotten out of bed and wandered around the hospital corridors. It is good policy not to give cardiacs any of the barbiturates.

The barbiturates should not be administered after the patient has eaten. In the first place, it is possible that the medication will not take effect inasmuch as it may be slowly absorbed.

A series of short selected articles by members of the Section will be published weekly.
Comments and questions by subscribers are solicited and will be discussed by members of the Section.

and, secondly, much more important, should the medication be absorbed, there is definite danger of the patient losing her swallowing reflex and inadvertently inspissating some vomitus or mucus in the trachea. This has not been an infrequent occurrence, and mortalities have been reported in the literature

The barbiturates are prone to stimulate the flow of mucus, sodium amytal being a worse offender than sodium pentobarbital. If the patient, therefore, shows a tendency toward mucus production, one should cut down the dosage of the barbiturates and keep her in a much more wakeful condition. A great many of these patients take gas oxygen, as a terminal anesthetic, very badly. They are prone to gag and vomit. Drop ether is much more satisfactory. In patients with upper respiratory infections or those with tuberculosis, barbiturates should not be administered. It is ideal, of course, to keep a patient comfortable especially if she has a long labor. In such cases, one should be very careful to administer very small dosages of the barbiturates so that the patient can be awakened to take fluids. If she is narcotized too deeply, she is quite apt to become dehydrated and also to develop acidosis.

The bladder, during labor, has always needed careful watching. Should the bladder become distended, there is a great possibility that the muscle fibers will become paralyzed and that the patient will consequently have urinary retention and be unable to void. If she is kept deeply narcotized, frequent catheterizations during labor are imperative. Likewise, following delivery, if she is too sleepy to void, the bladder should be emptied by catheterization ten hours after delivery even without apparent distention. In this way, much of the incidence of postpartum urinary infection will be avoided.

In conclusion, the barbiturates should never be administered to a patient at home. During labor and until fully awakened after delivery, a nurse should be in constant attendance. These drugs are contraindicated in cardiacs, in upper respiratory infections, tuberculosis, and if the patient has had a full meal. Drop ether is the most satisfactory terminal anesthetic. The bladder has to be carefully watched both during labor and during the postpartum period. In long labors, the patient should be kept semi-conscious so that she can take plenty of fluids, thereby avoiding dehydration and acidosis.

THIRD ANNUAL POSTGRADUATE MEDICAL EXTENSION COURSE

The following sessions have been arranged by the Committee for the week beginning October 27

Barnstable

Sunday, October 27, at 4 00 P M, at the Cape Cod Hospital, Hyannis Subject Arthritis

(a) Medical Care of Patient in the Home
(b) Orthopedic Treatment in Hospital and Aids in Home Treatment. Instructors L T Swaim and R T Phillips J I B Vail, Chairman.

Bristol South (Fall River Section)

Monday, October 28, at 4 00 P M, at the Stevens Clinic of the Union Hospital, Prospect Street, Fall River Subject Pediatrics Abdominal Disease in Childhood, Medical and Surgical Aspects. Instructors S H Clifford and H W Hudson, Jr Eugene A McCarthy, Sub-Chairman

Essex North

Friday, November 1, at 4 00 P M, at the Hotel Bartlett, 95 Main Street, Haverhill Subject Ophthalmology and Otolaryngology (a) The Major Hazards in Diagnosis of Diseases of the Eye, Ear, Nose and Throat as Seen in General Practice (b) Special Treatment in Acute Medical and Traumatic Diseases of Eye Emergencies Arising in the Treatment of the Ear, Nose and Throat. Instructors L G Richards and W P Beetham Francis W Anthony, Chairman

Essex South

Tuesday, October 29, at 4 00 P M, in the Nurses' Home of the Salem Hospital, Salem Subject Cancer of Stomach, Bowel and Genito-Urinary Tract. Modern Care of Inoperable and the Incurable, the Development of Improved Methods of Caring for These Cases with Less Pain and Discomfort with Minimum of Drug Therapy. Instructors Horatio Rogers and R C Graves Walter G Phippen, Chairman

Hampden

Thursday, October 31, at 4 00 P M, at the Academy of Medicine, Professional Building, 20 Maple Street, Springfield, and at 8 00 P M, at the Holyoke City Hospital, Holyoke Subject Kidney and Bladder Diseases, A (Surgical) Hematuria Its Significance in Surgical Diseases of Kidney and Bladder Instructor W C Quinby George L Schadt and George D Henderson, Chairmen

Hampshire

Wednesday, October 30, at 4 15 P M, in the Nurses' Home of the Cooley Dickinson Hospital, Northampton Subject Cancer of Stomach, Bowel and Genito-Urinary Tract. Modern Care of Inoperable and the Incurable, the Development of Improved Methods of Caring for These Cases with Less Pain and Discomfort with Minimum of Drug Therapy. Instructors David Cheever, W C Quinby and M C Sosman Robert B Brigham, Chairman

Middlesex East

Wednesday, October 30, at 4 00 P M, at the

Melrose Hospital Melrose. Subject Lung Diseases (a) Significance of Symptoms and Signs in Chronic Lung Disease Tuberculosis, Bronchiectasis etc. (b) The Value of Surgery in Above Disease Problems in Structures Cleveland Floyd and H F Newton. Joseph H. Fay Chairman.

Middlesex South

Tuesday October 29 at 4 15 P.M., at the Cambridge Hospital, Cambridge Subject Kidney and Bladder Diseases A (Medical) Acute Nephritis — Etiology Diagnosis and Treatment. Nephrosis and Its Treatment Instructor L. B. Ellis Edmund H Robbins Chairman.

Norfolk South

Monday October 28 at 8 30 P.M., at the Quincy City Hospital, Quincy Subject Diseases of the Liver Surgical Problems in Diagnosis of Acute Disease of Gall Bladder and Liver Instructors F D Adams and W R. Morrison David L Belding Chairman

Plymouth

Tuesday October 29 at 4 00 P.M. at the Brockton Hospital, Brockton Subject Neurological Aids in the Diagnosis and Treatment of Disease from the Medical Viewpoint. Problems of History and Examination with Special Reference to (a) Neurosyphilis, Multiple Sclerosis and Other Degenerative Conditions (b) Diseases with Acute Onset, such as Meningitis and Cerebral Accidents. Instructor T J Putnam. W H Pulsifer Chairman.

Worcester North

Friday November 1 at 4 30 P.M. at the Bank Hospital, Fitchburg Subject Kidney and Bladder Diseases, B (Medical) Chronic Nephritis Cardiorespiratory Disease. The Use of Diuretics. Instructor J P O'Hare Edward A. Adams Chairman.

HARVARD MEDICAL SCHOOL APPOINTMENTS
AND RESIGNATIONS

RESIGNATIONS EFFECTIVE SEPTEMBER 1, 1935

George W. D. Hamlett, Research Fellow in Anatomy

Robert Amory Member of Epilepsy Commission

APPOINTMENTS

From September 1 1935 to April 1, 1936

Albert E. Raub Research Fellow in Anatomy

From November 1, 1935 to July 1 1936

Paul E. Casaday Research Fellow in Medicine

For one year from September 1 1935

Enrique Savino Research Fellow in Epidemiology (School of Public Health)

Carl T. Nelson, Instructor in Bacteriology

Marjorie Fremont Smith Instructor in Medicine

Benjamin Castleman Instructor in Pathology

Gilbert Horrax, Instructor in Neurology Courses for Graduates.

Kurt H. Semarsoth Teaching Fellow in Bacteriology

Alfred Krane Assistant in Medicine

Lowrey F. Davenport Assistant in Medicine.

Isadore E. Budnitz, Assistant in Medicine.

William M. Meckley Assistant in Medicine

Benedict F. Massell, Assistant in Medicine.

Edgerton McO. Howard Assistant in Neurology

Christian F. Midelfart, Assistant in Neurology

Hugh P. Newhall Assistant in Neurology

Melior G. Karp Assistant in Orthopedic Surgery

Quentin M. Geiman, Assistant in Comparative Pathology in Medical School and School of Public Health.

Nells L. Anthonisen Assistant in Psychiatry

Grosvenor B. Pearsall, Assistant in Psychiatry

John D. Stewart, Assistant in Surgery

Frederick W. Klempner Research Fellow in Biological Chemistry

Georges J. P. Hornus Research Fellow in Bacteriology

James G. M. Hamilton, Research Fellow in Medicine.

Francis J C Herraid, Research Fellow in Medicine

Michel Pijoan, Research Fellow in Medicine

John A. V Davies, Research Fellow in Pediatrics

David Weinman, Research Fellow in Comparative Pathology

Felix Deutsch, Research Fellow in Psychiatry

Erik Homburger, Research Fellow in Psychology

Georges E P Coppee, Research Fellow in Physiology

DR. GASSER SUCCEEDS DR FLEXNER

Dr Herbert S Gasser has been appointed to the position of Director of the Rockefeller Institute for Medical Research to fill the position made vacant by the resignation of Dr Simon Flexner. Dr Flexner has been given the title of Director Emeritus after thirty-two years of service.

Dr Gasser was formerly Professor of Physiology and Director of Physiological Laboratories at the Cornell University Medical College.

A TESTIMONIAL DINNER AND MEETING IN HONOR OF DR. DAVID L EDSALL

A testimonial dinner, in honor of Dr David L Edsall, recently retired dean of the Harvard Medical School, was held by the Harvard Medical School Alumni Association at the Harvard Club of Boston, Wednesday evening, October 23. President James B Conant, of Harvard, presided, and Dr A Lawrence Lowell, president-emeritus of Harvard, delivered the principal address. Dean Charles S Butler, of the Harvard Medical School, also spoke.

Preceding the dinner, a meeting was held at the Harvard Medical School. Addresses on "The Development of Medical Education in the United States Since the World War" were made by Dr Walter A Jessup, President, Carnegie Foundation for the Advancement of Teaching, Dr Eugene DuBois, Professor of Medicine, Cornell University, and Dr Lawrence J Henderson, Professor of Chemistry, Harvard University. Dr Walter B Cannon, Professor of Physiology, Harvard, presided. Members of the medical profession in the Boston area were present.

APPOINTMENT OF DR. HOSEA W McADOO

The appointment has been announced of Dr Hosea Webster McAdoo as medical director of the Ring Sanatorium and Hospital in Arlington, Mass. Dr McAdoo, a Texan by birth, was graduated in medicine from Tulane University in 1920. After serving a year's internship at the Southwestern Railroad Hospital in St. Louis, he was resident physician for two years at the Warren State Hospital, Pennsylvania. This was followed by a three months' period as psychiatrist in St. Elizabeth's Hospital in Washington, D C. From 1924 to 1929 he was medical officer in psychiatry in the United States Veterans Hospital at Little Rock, Arkansas, and from

1929 to 1930 assistant professor of pathology at Baylor University in Dallas. Dr McAdoo became clinical director of the Springfield State Hospital in Sykesville, Maryland, in 1930 and was appointed superintendent in 1932, a post which he held up to the time of his present appointment.

CORRESPONDENCE

DIABETES AND CHRISTIAN SCIENCE

October 7, 1935

Editor, *New England Journal of Medicine*,

Within the past few weeks I have had to attend two diabetic patients who had been treated with Christian Science and were in coma when I saw them. One of them I had seen in consultation ten years before. She followed medical advice for a time with satisfactory results, but later succumbed to the teachings of Christian Science. Diet and insulin were discarded. When I saw her again two months ago, she was greatly emaciated, stuporous and acidotic and vomited persistently. Her family very sensibly had called their former family physician at the beginning of this episode. She was immediately removed to the hospital and after a strenuous three-day battle was out of danger.

The other patient, seen first by me about a year ago, came at the insistence of a relative, a physician, but made only one visit and did not accept medical advice. A month ago the call came to see her again. She was in deep coma and had been so for more than twenty-four hours. Her attending Christian Science friends had refused to call medical aid. This patient, also, was removed to the hospital, but despite heroic treatment did not regain consciousness and died a few hours later.

The question arises: Is this manslaughter? It certainly is not science, and I doubt that it is Christian.

I believe that Christian Science is a helpful form of psychotherapy, but its practitioners should recognize its futility in organic disease.

Very truly yours,

HELMUTH ULRIKH

99 Bay State Road,
Boston, Mass

RECENT DEATH

FALLON—JOSEPH FRANCIS FALLON, M D, of 440 Boylston Street, Brookline, Massachusetts, died at his home, October 14, 1935. Dr Fallon was born in Brookline in 1882 and after graduating from Boston College, entered Jefferson Medical College and was given his medical degree in 1908. He served his internship at the Bellevue-Gouverneur Allied Hospitals in New York and took a postgraduate course in London.

He served in the World War with the rank of lieutenant in connection with the transportation of troops.

Dr Fallon joined the Massachusetts Medical Society in 1912 and was a member of the American Legion the Clover Club and the Brookline Lodge of Elks

He is survived by his widow two sons two daughters two sisters and a brother

OBITUARY

HENRY JOSEPH FITZSIMMONS A.B. M.D.
F.A.O.S.

FEBRUARY 21 1880-OCTOBER 5 1935

A talented honest generous serviceable man. Thus is the Honorable Patrick Andrew Collins for mer mayor of Boston characterized on the statue erected to his honor. This is saying much of a man and all of these epithets may with equal truth be applied to Henry Joseph FitzSimmons. Gentleness also was his in attitude and action. His passing removes a living example of conduct which has been helpful to younger medical men. It will continue to endear him to those of us who walked the same paths as he.

Born on February 21 1880 he was graduated from Harvard College in 1903 and received his medical degree also from Harvard in 1908. His first internship of eighteen months was on the Surgical Service of the Boston City Hospital after which he became Resident Surgeon at the East Boston Relief Station. After completing with distinction a six months internship on the Orthopedic Service of the Boston Children's Hospital he determined to make orthopedic surgery his chief concern and was awarded a travelling fellowship for two years by the Boston Children's Hospital. These two years between 1910 and 1912 were profitable ones spent under masters of orthopedic surgery. Six months with Sir Robert Jones during part of which he was Resident Surgeon at the Liverpool Royal Southern Infirmary work in the clinics of Calvé and Mennard at Berck Plage work under Lamy in Paris, Putti in Bologna, Schanz in Dresden Bielsalski in Berlin Lange in Munich and in the orthopedic clinics of Rame and Vienna. While in Munich Lange perfected his original technique for the implantation of silk artificial ligaments and tendons. The young American orthopedic surgeon became one of his favorite pupils. FitzSimmons may be said to have introduced the method into this country. Upon his return from Europe he familiarized himself with the type of work being done in the orthopedic clinics of Baltimore Philadelphia, New York, Chicago and Rochester Minnesota. He settled in Boston was appointed a Junior Surgeon at the Boston Children's Hospital and had advanced to the position of full Visiting Surgeon and Instructor in Orthopedic Surgery at the Harvard Medical School at the time of his death.

He was consulting Orthopedic Surgeon to the Quincy City Hospital the Choate Hospital in Woburn the House of Providence in Holyoke and St. Margaret's and St. Mary's Infant Asylum and for many years conducted at regular intervals an

Orthopedic Clinic at the Day Nursery in Holyoke, Massachusetts

During the World War he enlisted in 1918 in the Medical Officers Reserve Corps with the rank of Captain and saw service at Camps Oreenleaf, Fort Oglethorpe McPherson Devens and finally at Base Hospital No 10 Parker Hill Roxbury Massachusetts being honorably discharged June 20 1919

Dr FitzSimmons was married in 1914 to Elizabeth Rogers. His wife and four daughters survive him.

He was a member of the American Medical Association American College of Surgeons American Academy of Orthopedic Surgeons, Massachusetts Medical Society Eastern States Orthopedic Club Boston Orthopedic Club Aesculapian Club Military Order of the World War and the Charitable Irish Society.

Clinical work absorbed most of this busy surgeon's time, but he managed to carry out over a series of years important research studies as to the causes and treatment of Congenital Torticollis or wryneck. His conclusions were made authoritative by a large true end result study. His final paper published in *The New England Journal of Medicine*, July 13 1933 is a noteworthy contribution.

One of Dr FitzSimmons' close medical associates is unable to remember ever hearing him speak in derogatory terms of any of his professional associates and all of us were conscious of his infinite kindness. His medical opinion was honestly given and valuable. He was a most generous consultant whose mind was open. His devotion to his private industrial and hospital patients was complete. His monument will be the abiding memory of a talented honest generous serviceable gentleman.

R. B. O.

NOTICE

MEDICAL CLINIC AND STAFF ROUNDS AT THE
PETER BENT BRIGHAM HOSPITAL.

At 3 30 P.M. on Thursday October 31 in the amphitheater of the Peter Bent Brigham Hospital Dr Henry A. Christian Physician-in-Chief Hersey Professor of the Theory and Practice of Physic in the Harvard Medical School, will give a medical clinic. To it are cordially invited practitioners and medical students. These clinics will be repeated on Thursdays October to May.

On Saturdays in the wards of the Peter Bent Brigham Hospital from 10 to 12 staff rounds will be conducted by Dr Christian.

REPORT AND NOTICES OF MEETINGS

MIDDLESEX SOUTH DISTRICT MEDICAL
SOCIETY

OCTOBER 9 1935 HOTEL CONTINENTAL, CAMBRIDGE

Nearly two hundred and fifty Fellows were assembled to honor Dr Charles E. Mongan an outstanding member of this district society and recent

ly elected President of the Massachusetts Medical Society

The meeting was called to order by the district President, Dr Sumner H Remick, after a luncheon had been served

The minutes of the previous meeting were accepted unread.

Dr Alexander A. Levi, the secretary, next summarized the present status of the various hospitals in the district in relation to the following resolutions which were adopted at a meeting held during October, 1934

Resolution (1) That the Trustees of Hospitals in this district be requested to make all industrial accident cases private patients in the hospital

Resolution (2) That the Trustees of Hospitals in this district be requested to require from each patient applying for ward service a letter from a physician certifying that it is a suitable case for such service

Up to the present the resolutions have been adopted and are functioning in the following named hospitals

- (1) Charles Choate Memorial Hospital
- (2) Framingham Union Hospital
- (3) Newton Hospital
- (4) Middlesex Hospital
- (5) Symmes Arlington Hospital
- (6) Whidden Memorial Hospital
- (7) Waltham Hospital
- (8) Winchester Hospital
- (9) Somerville Hospital
- (10) Malden Hospital
- (11) Leonard Morse Hospital

The resolutions have not as yet been adopted by

- (1) The Lawrence Memorial Hospital ("Some action taken by board")
- (2) The Marlborough Hospital ("No action taken by board of trustees")

A second letter requesting information as to whether any action had been taken by the Board of Trustees of the Cambridge Hospital and the Emerson Hospital to date has remained unanswered. The first letter acquainting these institutions with the resolutions as adopted by the Middlesex South District Medical Society was sent during December, 1934 and a second was sent during September, 1935

Dr Edward J O'Brien, Jr, a member of the subcommittee of the Public Relations Committee, presented the following report

"(1) The committee composed of representatives from Norfolk Middlesex South and Suffolk District Societies of the Massachusetts Medical Society to study and work on the abuse of medical charity in the City of Boston has been active during the summer months and now wishes to make a report of progress and some recommendations

"The committee has studied conditions covering the admission of patients to the Peter Bent Brig-

ham Hospital, Massachusetts General Hospital, Boston City Hospital, Children's Hospital and the Boston Dispensary

"With the exception of the Boston City Hospital, there are theoretical safeguards against the abuse of charity. Since April, 1935, the Boston City Hospital has promised to place some social workers in the Out-Patient Department in order, theoretically at least, to control the abuse of charity which is admitted by its trustees to exist there. Up to October 5, 1935, when this report was written, the social workers had not begun to operate

"In July, 1935, your committee asked the Boston Dispensary to admit to its Evening Pay Clinic only patients referred by physicians. The officers of the Boston Dispensary said that they would take this suggestion under consideration and report on their decision. No report has as yet been received

"Your committee believes that theoretically the Department of Health of the City of Boston tries to stimulate the public to go to private physicians for well baby clinic work and preventing tuberculosis work. If, however, the patients do not employ private physicians for this work, the Health Department makes no provision at these clinics run by the Department to separate those who can afford to pay from those who cannot. The reason they do not make this attempt is because the Department considers the work educational and fears that if patients were refused admission, the educational aspects of this work would be interfered with. Only preventive work is done at these clinics. Practically the same condition exists in regard to immunization work.

"(2) Several specific instances of doctors referring patients for operation to the charity services in hospitals in the City of Boston were cited. It is hoped that the physicians of the District Societies will pay attention to the votes passed by the District Societies urging the doctors not to try to have charity work done on their patients who are able to pay

"Your committee is interested in the experiment being tried in the District of Columbia on 'The Co-ordination of Resources for Medical Care in the District of Columbia' and wonders if some such program might not be worked out in Boston. It is felt that if this or some other program is to be worked out, the guiding force should be the recently established Hospital Council of Boston.

"In view of the above it is moved that each of the District Societies included in the City of Boston urge the Hospital Council to take active steps to eliminate the abuse of charity not only theoretically but practically in the free clinics for medical service in the City of Boston.

"It is further moved that each of the District Societies situated in the City of Boston urge its members to organize for immunization work at a fee commensurate with the ability of the patients to pay"

The report and the two motions contained in it were adopted by unanimous vote.

Dr Edward J O'Brien, Jr., then presented the following motion

"Resolved That the Secretary of the Middlesex South District be instructed to communicate either by letter or postal card with each member of the Middlesex South District, informing him of the abuses of medical charity and asking for aid and cooperation by not referring to charitable institutions or clinics persons who are able to pay for medical services It was seconded and unanimous ly accepted without debate

Dr William R. Morrice the Chairman of the Committee of Arrangements for the Annual Meeting of the Massachusetts Medical Society was next introduced. He described some of the plans which had been made and urged the members to attend the annual meeting to be held in Springfield June 8 9 10 As an added inducement he stated, the charge for the annual dinner would be one dollar only

Dr Reginald Fitz associate professor of medicine at Harvard University Medical School was then presented. He spoke of his fond regard for Dr Mongan. He said Dr Mongan as a member of the House of Delegates of the American Medical Association probably knows more doctors than any one other than Drs. Morris Fishbein and Olin West that "most of us make bad citizen-doctors but Dr Mongan has taught me what it means to be a good medical citizen"

Dr Henry D Chadwick, Commissioner of the State Department of Health then addressed the members and acquainted them with some early history of the Massachusetts State Department of Health He concluded his remarks by offering the felicitations of his Department to Dr Mongan and the Massachusetts Medical Society and stated that he would cooperate in every way possible to improve the circumstances of the public and physicians in Massachusetts

Dr Charles E Mongan who was next asked to speak was greeted by his fellow members The continuous applause indicated the esteem and good feeling in which the Society holds him After thanking Dr Remick and the two preceding speakers, Dr Mongan covered the wide field of economics and how it applies to medicine. He felt that he has "a mission to perform—namely to sell the Medical Society to its members that the Medical Society has every reason to be proud of its achievements and therefore expects the right to be heard in the Legislature as experts." Dr Mongan stated, "The welfare of the people is the fundamental purpose of all these laws

"The medical men is a cog in this thing called culture or civilization. You are loyal—you are willing. However you need to be directed You can do a great deal of work to prevent the lowering of the standard of living in Massachusetts to improve the standards of medical education and to in-

crease your sense of proprietorship in the Society" He asked the members to serve on committees when asked to do so and gave it them in charge to help carry out the traditions of the practitioner in Massachusetts

The meeting was then adjourned

ALEXANDER A. LEVI, M.D. *Secretary*

HAMPDEN DISTRICT MEDICAL SOCIETY

The regular Fall Meeting of the Society will be held at the rooms of the Springfield Academy of Medicine, 20 Maple Street, Springfield on Tuesday October 20 1935 at 4 15 P.M.

Paper for the afternoon Recent Advances in Medicine, Dr Reginald Fitz of Boston Discussion by Fellows

Supper at 6 P.M. at expense of Society

HERBERT L. SMITH *Secretary*

Censors meet for examination of candidates in the rooms of the Academy on Thursday November 7, at 4 P.M.

ESSEX NORTH DISTRICT MEDICAL SOCIETY

CENSORS MEETING

Censors Meeting at the Hotel Bartlett, Main Street, Haverhill, at 4 P.M. Thursday November 7 1935 Candidates must present applications and show diplomas to Secretary at least two weeks in advance

 - (g) Discharge Rates in First Admissions Compared with Readmissions
 - (h) Possible Sources of Error
4. Summary
1. FUNDAMENTAL ERRORS IN PRESENT METHOD OF COMPUTING DISCHARGE RATES BASED UPON CASES DISCHARGED PER 100 ADMISSIONS

IN the 1923 publication of the Bureau of the Census² reporting patients in hospitals for mental disease, there appeared a new table in which the discharge rates for the year 1922 were computed. In this table the number of discharges was compared with the number of admissions for the same year, by psychosis. A discharge rate was then calculated per 100 admissions of the same psychosis. As this method apparently had the approval of a governmental agency, it was accepted by other states and is now quite commonly used in statistics on mental diseases.

1. Read at the 31st annual meeting of the American Psychiatric Association, Washington, D. C. May 13-17, 1935.
From the Division of Statistics and Research, Massachusetts State Department of Mental Diseases. Miss Margaret Dolan, Chief Research Worker, collaborated in the preparation of the statistical material for this paper.

2. Table 42, page 58. Patients in Hospitals for Mental Disease, 1922. Department of Commerce, U. S. Bureau of the Census.

Dutton, Neil A.—Director Rockefeller Research Project in Mental Disease and Defect, Massachusetts Department of Mental Diseases. For record and address of author see "This Week's Issue," page 224.

Over the past few years, however, it has become evident that the Census approach in the matter of calculating discharge rates is not very satisfactory. This is partially due to the overlooking of basic differences between admissions and discharges and also to a lack of consideration of all cases subject to the chance of discharge. In the first place the admissions and discharges of any one year do not comprise the same patients. A study of the outcome of admissions shows that only a certain portion will be discharged and that these discharges will be spread out over many years in the future. Some of the admissions will die while in hospital, some will be deported, others will be transferred, while still others will remain within the institution. On the other hand, the discharges of any one year are the fractional remnants of the admissions that have occurred over many years in the past. The basic incomparability of the two groups and the overlooking of all patients within hospitals who are potential candidates for discharge compel serious questioning of the Census method of having a rate upon the number of admissions and discharges for the same year.

A second point of discrepancy lies in the variation between the proportions of first admissions and readmissions in both admissions and discharges. Under the old method, first and readmissions were combined, the total number of admissions being compared with the total number of discharges. Inspection of the actual differences reveals the danger of comparing such obvious mixtures of classification. For example, in the psychoses with cerebral arteriosclerosis, the discharges (1934) comprised 87 per cent of first admissions and 12 per cent of readmissions. On the other hand, the admissions made up 93 per cent of first admissions and but 6 per cent of readmissions. This factor again emphasizes the incomparability of the two groups, as first admissions and readmissions show widely differing discharge rates.

A third difficulty arises through differences between the ages of admissions and discharges. Over a given period the admissions of any one year tend to sort themselves into four groups in reference to age: (1) those dying, the

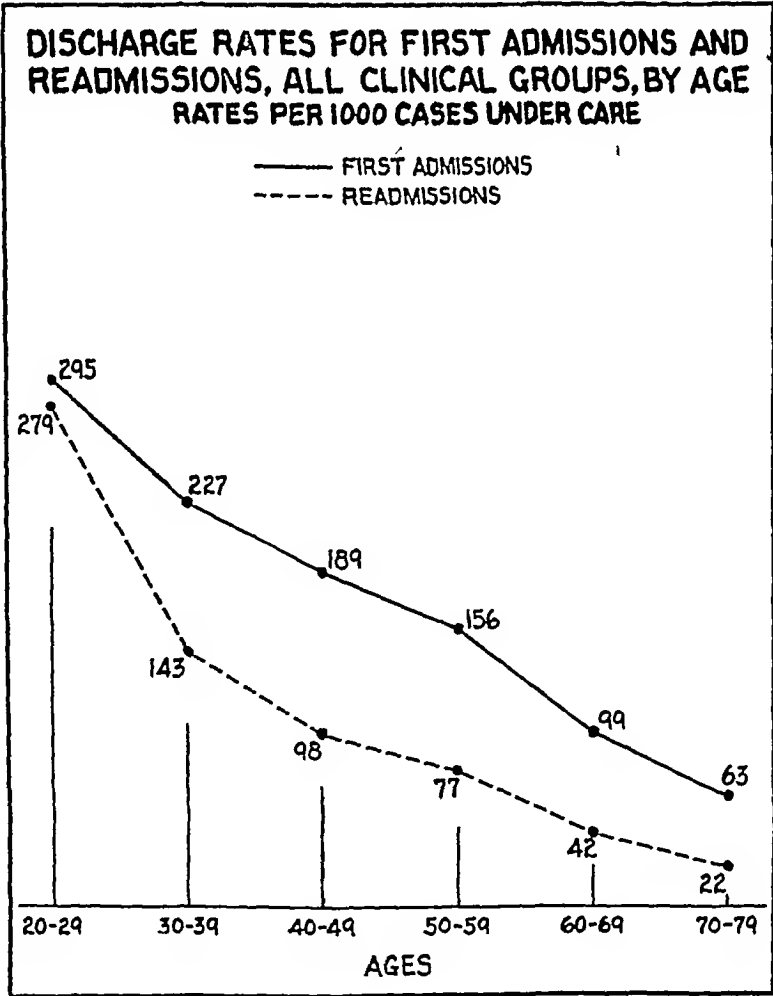

twenty-four groups of the condensed classification. It also records the total number of cases under care and the total cases discharged during 1934. Of each 1,000 first admissions under care during 1934, 183 or about one out of five were discharged. Of each 1,000 readmissions under care, 104 or about one in ten were discharged. The rate for first admissions is nearly twice that of the readmissions.

In the first admissions the psychoses due to drugs show the highest discharge rate of 702. The psychoneuroses are second with a discharge rate of 561. Psychoses with other infectious diseases with 460, and the traumatic psychoses with a rate of 330, are next in order. We then have a group of seven psychoses led by the manic-depressive group which show rates between 279 and 234. Starting with paranoia, we observe a group of six psychoses with discharge rates between 191 and 102, the latter being the rate for dementia praecox. Finally we have discharge rates below 100 occurring in psychoses with cerebral arteriosclerosis (94), psychoses with mental deficiency (93), psychoses with convulsive disorders, epilepsy (82), and the senile psychoses (44). There is a rather

remarkable spread between the highest and the lowest discharge rates for 1934. The psychoses due to drugs discharged about seven out of every ten patients under care, while at the other extreme the senile psychoses discharged but one out of every twenty-two patients under care.

Total Discharge Rates, by Age Table 3 presents the detail of the discharge rates per 1,000 under care for all psychoses together, by first and readmissions and by age. The first admissions present a total discharge rate of 183 per 1,000 for the year. Temporarily discarding the 10-19 and 80 years plus groups because of the small numbers involved, we note that the 20-29 year age group presents the highest discharge rate of 295 cases per 1,000, or about one case discharged in every three of the same age group under care (Graph 1). The age group 30-39 years shows a discharge rate of 227, or about one in four under care, the group 40-49 years a rate of 189 or one in five, the group 50-59 years a rate of 156 or one in six, the age group 60-69 years a rate of ninety-nine or one in ten, and the age group 70-79 years shows the low rate of sixty-three, or one in fifteen. Among first admissions the greater chance of discharge

the year 1934

very definitely confined to the younger cases under care.

The readmissions show a total discharge rate 104 for each 1,000 readmissions under care during the year. The highest rate throughout various ages occurs in the group 20-29 years; 279 cases discharged, or about one out of every three under care (Graph 1). The readmissions then show a much more precipitate drop in the remaining age groups than is evidenced in the first admissions. The age group 30-39 years shows a rate of 143, or one in seven, 40-49 years a rate of ninety eight or one in ten, 50-59 years a rate of seventy seven or one in thirteen, 60-69 years a rate of forty two or one in twenty four, and 70-79 years a rate of 22 or one in forty five. It will be noted that the readmissions present lower discharge rates than first admissions in all ages. In this group we also note definitely higher discharge rates in the younger age groups.

TABLE 4

CASES DISCHARGED FROM NUMBER UNDER CARE AND FIRST AND READMISSIONS BY AGE RATIOS

Ages	Cases Discharged from Cases Under Care	
	First Admissions	Readmissions
20-29 Years	1 in 3	1 in 3
30-39 "	1 in 4	1 in 7
40-49 "	1 in 5	1 in 10
50-59 "	1 in 6	1 in 13
60-69 "	1 in 10	1 in 24
70-79 "	1 in 15	1 in 45
Total	1 in 5	1 in 10

To simplify the comparison between first and readmissions table 4 is inserted presenting the ratios for discharges over cases under care in each age group. The first admissions make the best showing in the age group 20-29 years with a ratio of one in three discharged. The ratios increase gradually with the lowest discharge ratio of one in fifteen in the age group 70-79 years. The readmissions also show a very low ratio in the 20-29 year age group, with one out of three discharged. They then show precipitate increases in the ratios to a high of one case in forty five discharged in the age group 70-79 years. The first admissions make a better showing in all age groups except the 20-29 year group. In the totals, the first admissions discharged one case in every five, while the readmissions discharged but one case in ten^a.

a. Owing to space limitations, sex differences are not presented in the tables but are being outlined briefly in this footnote. Among the first admissions the females showed higher discharge rates than the males in eleven clinical groups. These are as follows: with other infectious diseases; traumatic psychoses; alcoholic psychoses; due to other metabolic diseases, etc.; with other disturbances of circulation; with psychopathic personality; with epidemic encephalitis; with syphilitic meningitis; with dementia praecox; with cerebral arteriosclerosis

Discharge Rates by Psychosis and Age We now return to a discussion of the discharge rates within the different age groups for certain psychoses of the condensed classification as outlined in table 3. We have arbitrarily limited these sections to a discussion of the eleven psychoses of the condensed list which had 800 or more cases under care during the year. Dividing those psychoses with less than 300 under care would mean very small numbers in any one age group. Consequently the resulting rates would be more subject to chance fluctuation. We also eliminate consideration of the age groups 10-19 years and 80 years plus as they present even smaller numbers. The eleven psychoses divide themselves into three groups in reference to discharge rates throughout the age groups. These are as follows:

Groups with High Discharge Rates The first admissions in the psychoneuroses, the manic depressive and the alcoholic groups, show rather high discharge rates in all age groups (Graph 2). The psychoneuroses show a high discharge rate of 675 in the 20-29 year group, and a low of 292 in the 60-69 year group. The alcoholic psychoses start with a discharge rate of 574 in the 20-29 year group and fall to a low of 83 in the 60-69 year group. The manic-depressive group starts with a high discharge rate of 408 in the 20-29 year group and falls to a low of 49 in the 70-79 year group. The outstanding characteristic of these curves is their rapid fall in rates as the older age groups are approached. The curves for the psychoneuroses and the manic-depressive group are somewhat flatter than that of the alcoholic and tend to preserve fairly high discharge rates for the age groups 20-29, 30-39, 40-49 and 50-59 years. However, in the groups over 60 years of age both show a rapid fall to lower levels. The curve for the alcoholic group shows a more precipitate fall throughout the various age groups.

The readmissions also show rather high discharge rates in practically all age groups (graph 5). Again we note the decidedly higher rates for the younger ages.

and with mental deficiency. In the remaining thirteen groups the males showed higher discharge rates. In the readmissions the females showed higher discharge rates but at five psychoses namely with psychopathic personality; paranoia with epidemic encephalitis; with syphilitic meningitis; and in psychoses with mental deficiency. In the remaining nineteen clinical groups the males demonstrated higher rates for discharge. In the totals for all psychoses the males presented a discharge rate of 198 among the first admissions while the females showed a rate of 169. The total readmissions showed a discharge rate of 116 for the males and ninety-one for the females.

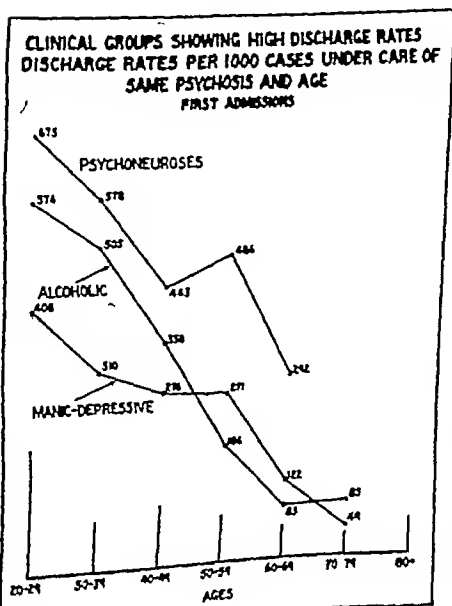

The female first admissions present higher total discharge rates in the groups 10-19 years, 30-39 years and 50 plus years, while the males show the higher rates in all age groups from 20 to 79 years. Among the readmissions the females show the higher rates in but two age groups, 10-19 years and 50 plus years, while the males present higher discharge rates in all of the remaining age groups. (For full data see Table 45 of the 1914 Annual Report Massachusetts State Department of Mental Diseases.)

b. Cases under care by psychosis are shown in table

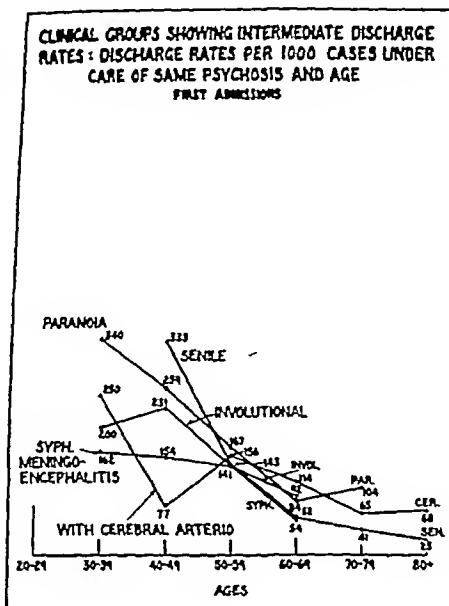

Groups with Intermediate Discharge Rates
Certain psychoses show discharge rates within the various age groups which may be termed intermediate. They are, syphilitic meningo-encephalitis, paranoia, with cerebral arterio-sclerosis, and the involutional and senile groups

the cases have passed the age of 50 years. Paranoia and the senile group tend to be more closely associated with age, as we see higher rates in the younger ages and a sharper fall in rates as we approach the older age groups. On the other hand, the curves for syphilitic men-

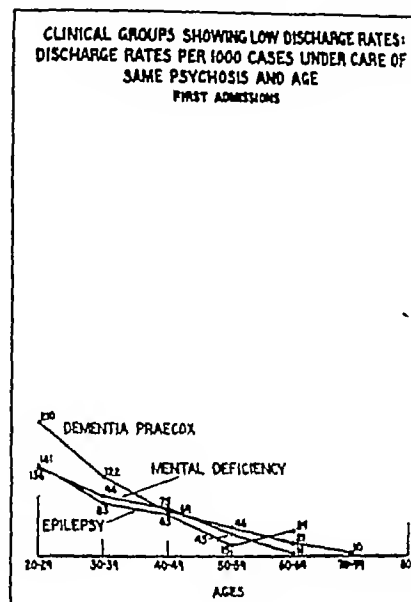

GRAPH 2

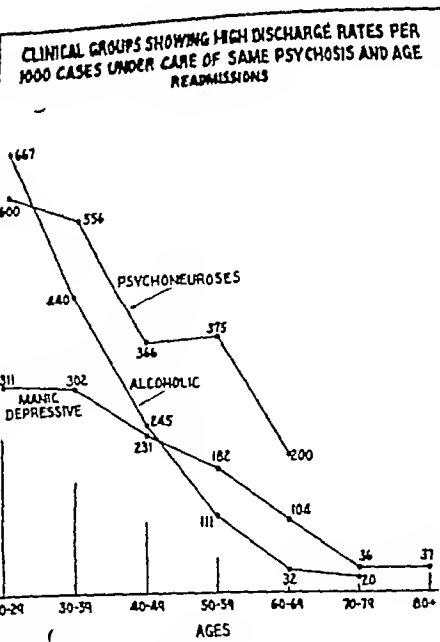

GRAPH 3

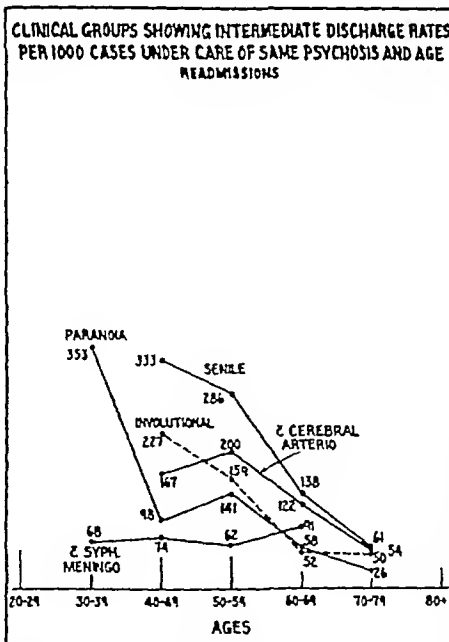

GRAPH 4

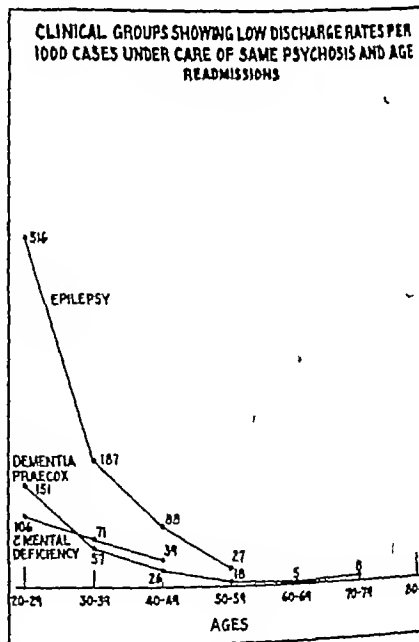

GRAPH 5

GRAPH 6

GRAPH 7

(graph 3) Among the first admissions the same trend for lower discharge rates in the older age groups is seen. We observe, too, that the rates tend to cluster beginning with the age group 50-59 years, suggesting that age as well as psychosis is an important factor in the matter of discharge. These five psychoses, widely differing from the clinical viewpoint, tend to present the same discharge rate once

meningo-encephalitis and the involutional group are flatter and suggest that age is of less importance.

The readmissions of this intermediate group show certain variations, but the same tendency for higher discharge rates in the younger age groups is observed (graph 6).

Groups with Low Discharge Rates First admissions in the psychoses dementia praecox,

with mental deficiency, and with epilepsy tend to show low discharge rates in all of the age groups (graph 4). Starting with comparatively low rates in the 20-29 year group they have less opportunity to show any rapid degree of fall in the older ages. However we note the same general characteristics noted in the other psychoses, namely, higher discharge rates in the younger age groups and lower discharge rates in the older age groups. While the differences appear minor, actually this is not the case. Dementia praecox, for example, discharged one out of five patients in the age group 20-29 years, but only one out of each hundred under care in the age group 70-79 years. Mental deficiency discharged one out of seven patients in the group 20-29 years but only one out of twenty two in the group 50-59 years. In reality, marked differences exist here which are not distinctive on the graph because of the low rates in the younger age groups.

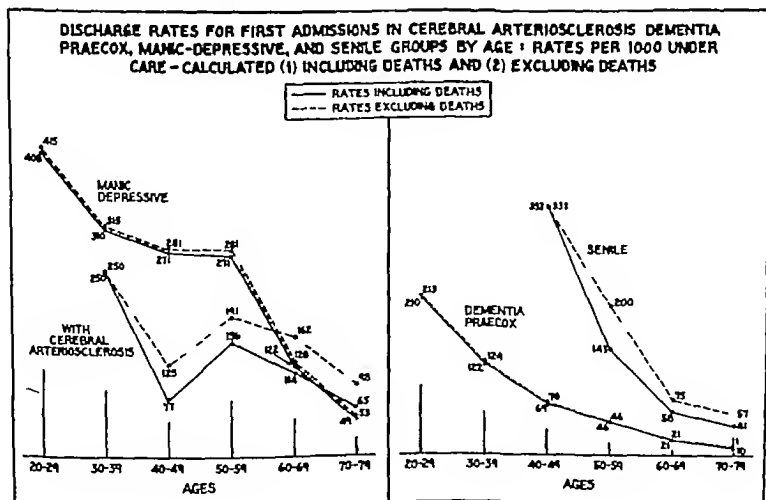

In the readmissions, dementia praecox and the psychoses with mental deficiency show uniformly lower discharge rates than the first admissions (graph 7). With a flatter curve and smaller differences between the rates for the younger and older age groups, these readmissions show the least association between the matter of discharge and age. The epileptic psychoses, however, present a marked contrast in showing higher discharge rates in readmissions than in first admissions for all age groups. In the readmissions the rates for this psychosis show an extremely precipitate

fall so that the first and readmissions from the age of 50 years onward show only a slight separation.*

Possible Sources of Error When it became evident that lower discharge rates in the older age groups were appearing quite uniformly in all of the psychoses, an effort was made to uncover possible contributing factors other than age alone. One possibility seemed worthy of serious analysis. The very high death rates in the older age groups and the consequent withdrawal of large numbers of cases under care through death, might be expected to produce a lower discharge rate in the older ages. With more patients dying fewer would be available for discharge. To test this point the discharge rates were calculated *excluding* the deaths. If the deaths were the cause of

There is an apparent consistency in the placement of some of the psychoses in the groups with high intermediate and low discharge rates. For example, dementia praecox is placed in the group with low discharge rates, while the senile psychoses are placed in the intermediate group. This apparently disagrees with the data as outlined in table which would place dementia praecox in the intermediate group (total rate 182) and the senile psychoses in the low group (total rate 44). Yet if we compare the distribution of these discharge rates in graphs 3 and 4 first admissions, and graphs 5 and 7 readmissions, we note that the distribution for the senile group is actually higher than that of dementia praecox, both in first and readmissions. This apparent paradox occurs because each of these psychoses will tend to have its total rate approximate the rate for the age group presenting the largest number of cases discharged and under care. Dementia praecox tends to present larger numbers discharged and under care in the younger age groups. Therefore, the total rate for this psychosis will tend to cling to the higher rates observed in the younger age groups. Conversely, the senile group has the largest number of cases discharged and under care in the older age groups. Therefore, the total rate for the senile psychoses will tend to approximate the low rates observed in the older age groups. This shows the advisability of comparing comparisons between psychoses to the same age groups and to guard against being too greatly influenced by the total rates for different psychoses.

GRAPH 3

diminishing discharge rates in the older age groups, then the calculation of a rate excluding them should produce a flat curve with approximately the same discharge rate in every age group. However, the results for the various age groups were quite uniform with those of the rates including deaths, for all psychoses and in both first and readmissions. Graph 8 presents these in four of the psychoses. Two were selected from the point of large numbers involved, dementia praecox and the manic-depressive group. The senile psychoses and the psychoses with cerebral arteriosclerosis were chosen because they involved the older ages with high death rates. Graph 8, in presenting two curves for each psychosis (1) including the deaths and (2) excluding the deaths, shows quite definitely that the deaths have not been a deciding factor in the determination of the trend in discharge rates. In the senile group and the group with cerebral arteriosclerosis the removal of the deaths from cases under care does result in a higher discharge rate, but the two curves in the various age groups remain practically parallel. That is, the resulting discharge rates are higher in the younger as well as the older ages. While the differences are smaller in both dementia praecox and the manic-depressive psychoses, the two discharge rates parallel each other throughout the age groups. It becomes quite clear that the low discharge rates in the older age groups are not to be attributed to the high death rates in those particular ages.

SUMMARY

1 The Census method of calculating discharge rates in mental diseases, based upon the number of cases discharged per 100 admissions of the same psychosis, presents certain inconsistencies which render its use inadvisable. Fundamental errors arising through the lack of separate consideration of first and readmissions, and the disregarding of the age factor, are discussed. These points emphasize the necessity of changing the present method of approach in the matter of determining discharge rates.

2 A new method of calculating discharge rates is presented (table 1). Each psychosis is divided into first admissions and readmissions, and into ten-year age groups. We then determine the number under care in each age group for each psychosis. This is accomplished by adding (1) cases in residence in hospitals at the end of the statistical year, (2) cases temporarily out of hospitals on visit, parole, etc., (3) cases discharged during the year, and (4) cases dying during the year. The resulting total under care is then compared with the total number discharged of the same age, and a rate determined. This new method is applied to each of the twenty-four clinical

groupings of the condensed classification, presenting a discharge rate for first and readmissions separately, by age.

3 Of each 1,000 first admissions under care during 1934, 183 were discharged. Of each 1,000 readmissions under care, 104 were discharged (table 2). The total discharge rates on the eleven psychoses presenting more than 300 cases under care during the year are as follows:

Mental Disorders	Discharge Rates Per 1,000 Under Care	
	First Admissions	Readmissions
Psychoneuroses	561	449
Manic depressive psychoses	279	197
Alcoholic psychoses	261	134
Paranoia and paranoid conditions	191	102
Involuntal psychoses	139	112
With syphilitic meningo-encephalitis	136	72
Dementia praecox	102	34
With cerebral arteriosclerosis	94	98
With mental deficiency	93	45
With convulsive disorders (epilepsy)	82	125
Senile psychoses	44	91

4 Considering all psychoses together, the discharge rates in both first and readmissions are very much higher in the younger age groups and decrease as the older age groups are approached (table 3 and graph 1). In the totals about one out of five first admissions under care were discharged and one out of ten readmissions. Eliminating the 10-19 and 30 years plus groups because of the small numbers involved, the rates and ratios are presented in the following table:

Ages	Discharge Rates		Ratios of Cases Discharged from Cases under Care	
	First Admissions	Readmissions	First Admissions	Readmissions
20-29 Years	295	279	1 in 3	1 in 3
30-39 "	227	143	1 in 4	1 in 7
40-49 "	189	98	1 in 5	1 in 10
50-59 "	156	77	1 in 6	1 in 13
60-69 "	99	42	1 in 10	1 in 24
70-79 "	63	22	1 in 15	1 in 45

5 When we study the discharge rates by age groups we find that the psychoses group themselves in three classes presenting, in general, high, intermediate or low rates. All show the same characteristic curve, with higher discharge rates in the younger age groups and lower in the older age groups (table 3 and graphs 2, 3, 4, 5, 6 and 7). The following table is inserted to show these tendencies toward high or low rates for each psychosis ac-

accompanied by the age group in which the rate occurs. The 10-19 and 80 years plus groups have been eliminated because of small numbers. The figures for the eleven important groups among the first admissions are as follows:

Mental Disorders	High and Low Discharge Rates for Age Groups	
	High	Low
High Discharge Rates		
Psychoneuroses	675 (20-29)	292 (60-69)
Alcoholic psychoses	574 (20-29)	87 (60-69)
Manic-depressive	408 (20-29)	49 (10-19)
Intermediate Discharge Rates		
With syphilitic meningo-encephalitis	162 (30-39)	34 (60-69)
Paranoia and paranoid conditions	333 (20-29)	54 (60-69)
With cerebral arterio-sclerosis	250 (30-39)	65 (70-79)
Involuntary psychoses	231 (40-49)	91 (60-69)
Senile psychoses	333 (40-49)	41 (10-19)
Low Discharge Rates		
Dementia praecox	210 (20-29)	10 (70-79)
With mental deficiency	136 (20-29)	45 (60-69)
With convulsive disorders (epilepsy)	141 (20-29)	15 (50-59)

6 To test whether the high death rates in the older age groups were producing the low discharge rates in these ages, the discharge rates

were calculated *excluding* deaths. Graph 8 shows the discharge rates both *including* and *excluding* deaths for four psychosis groups. In the senile group and the group with cerebral arteriosclerosis, the removal of the deaths from cases under care results in a slightly higher discharge rate although the trends of the curves remain parallel. In the dementia praecox and manic-depressive psychoses, the discharge rates parallel each other very much more closely. Low discharge rates in the older age groups are not attributable to high death rates in these ages.

7 For many years psychiatrists have been stressing the point that mental disorders should have early recognition and care before they in terject a serious handicap into the life of the individual. The findings of this communication support these assumptions in a rather striking way. We see that mental disorders under care in the 20-29 year decade have a much better chance for discharge than cases under care in the older age groups. Even the psychoses occurring in the older ages have this same characteristic, with cases under care in the 50-59 year group showing higher discharge rates than those of the 60-69, 70-79 or 80 plus groups. The younger cases under care have the greater chance of discharge in every psychosis and in both first and readmissions.

HEMOPTYSIS IN TRICHINIASIS*

BY LEONARD J. GOLDWATER, M.D.,† ISRAEL STEINBERG, M.D.,† HARRY MOST, M.D.,† AND JOSEPH E. CONNERY, M.D.†

THE occurrence of pulmonary signs and symptoms in trichiniasis is relatively well known. A great variety of pathological lesions of both lungs and bronchi has been described to account for these findings. Minot and Rackemann¹ in reviewing 102 case histories of trichiniasis to ascertain the frequency of respiratory signs and symptoms quote a number of earlier authors who have written on lung changes in trichiniasis. In Minot and Rackemann's series 50 per cent of the patients showed pulmonary signs or symptoms. There were three cases with blood tinged sputum but no case of frank hemoptysis. As early as 1860 Wunderlich² reported a case of hemoptysis in a butcher whose illness was at first diagnosed as acute tuberculosis but later, upon recovery was believed to be trichiniasis. Kestner³ has described what he calls pneumonia due to trich

inae occurring in the fourth week of the infestation. His description of the symptoms strongly suggests infarction. The sputa according to his report differ from those of true pneumonia in that they are composed mostly of blackish blood. Hunt⁴ (1869) described a case of trichiniasis in which blood streaked sputum occurred about six weeks after the onset of the disease. His description, however, sounds like that of a terminal pneumonia, the sputum being at times rusty. Spink and Augustine⁵ more recently in a review of thirty-five cases of trichiniasis observed two patients in whom coughing was productive of bloody sputum.

Askanazy⁶ in experimental trichiniasis in rabbits found young trichinae in the lungs causing embolization with hemorrhage into the alveoli and small bronchioles. Frothingham⁷ reported an autopsy on a case of trichiniasis which showed many areas of hemorrhage into lung tissue. Trichinellae were found free in the hemorrhage. Thus Askanazy's experimental findings were confirmed in man.

Ordinarily in the differential diagnosis of hemoptysis in our opinion, one is not likely to consider trichiniasis as a possibility. In the articles on trichiniasis in several of the commonly used "Systems of Medicine", no men

tion is made of hemoptysis, nor is it listed in French's or Cabot's Differential Diagnosis. In none of the textbooks of medicine or diseases of the chest which we consulted did we find any mention of blood-spitting in the course of trichiniasis.

Clinical cases of trichiniasis are not uncommon. The number of cases so mild or so atypical that they pass undiagnosed cannot be determined with certainty. In this latter connection the finding by Riley and Schenley⁸ of trichinae in the diaphragms of 182 per cent of 520 unselected cadavers and autopsy cases is significant. In view of this apparent frequency of infestation with trichinae, and because of the fact that the symptom of hemoptysis in trichiniasis has not received wide attention, the following cases are being reported.

CASE 1 Patient H S, white, male, aged thirty six, nativity U S, occupation peddler. Admitted to the hospital Feb 9, 1934. Chief Complaints: Swelling of the face, arms and legs, and loss of appetite. Previous History: The patient stated that he frequently ate bacon and pork and that recently he had eaten fresh ham.

Present Illness On the morning of February 1, 1934 the patient was awakened by severe abdominal cramps. These lasted throughout the day. On February 2, 1934 he noticed swelling of his legs from the knees down, and of the arms, eyelids and face. He vomited once on February 3, 1934. Muscular pains appeared on February 5, 1934 and grew worse until the time of admission.

Physical Examination at the time of admission revealed puffiness of the eyelids and engorgement of the conjunctival vessels. The lungs were clear. There was tenderness in both upper quadrants of the abdomen, but the liver and spleen were not palpable. There was tenderness of the triceps and gastrocnemii muscles and pitting edema of the legs up to the knees. The temperature on admission was 99°F, pulse 100 and blood pressure 112/68. The blood count was RBC 2,800,000, Hb 9 grams per 100 cc, WBC 7,800, polymorphonuclear leukocytes (young) 7 per cent, (mature) 41 per cent, lymphocytes 16 per cent, eosinophiles 36 per cent. The urine showed nothing abnormal at this or any other time, nor did the stools.

Course A biopsy of the left deltoid muscle done on February 14, 1934, revealed the presence of typical trichinellae. On February 20, 1934, the patient developed pain in the left chest, which was relieved by adhesive strapping. On February 22, 1934 the entire right leg became swollen and tender. On the following day the patient began to raise sputum heavily streaked with blood and containing clot-like masses of blood and mucus. For seven days the patient continued to raise this type of bloody sputum. By March 5, 1934 the swelling of the right leg had subsided. A chest x-ray taken at this time revealed a flattening of the left diaphragm with obliteration of the left costophrenic sinus, and a small patch of parenchymal infiltration in the fifth left interspace. Several days later the left leg showed changes similar to those in the right, indicating at first phlebitis and later thrombosis of the femoral vein. This ultimately subsided, and no further complications arose.

In this case the diagnosis of trichiniasis was definitely established by the finding of trichinel-

lae in a muscle biopsy specimen. In the following two cases the parasites were not demonstrated, but the history, clinical course, and laboratory findings were such that there seemed to be little doubt that trichiniasis was the diagnosis.

CASE 2 Patient H C, white, male, aged twenty four, nativity U S, occupation medical student. Admitted to the hospital November 7, 1933.

Chief Complaints Headache, malaise, muscular pains, swelling of the eyelids.

Previous History There was no recollection of the ingestion of raw or poorly cooked pork, and no diarrhea.

Present Illness On November 2, 1933 upon awakening in the morning the patient noted edema of both upper eyelids, especially the left. On November 4, 1933 generalized malaise was experienced. The edema of the eyelids became more marked. On the same day muscle and joint pains developed. Diplopia, lasting from three to five minutes, was experienced on November 4, 1933 and again on November 5, 1933. Severe frontal headache began on November 5, 1933. Hoarseness with cough and moderate mucoid expectoration developed on November 6, 1933. The patient was seen at the student health office during this time but could not be prevailed upon to enter the hospital until the fifth day of his illness.

Physical examination at the time of admission to the hospital revealed nothing significant except tenderness over the left maxillary sinus, and a slight mucopurulent exudate on the posterior pharyngeal wall. The temperature was 101.8°F, pulse 106 and blood pressure 128/82. The blood count on admission was as follows - RBC 4,490,000, Hb 11 grams per 100 cc, WBC 9,500, polymorphonuclear leukocytes (mature) 33 per cent, (young) 10%, lymphocytes 7 per cent, monocytes 1 per cent, eosinophiles 44 per cent. The urine at no time showed any abnormality.

Course On November 8, 1933 the temperature rose to 104.4° but later fell to 103°. The following day pterygia were present in both eyes and the spleen was palpable. The patient was hoarse at this time. A skin test with trichinella antigen was strongly positive. On November 10, 1933 the temperature was lower, but there were muscular soreness and tenderness in the extremities. During the next seven days there was gradual improvement. On November 17, 1933 the white cell count was 14,500 with 41 per cent eosinophiles and three days later it was 17,000 with 38 per cent eosinophiles. At this time (November 20, 1933) the patient complained of severe pain and marked tenderness in the right subscapular region. There had been no chill and there was no cough. The skin over the right side of the chest posteriorly was hyperesthetic, and there were diminished expansion and decreased breath sounds over the right lung. The pain was relieved by strapping the chest. At no time was there any evidence of consolidation. On November 21, 1933 and November 22, 1933 on several occasions the patient raised small amounts of tenacious mucoid sputum mixed with bright red blood. No trichinae were found in this sputum. On November 23, 1933 pain similar to that just described developed on the left side. There was no significant rise in temperature accompanying either of these attacks of pain. The course from this point on was uneventful and the patient was discharged on December 3, 1933.

CASE 3 Patient S S, white, male, aged thirty seven, occupation butcher, nativity Austria. Admitted February 27, 1934.

Chief Complaint Cough accompanied by pain in the chest, and bloody sputum

Family History Irrelevant

Previous History Irrelevant except that patient stated that he had "bronchitis" for fifteen years

Present Illness On February 2, 1934 patient developed what he called a cold with coryza, chills, fever, malaise and nonproductive cough. There was a transient attack of nausea and diarrhea. After several days weakness, backache and pains in the extremities developed, confining the patient to bed for a week. He was treated by his local physician for "grippe" and improved somewhat but there persisted a dull pain in the chest, weakness, occasional feeling of chilliness associated with sweating and a cough productive of tenuous mucoid sputum. He returned to work but on February 23, 1934 he coughed up about two drams of blood. The following night he raised a similar amount of blood. Subsequently the amount of blood decreased so that when he entered the hospital there was merely a blood-streaked sputum.

Physical Examination on admission revealed nothing abnormal except for numerous sibilant and sonorous rales over both lungs and a few faint moist râles at the left base and in the left axilla. There was some dullness at the left base.

Laboratory data. Hb 12.2 grams per 100 cc. E. R. C. 4100,000. W. B. C. 8,000 polymorphonuclear leukocytes (young) 4 per cent (mature) 60 per cent lymphocytes 37 per cent Wassermann negative. Sputum on two occasions negative for acid-fast bacilli but was definitely bloody. The temperature was 100° F at the time of admission but subsequently was never above normal. Chest roentgenograms on February 28, 1934 and March 3, 1934 revealed changes associated with chronic bronchitis and emphysema. Bronchial neoplasm or bronchiectasis was suspected but bronchoscopy and lipiodol studies revealed nothing abnormal and the patient was discharged.

After the patient returned to his home additional history was obtained by a member of his family who is a physician. It was learned that the patient had eaten poorly cooked pork immediately before the onset of his illness and that he had had edema of the eyelids for several days before he entered the hospital. Further blood studies revealed on several occasions an eosinophilia of 20 per cent to 30 per cent.

COMMENT

It is interesting that in all three cases hemoptysis occurred approximately three weeks after

the onset of symptoms of trichinosis. This is in accord with the results of Askanazy⁹ who found trichinae in the lungs of infected animals no sooner than three weeks after experimental infestation. In cases 2 and 3 there is no explanation for the hemoptysis except that proposed by Askanazy, namely embolization due to trichinae. In case 1 however, the presence of femoral thrombophlebitis offers another possible etiology for the bloody sputum, although there is no reason to believe that the mechanism in this case was different from that in cases 2 and 3.

The failure to find trichinae in the sputum is consistent with the observations of other workers⁹

SUMMARY

1. Three cases of trichinosis with hemoptysis are reported.
2. In one case the diagnosis was missed because of failure to demonstrate eosinophilia and failure to obtain a complete history.
3. In two cases, in which the sputum was examined, no trichinae were found.
4. The importance of considering trichinosis in the differential diagnosis of hemoptysis is emphasized.

UNCINARIASIS AND APPENDICITIS*

BY M. K. KING, M.D.†

DURING the past eighteen months we have had the privilege of seeing in this hospital a large number of young adults from a section of the country where hookworm, *Necator americanus*, is quite prevalent. In a number of these cases, presenting fairly characteristic signs and symptoms of acute appendicitis, the appendix was found at operation to be not sufficiently

pathological to account for the clinical picture. This observation was especially frequent in those patients infested with hookworms. In an attempt to find a relationship between uncinariasis and this syndrome resembling acute appendicitis a study was made of 100 cases treated in this hospital for suspected appendicitis.

In the extensive literature dealing with uncinariasis and appendicitis separately there has been little intimation of any connection between the two.

*From the U. S. Marine Hospital, Savannah, Georgia.
†King, M. K.—In charge of Surgical Service, United States Marine Hospital, Savannah, Georgia. For record and address of author see "This Week's Issue," page 884.

The differential diagnosis is difficult or impossible preoperatively

2 In patients with uncinariasis the small intestine and cecum are frequently found to be acutely inflamed at operation. The appendix may or may not be involved. The inflammation involves chiefly the mucosa and muscularis leaving the peritoneum relatively clear.

3 There is little evidence that hookworms are a common cause of acute appendicitis. No hookworms were found in sixty-eight appendices removed surgically from patients coming from a highly infested hookworm district, in thirty-eight of these patients hookworm ova were found in the stool. It is conceivable, however, that a widespread intestinal inflammation

caused by hookworms might involve the appendix, where the process, due to the anatomy of this organ, might become fulminating.

CATARACTS AND DINITROPHENOL*

BY DAVID G. COGAN, M.D.,† AND FRANCES C. COGAN, M.D.†

DURING the past two and one half months, there have occurred in the literature no less than twenty cases of cataracts developing after the use of dinitrophenol. This sudden and somewhat tardy appearance of the entity is striking in view of the widespread use of the drug over the past several years. The physiological action of the drug is fairly well understood, and the type of cataract is remarkably constant (vide infra). With this in mind, it is our intention to review the reported cases and to suggest a possible pathogenesis for dinitrophenol cataracts.

SURVEY OF CASES

Age. Average age of occurrence was 37.9 years with extremes of 25 and 50. Even the oldest member in this group is younger than the age at which we find the usual senile cataract.

Sex. With one exception (No. 13), all cases occurred in women. This is undoubtedly due to the relatively greater consumption of dinitrophenol among women.

Dosage. Here we wish to make an extremely significant observation, and one of great importance to the dispensing physician. Excepting one case only (No. 11), all were taking dinitrophenol in the recommended therapeutic doses and the majority were taking it under the supervision of a physician. The average maximal daily dose of the patients in this series was 45 grams which is not large when one considers the weight of most of the patients taking the drug. Furthermore there were three patients, developing cataracts, who took a daily dose which at no time exceeded 3 grams (No. 12, No. 14, No. 17).

Time of taking dinitrophenol. The total period during which dinitrophenol was taken was stated definitely in sixteen of the twenty cases. It averaged 8.4 months with a minimum of one month (No. 14)† and a maximum of 21 months (No. 7).

Loss of weight. By some this is taken to be proportional to the efficacy of the drug and hence is recorded here. Total loss of weight was noted in twelve of the twenty cases. It averaged 50¾ pounds over an indefinite period. Minimum weight loss was 21¼ pounds and maximum was 100 pounds.

Other toxic reactions. In only three of the twenty cases is there any mention of other toxic manifestations. Of these three, one (No. 20) had merely slight gastrointestinal upsets when she took the drug, one (No. 10) complained that her feet and hands became numb, and one (No. 13) had a frank peripheral neuritis.

Rate of cataract development. It is impossible to give any average for this group but a glance at the table will show the characteristic rapidity with which the cataracts develop, once that they are first noticed. Thus, in at least one case (No. 1), vision declined from the first observable dimness to mere light perception, all in the short space of a single week. In five more cases virtual blindness ensued within a month (No. 2, No. 3, No. 7, No. 8, No. 13).

Type of cataract. This is probably the most significant from the ophthalmologists' point of view for two reasons: first, the cataracts have a characteristic morphology; secondly, cataracts of this type point to some exogenous etiology. In ten of the twenty case reports, there is adequate de-

*Massachusetts Eye and Ear Infirmary, September 19, 1935.

†Cogan, David G.—Clinical Assistant in Ophthalmology, Massachusetts Eye and Ear Infirmary. For records and addresses of authors see This Week's Issue, page 854.

†There is some question of this patient having taken dinitrophenol for a short time one year previously. In this case the minimal time of taking dinitrophenol would have been a three month period (No. 13).

scription of the lens changes to recognize the type as "Cataracta Complicata." In the remaining ten the descriptions are insufficient to tell just what the nature of the lens changes is, but we may infer they were of the same type. The characteristics, par excellence, of Cataracta Complicata are the subcapsular position of the opacities, and the initial involvement of the posterior cortex. This is aptly described as having a "brass filing" appearance. In cataracts of this type the ophthalmologist suspects a source of systemic intoxication.

With the data listed in the accompanying table we have attempted to correlate the time at which the cataracts appeared following the first ingestion of the drug with (1) the total dosage taken, (2) the total time during which the drug was taken, (3) the average rate of dosage per month, and (4) the loss of weight. The relations have been computed on a scale varying from +100, which represents a 100 per cent direct correlation, to -100 which represents a corresponding inverse correlation.

The total dosage and time of appearance of cataracts have a relation of +26. This has only slight statistical value in a small series. We might expect a correlation of this order inasmuch as the total dosage will be greater the later the cataracts develop. The total time of drug ingestion and time of appearance of cataracts have a relation of +58 which has a somewhat higher statistical value. But here again, the longer it takes for the cataracts to appear the more time will there have been to take the drug. It is doubtful if these two factors have any further causal relationship. It should be noted here however that, with the exception of one case (No 14), the minimum time between first taking the drug and appearance of cataracts was six months. The one exception we exclude because of its alleged unreliability. The average time between first taking the drug and appearance of cataracts was slightly more than fifteen months. It is because of this delayed effect that cases are only now beginning to appear although the drug has been used for several years. For the same reason we may expect many more cases in the near future.

The relation between the time of appearance of cataracts, both with the rate of dosage and with the loss of weight approximate a statistical value of -12 and +17. Neither of these figures is large enough, positively or negatively, to be significant in a small series.

As a result of these studies, therefore, we cannot say that the production of cataracts by dinitrophenol is a function of the total amount taken nor of the length of time that it was taken, nor of the rate with which it was taken, nor of the loss of weight.

COMMENT

The above points to an individual susceptibility as the significant factor in the development of dinitrophenol cataracts. Other toxic manifestations of the drug show a similar variability. Thus, however, is not a unique characteristic of the drug as the allied chemical, trinitrophenol (T.N.T.), has also shown a varying susceptibility among ammunition workers.

We have had the opportunity to examine nine other patients who had been taking small doses of the drug, over a period of forty nine days, none of whom showed lens changes or any notable toxic reactions. Others have made a similar observation.

The *modus generendis* of these cataracts presents an interesting problem. The drug dinitrophenol, is chemically and physiologically allied to the naphthol group especially dinitro- α -naphthol. Edsall⁴ states that the two drugs have similar metabolic and toxic effects, which vary widely for individuals of the same species. The chief difference between the two is quantitative only. It may be of significant interest therefore, that cataracts have been produced in both industrial naphthol poisoning and in experimental rabbits, and that these cataracts, as in this series developed in the short period of a few weeks. However there are to date two incompatibilities in this analogy. In the first place we have not been able to produce dinitrophenol cataracts in our limited experiments on rabbits⁵; secondly, there is no report of retinal or iris lesions in these cases as have been noted to accompany naphthol cataracts. We cannot say at present, therefore, that the cataracts of dinitrophenol have the same pathogenesis as those of naphthol poisoning.

On the other hand, the tissue anoxemia produced by dinitrophenol may account for much of the damage. Dinitrophenol apparently increases the cellular metabolism to a degree inordinately with its oxygen supply. The tissues become acidotic, lactic acid is piled up and the products of decomposition are incompletely oxidized. That this is largely responsible for the toxicity of dinitrophenol is shown by the marked reduction of its toxic effects through the inhalation of pure oxygen⁶. There is no reason why the lens epithelium should not partake of this general tissue anoxemia and be thereby damaged. In fact it is our opinion that the relatively remote position of the lens from its nutritive source renders it more vulnerable than other tissues.

In view of the morphology of the lens changes and the known effects of dinitrophenol on tissue metabolism it seems likely as we have noted in a previous publication⁴ that

⁵ We have been giving large doses of dinitrophenol to two rabbits for a period of two months without the development of cataracts.

the cataracts are the result of damage to the lens epithelium rather than to precipitation of the lens constituents. This is why the toxic effects occur, not as immediate reactions, but after more or less prolonged use of the drug, and may occur after the drug has been discontinued altogether. Four cases in this series (No 9, No 12, No 13, No 20) developed cataracts practically a year after the discontinuance of the drug while two more cases (No 4, No 15) developed them, four and three months after it was discontinued. Furthermore, we have immersed immature cataractous lenses (removed intracapsularly) in a 2 per cent solution of dinitrophenol without the development of more opacities as we might expect were it a primary precipitation of the lens substance. We conclude, therefore, that the anoxemia of the lens epithelium resulting from dinitrophenol is, in all probability, responsible for the cataracts.

SUMMARY

The entity of dinitrophenol cataracts appears to be established by the number of recent reports. The cataracts have a characteristic morphology and rate of development. A statistical study of the relationship of time of

cataract formation with (1) total dosage, (2) total time of taking drug, (3) average rate of dosage, and (4) loss of weight, shows no definitely causal connection. Like other toxic manifestations of the drug, the development of cataracts shows a bizarre idiosyncrasy but unlike most other toxic reactions, cataracts develop from merely therapeutic doses. The pathogenesis of cataract formation may be similar to that of the allied drug, naphthol, but seems more likely a result of tissue anoxemia with consequent damage to the lens epithelium.

ELECTROSURGICAL APPENDECTOMY*

BY LESTER R. WHITAKER, M.D.†

AMONG surgeons there is considerable difference of opinion with regard to inversion of the stump of an appendix. The opponents hold that when the stump is tied and inverted it is simply buried in the wall of the cecum, that this leads inevitably to inflammatory changes in the wall, and possibly to abscess. They maintain that perforation of the gut during the insertion of the purse-string suture may lead to infection, and finally that the whole process may result in extensive adhesions around the cecum.

On the other hand, the proponents of inversion hold that any abscess that forms in the wall after the inversion will quickly slough into the lumen of the bowel, especially if the stump of the appendix has been crushed and a tie of fine plain catgut used. And they say further that any capable surgeon should be able to insert a purse-string suture without perforating the gut. They hold that when not inverted inflammatory reaction in the stump may result in adhesions of the small intestine to the appendiceal site, or, that since the circulation is shut off distal to the tie, sloughing may result in leakage.

*From the Evans Memorial for Clinical Research and Preventive Medicine and the Surgical Clinic of the Massachusetts Memorial Hospitals.

†Whitaker Lester R.—First Assistant Visiting Surgeon, Massachusetts Memorial Hospitals, Boston. For record and address of author see *This Week's Issue* page 884.

Still others assume that the whole discussion is "much ado about nothing", and that good results are obtained by either method. There is one point, however, to be brought up here. If a surgeon should nick a hole in the colon during an operation, would he pick up the tissues and close the opening with a catgut ligature, cauterizing the stump thus created, or would he place inverting stitches? There is little difference between this situation and that with a dangling stump of an appendix. It is generally agreed, however, that with a gangrenous appendix and indurated cecum inversion should not be attempted, but adequate drainage employed.

In the past well-conceived methods have been used to avoid abscess of the cecal wall following inversion of the appendiceal stump. One of the best is that of Lexer¹. For several years a slight modification of this method has been used at the Massachusetts Memorial Hospitals. A brief description follows. With linen or catgut suture material a stitch is taken just distal to the base of the appendix on the wall of the cecum, and a tie made, the object being to secure a small vessel usually present at this point. Then, running a continuous Lembert stitch, picking up the cecum on either side of the base of the appendix, a cuff is built around the appendix for about a half-inch, the sutures being

so placed as to pull the cecal wall rather tightly around the appendix. The base of the appendix is crushed and the clamp applied. The continuous suture is loosened, but held ready to be pulled up. Then the appendix is cut off with a knife below the clamp, and the stump of the appendix retracts as the suture is tightened. One or two sutures are taken over the top completing the operation.

Obviously, this method is open to criticism on the ground that contamination may occur as the stump of the appendix retracts. Cautey excision would tend to prevent this. To place a ligature around the stump before it is pulled in would defeat the object of the whole procedure and amount to the same thing as inversion with a purse string suture. In the absence of the tie, however, there is sometimes considerable hemorrhage into the lumen of the colon.

The question of inversion of the stump of the appendix, as against the method just described (Lexer), has been investigated by Birkle-de la Camp.¹ This author found on monkeys that, when the stump was tied and inverted, there was pronounced exudation between the stump and the overlying serosa, with considerable leucocytic infiltration and inflammation of the cecal wall. The Lexer technique however showed no such disadvantage.

Electrosurgical appendectomy by the method to be described avoids the danger of contamination and hemorrhage, and at the same time prevents formation of an abscess in the cecal wall about the inverted stump.

The method follows. After cutting away the mesentery, the base of the appendix is crushed over a distance of about a half inch, down to and perhaps, including a small portion of the cecal wall. The pressure should not be vigorous enough to crack through and produce contamination. The crushed mucosa and fecal contents of the lumen are pushed out by squeezing with the clamp, which is discarded. A tie of coarse linen is placed around the base of the appendix in the crushed zone, that is, a small devitalized section is left below the linen tie. Then a clamp is applied about a half inch distal to the tie. With the "cutting current" heavy dehydration, low voltage, and using a

needle electrode, the appendix is cut off. The cutting is done with the side of the needle, progressing slowly, perhaps moving the needle from side to side a short distance to make it act more as an ordinary canter, to seal off the lumen as it is cut across, and to sterilize the fecal contents. Then with the "coagulating current", using biterminal fulguration (sparking), the whole stump is thoroughly treated, including the small crushed portion of the cecum below the linen tie. The devitalized stump is then inverted with a double row of Lambert sutures. A closure as secure as would be required with a hole in the bowel is necessary.

Experimentation upon dogs has shown that the stump sloughs off into the cecum within twenty-four hours, leaving the walls nicely inverted and approximated at this point.

In three patients who died after major abdominal operations where incidental appendectomy was performed by this method, the cecum was examined postmortem. In one, after forty-eight hours the stump had sloughed into the lumen of the bowel leaving the inverted edges closely approximated. In the second, also after forty-eight hours the stump was hanging by a few small threads of necrotic tissue, and the closure of the cecum underneath it was firm. In the third, after four days, the edges of the infolded gut were clean.

Examination of the records of fifty personal cases of electrosurgical appendectomy reveals good results. The method was used only in those cases in which there was no induration of the cecum itself. The average stay in bed was eight and one-half days. There were no untoward symptoms, nor any complications referable to the abdomen.

The advantages of electrosurgical appendectomy as described are as follows. It is simple and aseptic, it promotes rapid sloughing of the stump into the lumen of the colon, without danger of hemorrhage or abscess of the cecal wall; and it leaves a firm closure of undamaged tissues.

PRIMARY ABSCESS OF THE OMENTUM*

BY RALPH W. FRENCH, M.D.†

THE great omentum is a structure to which are ascribed multiple functions, yet a discussion of its pathology rarely appears in the literature. Von Recklinghausen and Bizzozzero¹ as early as 1885 by experimentation with animals demonstrated the major rôle of the

omentum to be the absorption of substances from the peritoneal cavity. When the omentum was removed, there was marked increase in susceptibility to abdominal infection. If the circulation of a particular organ was impaired, as in the spleen or kidney, the omentum formed a capsule over the necrotic organ and walled it off, retarding the spread of infection. By the formation of adhesions the omentum walled off inflammatory processes and lessened the es-

Read before the Newport Medical Society, February 1, 1924.

*French, Ralph W.—Surgeon, Truist Hospital, Fall River, Mass. For record and address of author see "This Week's Issue," page 854.

cape of intestinal contents in cases of rupture of a viscus. It furnished protection and warmth and filled in irregularities between intestinal coils. Arnaud² ascribes to the omentum the following functions:

"It fixes microscopic bodies, surrounds large im-movable foreign bodies, has secretory powers, regulates isotonicity and maintains the sterility of the peritoneal cavity. It has greater power of exudation and fibrin production than the peritoneum."

It is, therefore, something of a paradox when the omentum, which is known to possess these bactericidal and protective powers, itself becomes inflamed or infected. Experience with a recent case of inflammation of the omentum which went on to abscess formation led to a search of the literature for similar cases. Few reports of primary abscess of the omentum were available, but those found presented interesting hypotheses as to the etiology and altogether showed a wide range of pathology.

The condition it seems, of primary acute epiploitis or inflammation of the omentum was first observed by Championnière³ in 1892. He encountered two cases in a series of 275 herniotomies in which a portion of the omentum was found in an old hernial sac at the time of operation or became inflamed shortly afterwards. (The French and German authors always refer to the condition as epiploitis and never use the word omentitis in their descriptions of this entity.)

Schnitzler⁴ collected twenty-four cases including his own. Braun⁵ added eight others and Zesas⁶ collected twelve more, so that by 1909 the total number of cases reported was forty-four. Since this time about thirty more have appeared in the literature.

Chronic abscess of the omentum may not be so rare as these statistics seem to indicate. It is difficult to determine the exact pathology at operation when one simply drains a localized abscess of the abdomen adherent to the abdominal wall. The abscess in such cases is generally considered secondary and there is no opportunity to locate the origin of the inflammatory process. The cases recorded, however, are sufficiently numerous to compare the various theories offered in answer to the question, "Why should the omentum fall victim to infection?"

There is controversial opinion as to the mobility of the omentum and its property of migrating to areas of inflammation. The most plausible explanation is offered by Schutz⁷. After experimenting with dogs he found that peritoneal irritation caused hyperemia and as the blood vessels of the omentum lost their tortuosity there was a blind mass movement of the entire omentum toward the focus of irritation. Hertzler suggests a chemotactic attraction between the area of irritation and leucocytes in the infiltrated omentum. Some au-

thorities claim that only the edge of the omentum has the power to migrate, slowly drawing the omentum to wall off an infected area. When the omental edge has been removed in animals, the power to migrate seems to have been lost.

For the most part, the anomaly of omentitis is ascribed to operations or to the rise of inflammatory processes within the abdomen. It is affirmed that ligation of the omental flaps with silk or catgut can cause inflammation of the omentum. After an operation for, let us say, inguinal hernia, a portion of the omentum might accidentally have been tied off, if the patient experiences abdominal pain with rise of temperature, it is natural to infer that infection resulting from a break in asepsis or from the ligature material is the cause of symptoms. The site of the inflammatory mass is usually in the region where the omentum was tied off. Proof of this condition is borne out by the fact that a piece of catgut was found in the abscess cavity in several instances.

From a study of his eight cases Braun draws the following conclusions:

"These inflammatory tumors of the omentum appear at a period varying from one to ten weeks after operations in which the omentum is tied off, there are recorded cases in which the interval was as long as four months and even three years. It is natural to infer that infection, either previously existing or resulting from the ligature material, is the cause. The swellings may be found almost anywhere in the lower abdomen depending partly upon the locality in which the omentum was tied off. Usually, however, they are in the vicinity of the umbilicus. The surface is smooth, the mass is firm in consistency, sensitive to pressure, and is not influenced in its position by respiratory movements. If there are no parietal adhesions, the swelling is movable laterally and upward but not downward, as the intestines lie behind it, there is dullness on percussion. Usually pain is the first evidence followed by fever, occasionally chills and vomiting, the course of the temperature depends upon whether or not suppuration takes place."

As a preventive measure, Braun cautioned us to ligate only non-inflamed omentum and to include only small portions of the omentum in each ligature. This theory of etiology is all the more plausible because of the fact that the pus in some cases with abscess has contained shreds of silk as well as catgut. Hamann⁸ added three cases attributable to this cause.

Steiger⁹ mentioned a case in which a stab wound in the abdomen caused infection of the omentum from perforation of the intestine. Sowles¹⁰, Giraud¹¹, and Labry and Arnulf¹² each reported a case in which the inflammation of the omentum followed as the result of a blow in the abdomen. After resection of the inflamed area the patients recovered.

It is well established that the omentum may also become inflamed by contact with an inflamed viscus or as a result of operative trauma. After operating upon three patients with hy-

peritoneal inflamed omentum, Emerson¹³ came to the following conclusion

"The abnormal condition of the omentum at the site of pain and the relief after partial omentectomy warrant the conclusion that there is a distinct entity as a late sequela of the pelvic surgery which I call chronic localized omentitis"

These three patients after pelvic surgery complained of severe abdominal pain and exerting tenderness with fullness and resistance in the pelvis suggestive of tumor. When the abdomen was explored the only lesion found was the hypertrophic omentum.

Symptoms often make their appearance after appendectomy, cholecystectomy, or other pelvic operations, and in these cases operative finding cannot be ruled out, especially when the pain is localized at the site of the previous operation. Arnold¹⁴, Thévenard¹⁵, and others reported cases of postoperative inflammation of the omentum in which, although the omentum had not been disturbed during operation the patient did not make a complete recovery and symptoms of inflammation appeared from one month to one year afterwards.

There are some cases, however, which must be placed in another category, those in which there has been no previous operation. In these the origin of the condition must be considered embolic, since the inflammatory tumor is apparently not connected with any demonstrable intraperitoneal pathology at the time of exploration. The only pathology in the abdomen is that found in the omentum where the inflammatory process appears to be primary. In Adams's case¹⁶ there was no previous operation or injury and the only recent illness had been pneumonia one year previously and frequent colds. This patient complained of acute pain in the lower right abdomen for four days. At operation an abscess of the omentum was found overlying a normal appendix and cecum.

Panchet¹⁷ reported two cases which he interpreted as acute exacerbation of a chronic omentitis. The omentum showed inflammatory change at the lower border. The omentum was resected and a normal appendix removed incidentally with recovery in both cases. He stated that the epiploön in this type of case became infected by way of the lymphatics.

In 1929 Schomburg¹⁸ reported three cases of acute hemorrhagic epiploitis. A section of the omentum was discovered to be dark red, densely infiltrated, and there was considerable serosanguineous fluid in the abdomen. Two of the patients had always been in good health, the third man had epididymitis several years before the onset of symptoms of epiploitis. In these three cases the appendix was normal. After resection of the omentum the three patients recovered.

In McWhorter's¹⁹ three cases the condition in the first apparently followed severe bronchi-

tis, in the second it was probably due to an infected thrombus from appendicitis, and in the third no etiology was found. Walther²⁰ reported several cases in which there was no pathology except the inflamed omentum in the peritoneal cavity. He pointed out, however, that it might be argued that the original pathology subsided and the omentum detached itself from the old lesion.

Thorek¹ divided cases of omental suppuration into two groups: (1) the Schmitzler-Braun or chronic type, and (2) the Küttner-Schmeden or fulminating type. Boltanski²¹ and Rouslaire²² also reported cases as either congestive inflammation or chronic adhesion. Thorek ascribed an embolic origin to the acute inflammatory omentitis and believed that both types might occur with or without adhesions to neighboring viscera.

It appears from Haller's¹ research that the omentum is found altered in patches in many laparotomies, thus he reported 372 patients treated for epiploitis. In many of these cases, however, the degree of inflammation was slight. Instances were few in which the condition simulated malignant disease and in these the prognosis was discouraging.

In Pantzer's two cases²³ the condition followed an operation in which convalescence was retarded by peritonitis, and he interpreted the pathology thus:

"The *materie morbi* passed the prohibitory portals of the omentum became implanted there at various points and were held in inactive isolation for a long time. Then owing to faulty metabolism or debility as a result of severe physical strain, the poisonous elements in these foci were liberated and caused grave systemic sepsis."

These patients did not get well after operation and remained semi-invalids complaining of abdominal tenderness and pain, yet between attacks showed no evidence of disease. At operation the omentum was found studded with numerous minute abscesses and the structure was thickened in the areas in which the abscesses were located. Pantzer believed that in these two cases the products of inflammatory reaction were held in retention in the omental tissue, contrary to the usual process whereby the infected emboli are gradually taken up by the lymph channels of the omentum and eventually disappear. In the milder cases, the portion of omentum which has become adherent to an inflamed viscus when stripped off shows little evidence of inflammation within itself.

Once the omentum becomes infected the process seems to take one of two courses: either the omentum becomes more and more hypertrophied or multiple tiny abscess cavities form in scattered areas of the thickened and inflamed omentum. Of all the cases reviewed, Pantzer's two fatal cases of multiple abscesses of the omentum and Maunsell's²⁴ report of chronic fibrous epiploitis, in which the omentum

was transformed into a smooth, pearl-white membrane adherent deep down in the pelvis, are examples of the two extremes of this pathology of the omentum.

The case which I encountered recently and which prompted a study of the cases reported in the literature was one of acute primary inflammation of the omentum that went on to abscess formation.

The patient was a woman forty-six years old, who was admitted to the Truesdale Hospital October 25, 1934, complaining of pain and soreness in the left lower quadrant of the abdomen which had persisted for six weeks. Two years previously she was in the hospital for bronchopneumonia complicated by anemia. At that time it was noted that the spleen was slightly enlarged. Shortly afterwards she returned for cholecystectomy for gall stones and her convalescence was very satisfactory, except that it was complicated by a small ischio-rectal abscess. The condition cleared up readily, however, and the patient remained well for a year and eight months until the onset of her present illness.

On admission the patient gave a history of moderate abdominal pain for two weeks in the left lower quadrant gradually increasing in severity. A large, hard, smooth, tender mass was palpable in the left lower quadrant of the abdomen. Her temperature was 100.4 degrees, pulse 100 and respirations 24. The red blood count was 4,420,000, white count 9,400, and hemoglobin 60 per cent. The nonprotein nitrogen was 30.6 mgm., the blood sugar 100 mgm. The blood Wassermann was negative. The general physical examination was otherwise not remarkable. A diagnosis of ovarian cyst with twisted pedicle was made and the patient prepared for operation.

Exploration revealed an inflamed omentum like a mat, six inches in diameter, in the left lower abdomen and pelvis. The center was broken down and contained thick staphylococcus pus in a cavity two inches in diameter. Around this the omentum was very hard and fully two inches thick. (See illustration.) It was easily lifted up from the pelvic organs and intestines which it covered and showed no adhesions to these organs. It involved approximately the left half of the omentum, whereas the right half was apparently normal and free. There were only a few filmy adhesions under the scar of her gall bladder operation. They did not appear to play any part in this picture. From the omental edge the induration extended upward to the transverse colon. Because of the extensive suppuration and its proximity to the colon, it was deemed safer to drain the abscess cavity than to remove the cakelike mass.

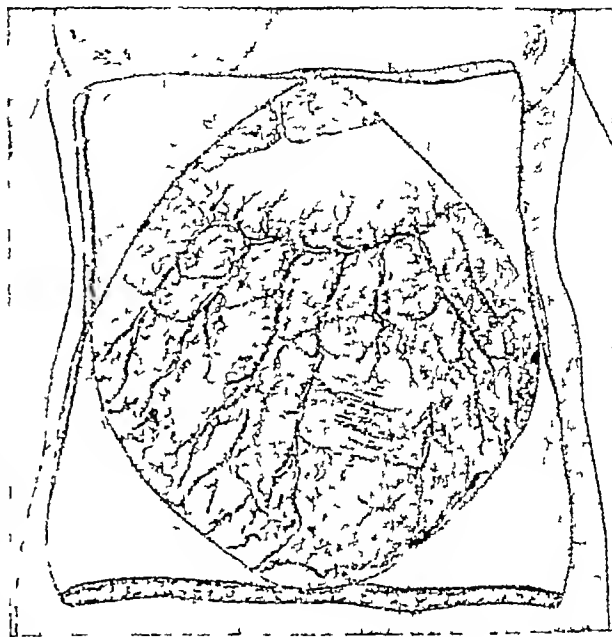

Since the process was so hard that I thought it simulated malignancy, a piece was removed for microscopical examination. The pathologist reported an acute exacerbation superimposed on a chronic inflammation.

The pelvic organs were all found to be normal and the sigmoid and small intestines under the mass showed no sign of inflammation or other abnormality.

Her convalescence was slow. She complained of general abdominal discomfort and a substernal burning sensation, and slept poorly. There was a cramplike pain in the upper abdomen after the ingestion of food which persisted for nearly two weeks following operation. On the tenth post operative day the white count was still 21,700.

Drainage, which was profuse at first, gradually diminished but the patient continued to complain of tenderness in the left lower quadrant, and the temperature remained elevated around 102 degrees.

Five weeks after the first operation a secondary abscess developed and pointed to the left and above the center of the previous abscess. Her temperature continued at 102 degrees and the white count varied from 21,700 to 11,200. This abscess was opened through a counterincision. There was a soft area of necrotic tissue in the thickened omentum into which drains were placed. Thereafter her

Primary abscess of the omentum

recovery was steady with a gradual drop in the temperature and white count to normal ten days after the second incision was made. After this second operation the mass palpable beneath the abdominal wall became slowly but steadily smaller. The patient left the hospital nearly six weeks after the first operation. She has remained well with no inflammatory symptoms and is leading a normal active life.

In this case drainage of the abscess cavity effected a cure. According to Hamann,

"If the progressive increase in the size of the swelling, fever, parietal adhesions and leukocytosis indicate the presence of pus, an incision is to be made and the abscess cavity evacuated and drained. The ultimate results are in the vast majority of cases favorable."

Drennan²⁷, however, disagrees and states

"Unless there is abscess formation, the outlook usually is good. In the presence of abscesses, however, a less favorable prognosis must be given, for these abscesses may break, thus causing a fatal peritonitis."

He advises laparotomy in every instance where abscess formation is suspected. Whenever it is feasible, extensive resection has been the method of choice when induration and abscess formation are present.

COMMENT

Cases of acute primary omentitis coexistent with pancreatitis, sigmoiditis, and diverticulitis have been reported by Bann²³, Hatzegann²⁰, Lepoutre²⁰, and Canonne²¹. An acutely inflamed omentum gave rise to encapsulating peritonitis in two cases reported by d'Allaines and Jomain²², and was the cause of intermittent fever of long duration in several instances²³. Thus the omentum, whatever may be its pathology, is a structure to be reckoned with in complications of the abdomen and may be the sole cause of symptoms. The differential diagnosis is difficult because acute primary omentitis may simulate many other inflammations such as acute appendicitis, cholecystitis, ovarian cyst with twisted pedicle, or diverticulitis. As Schragar pointed out

"If the mass is at or above the level of the umbilicus, there must be differentiation from pathology of the appendix or the gall bladder wandering liver neoplasms of the spleen or tumor of the colon. If the mass is below the umbilicus one must rule out ovarian cysts, or inflammatory mass or tumors of the pelvis."

Furthermore, the condition must be differentiated from other pathological conditions of the omentum itself, such as simple torsion, lipoma, cysts, malignancy, tuberculosis, or syphilis.

In the severe cases the prognosis is discouraging, whether treatment is conservative or daring, but if operation is performed fairly early in the course of the disease, the usual outcome is recovery.

THE ROLE OF PERIPHERAL CIRCULATORY FAILURE IN CLINICAL MEDICINE*

BY DANA W. ATCHLEY, M.D.†

In addressing the New England Heart Association on the subject of circulatory failure my New England conscience forces me to state that I am not a cardiologist and that although my interest in the shock syndrome has included many phases of the problem my actual investigative work has been confined only to those aspects which are related to electrolyte physiol-

ogy. If one is interested in this ubiquitous complication of disease, there is a fascinating literature available for his consumption. The whole gamut of man's absurdity and man's brilliance in the study of natural phenomena is included in the various writings about shock. One may see off recurring the almost obsessive urge to invent a foreign toxin to explain a simple physiological process. The so-called "toxemias" of burns, diabetic coma, pyloric obstruction, Addison's disease and traumatic shock are examples of this misguided ingenuity. On the other hand in few fields have the obvious truths been so clearly stated and so long

*From the Department of Medicine, College of Physicians and Surgeons, Columbia University and the Presbyterian Hospital, New York City.

†Read before the New England Heart Association in Boston, Massachusetts, April 28 1935.

buried I shall point out to you that about seventy years intervened between the first rational analysis of shock in cholera including the appropriate therapeutic suggestions and its general practical application. Janeway pointed out clearly, in 1907, the more frequent termination of severe infectious diseases by peripheral vascular failure than by cardiac failure, yet most modern textbooks of medicine still place their emphasis on the use of cardiac stimulants in such situations.

However, a large number of painstaking investigations, many of them remarkable in their vision far beyond contemporary scientific boundaries, have brought to this field a knowledge of the underlying disturbances of physiology that may produce the shock syndrome and have, moreover, clarified in great detail the effects of shock itself upon the organism. As one reviews the research of these workers, it is apparent that there are a few simple mechanisms which constantly recur and that the appearance of this complication in a wide variety of totally different diseases may be correlated with one or more of these mechanisms. Thus are we able to understand the apparent identity of the final stages of such totally different diseases as cholera, diabetes and severe burns.

For purposes of simplification it may be stated that whenever it occurs, the state of shock is the physiological result of an acute disparity between the circulating blood volume and the functioning capacity of the vascular bed. This result can, of course be brought about by a relatively rapid decrease in blood volume or by a sudden expansion of the vascular bed, and also by a concurrent appearance of both changes. When this discrepancy reaches an advanced stage its ill effects upon the individual are profound and indeed often fatal. I need offer only brief reminder of the clinical picture with its evident great prostration, cold extremities, sweating, pinched features, pallor, sunken eyes, small rapid pulse and low blood pressure. As the result of varied researches, many of them from the Harvard physiological laboratories, the pathological physiology is well understood. There is stasis of blood in the capillaries with a generalized anoxemia and tissue asphyxia. Before the blood pressure actually drops the cardiac output in most instances decreases, thus augmenting the process. The capillaries dilate due to oxygen want, with consequent increase in the vascular bed and leakage of serum into the tissues. Dissipation of serum into the tissue spaces contracts the blood volume and increases blood viscosity. A vicious circle is thus initiated that rapidly hastens the downward course. The kidneys cease to serve their purpose in relation to acid base and electrolyte physiology. Nitrogenous waste products accumulate. If infection be present there is serious interference with the

immunity mechanism. Bacterial toxins cannot be normally neutralized or removed. The whole body economy is at a standstill during what is usually a very critical period because of the original disease process of which the circulatory failure is a complication. However, it is not alone the seriousness and frequency of shock in clinical medicine that demands attention but also and, perhaps more important, the fact that it is in many instances an avoidable danger. In order to prevent shock or treat it properly when it occurs, it is necessary to be familiar with the various routes by which the final stage may be reached. In no realm of clinical medicine is theoretical physiology more fruitfully productive of practical therapy than in this.

The mechanisms that produce a discrepancy between the blood volume and the vascular bed are in ultimate analysis few and simple. A decrease in blood volume may be due to direct loss of whole blood as in hemorrhage, it may be due to loss of salt and water from the blood by a variety of routes and, finally, it may be due to loss of serum from capillaries that have dilated and hence become more permeable to protein. The vascular bed may be increased in size by toxins that cause the capillaries to dilate either by direct physiological effect or by poisoning them. Vasodilatation may also be produced by the neurogenic route, through the sympathetic nervous system.

These underlying mechanisms offer an excellent framework for a discussion of the occurrence of shock in clinical medicine. Because it is the first competent analysis of such an underlying mechanism that I have been able to discover, I would like to detail to you a letter that Dr W B O'Shaughnessy of Newcastle-upon-Tyne wrote in 1831 to the *London Medical Gazette*. This letter embodied the results of several years of what he termed his "experimental inquiries" into the cholera. His terse summary of a physiologic mechanism in terms of modern chemistry is a delightful contrast to the usual clinical sophistry of that day. As I quote his conclusions, I am sure you will agree that his work would still be modern 100 years after he lived. He states

"1 The blood drawn in the worst cases of the cholera, is unchanged in its anatomical or globular structure

"2 It has lost a large proportion of its water, 1000 parts of cholera serum having but the average of 850 parts of water

"3 It has lost also a great proportion of its neutral saline ingredients

"4 Of the free alkali contained in healthy serum, not a particle is present in some cholera cases, and barely a trace in others

"5 Urea exists in the cases where suppression of urine has been a marked symptom

"6 All the salts deficient in the blood especially the alkali or carbonate of soda, are present in large quantities in the peculiar white dejected matters."

Quite wisely I believe, a contemporary reviewer of Dr O'Shaughnessy's "Chemical Pathology of Cholera" called particular attention, in *The Lancet* of 1832, to the 'strictly logical series of deductions disfigured neither by empty hypothesis nor by untenable and wild speculations.'

In other words by quantitative chemical analysis, he demonstrated dehydration salt depletion, acidosis and urea retention and he covered that the base loss occurred via the copious stools

Turning next to the therapeutic implications which naturally follow from the biochemical disturbances found in the disease Dr O'Shaughnessy states further that the cure is seemingly dependent upon two principles: "First, to restore the blood to its natural specific gravity (i.e., its water content) secondly to restore its deficient saline matters. He then states that, "The first of these can only be affected by absorption, by imbibition or by the injection of aqueous fluid into the veins. The same remarks, with sufficiently obvious modifications, apply to the second. The practical application of these principles was described as follows "In severer cases copious enemata of warm water, holding the natural salts of the blood in solution are strongly recommended." When absorption is entirely suspended the author recommends the injection into the veins of tepid water holding a solution of the normal salts of the blood. Thus it is apparent that over one hundred years ago a physician with an investigative and critical mind was able, with the crude methods at his disposal to unravel the mechanism of the essential manifestations of cholera, viz., dehydration, salt depletion and shock. Furthermore he logically employed the specific therapy indicated by such a disturbance in physiology.

Although the implications of O'Shaughnessy's extraordinary work were confirmed by a number of workers in Britain as well as on the Continent, the struggle to overcome the traditional prejudices of those in authority is beautifully exemplified by the following words written by Dr J Piddock to the *London Medical Gazette*, August 21 1832

"Turning hopelessly away from the Central Board and Local Hospital, I resolved to pursue the experiment (i.e. saline therapy) among the poor in my district convinced that the brandy and landanum system had been too highly recommended, and too long sanctioned by authority to admit of the introduction by the same individuals of another system so diametrically opposed to it. Perhaps such a revolution in a cherished opinion, and a favourite

practice, would be a stretch of candour and liberality almost superhuman."

In spite of the fact that in 1850, the German biochemist Karl Schmidt repeated and greatly amplified these analytical results of O'Shaughnessy, there were subsequently but occasional references to the therapeutic value of intravenous salt solutions. It was not until Rogers, and Nichols and Andrews in 1909 used saline injections with a remarkable decrease in the mortality of a cholera epidemic in the Philippine Islands that this rational treatment became generally accepted.

I have taken time to trace the development of the chemical pathology of cholera because it presents, as I have already said, one of the earliest instances in which there was an understanding recognition of the physiologic processes involved in the development of this common complication of many disease conditions, viz., dehydration, salt depletion and shock. Furthermore it was in the treatment of cholera that for the first time a rational replacement therapy was instituted with I might add, the anticipated clinical benefit.

Chronologically, the next correct appraisal of this problem of dehydration may be found in the Guy's Hospital reports of 1874. Dr C. Hilton Fagge described, therein, "A Case of Diabetic Coma treated with partial success by the injection of a saline solution into the blood." The most impressive feature of this pioneer experiment in therapy was the rationale which he offered. It is best expressed in his own words, "What suggested to my mind the advisability of injecting a saline solution into the blood in this case was the idea that coma was due to the drain of water from the system, caused by the diabetes. I suppose that the hypothesis upon which I acted was essentially similar to that which formed the basis of the like treatment in the collapse of cholera." The importance of this observation was nine years later overshadowed by Stadelmann's discovery of the existence of an acidosis in diabetic coma. Stadelmann quite logically felt that the replacement of alkali was the obvious point of attack. This concept so completely dominated the treatment of diabetic coma that even the more modern textbooks omit mention of the clear correlation between dehydration and circulatory collapse which Fagge had demonstrated in 1874. One must not neglect to state that for at least twenty five years salt solution has been routinely employed in the treatment of diabetic acidosis. However, it was usually done with the coincident assumption that the picture of low blood pressure, thready pulse, oliguria and collapse resulted from 'toxic' cardiac failure rather than from shock due to decreased circulating blood volume and vasomotor paralysis. We were able to show in our clinic that the loss of salts and water in

diabetes is dependent upon two apparently unrelated mechanisms. One of these is the obviously necessary loss of base resulting from the excretion of salts of the ketone acids. The other is more difficult to understand but it is definitely associated with the occurrence of severe glycosuria, and may be found even in the absence of ketosis. These two forces working together in an acute diabetic crisis bring about a loss of salts and water that is cataclysmic in its effects upon the patient. It is amazing to note the failure of the textbooks to emphasize this predominant pathological force in diabetic coma, it is not an exaggeration to assert that aside from wholly unrelated complications such as pneumonia, the chief cause of death in severe diabetic acidosis is shock, a death which may occur with normal blood sugar and bicarbonate levels. I belabor the point because it is usually easy to prevent such deaths.

The clinical picture dependent upon dehydration, salt loss and consequent shock is found in many other disease conditions. Prominent among these is the group characterized by pyloric or high intestinal obstruction, as well as those patients in whom for some reason there exist fistulous openings from the upper gastrointestinal tract or the bile ducts. It naturally follows that the picture of shock in these patients results in part at least from constant vomiting or persistent drainage of body fluids normally rich in sodium salts. It should be pointed out that in certain cases of intestinal obstruction no actual loss of salt from the body occurs, but the same result is effected by the outpouring of salts and water into the distended loops of intestine, thus removing them from the circulating blood and tissue spaces. The chemical changes in the blood under these conditions, viz., decreased water, sodium and chloride contents and increased urea concentration, have been recognized for many years. Furthermore, clinicians have for a long time appreciated the therapeutic value of intravenous salt solution. The original hypotheses assumed that the condition was due to a toxemia and that the saline therapy acted as a detoxicant. Gamble's careful balance experiments finally proved that for pyloric obstruction, at least, no other factors than salt loss and dehydration were required to produce the entire disease picture. As in cholera and diabetic acidosis, striking clinical improvement follows the replacement of salt and water.

Underhill and others have studied the serious consequences of extensive burns and have demonstrated that the exudations into the burned area deplete the blood to such an extent that fatal shock may ensue. Animal experiments by Blalock indicate that it requires approximately the same total fluid loss whether by hemorrhage or as edema fluid in burns to

cause fatal circulatory paralysis. More recently Harkins has studied the causes of death by freezing and has observed that there is a definite similarity to the effect of burns, viz., extensive loss of fluid from the circulating blood into the damaged tissues. Of course, I would not assert that there are no other factors contributing to the pathology of burns, but certainly there is none so well understood or so practical an aid to therapy as the fluid depletion.

The clinical syndrome of acute adrenal insufficiency as seen in Addison's disease bears a striking resemblance to that present in the other pathologic states which we have discussed. For example, weakness, prostration, rapid pulse, nausea and vomiting, fall in blood pressure, decrease in water content of the blood, increase in blood urea and decrease in the concentrations of chloride and bicarbonate are characteristic. Indeed, Addison in his original description commented on the similarity of the terminal stage to that seen in cholera. Loeb, in our clinic, has shown that in adrenal insufficiency in man, the sodium of the blood is markedly lowered, as Marine and Bauman and also Zwemer had shown in cats. Furthermore, he was able to show that the administration of sodium chloride alleviates to a striking degree the clinical manifestations just described. On the other hand, it is possible to precipitate an acute and alarming attack of adrenal insufficiency by the withdrawal of salt from the diet of patients who are in relatively good clinical condition as a result of salt therapy. It is truly remarkable to observe the difference that 15 Gm. of salt a day will effect in the health and well-being of such a patient. Loeb and I have demonstrated that the decrease in salt content of the blood in adrenalectomized dogs is due to an enormous increase in the excretion of sodium by the kidney. This loss of sodium is accompanied by an augmented but not parallel water output and results in the characteristic picture of dehydration, salt depletion and shock. It seems likely that the mechanism by which salt depletion and dehydration are produced in adrenal insufficiency is different from the disturbances resulting in shock in the clinical conditions described previously. On the basis of the evidence so far accumulated we are inclined to believe that the active principle of the adrenal cortex exerts a controlling influence upon sodium metabolism through the medium of the kidney, and that the breakdown of this regulatory mechanism results in an increased rate of sodium excretion. The regulatory effect of the adrenal cortex upon salt and water metabolism is not its sole function. This seems proved by the fact that adrenalectomized animals eventually succumb although the period of survival may be appreciably prolonged by salt administration.

Clinical descriptions of heat prostration suggest the shock syndrome and the observations made by the Harvard group at Boulder Dam support the suggestion that salt depletion and dehydration play a prominent role in this condition. Replacement therapy in the acute phase has been successful and preventive measures directed to the conservation of base have been valuable.

It has been shown experimentally that the rapid death in shock that occurs in so-called bile peritonitis is due in part at least to dehydration of the body by loss of fluid into the peritoneal cavity. This type of reaction illustrates clearly the fact, at times overlooked, that it is not necessary that the fluid and salt be lost from the body to the external environment in order to initiate the shock syndrome. A sufficient quantity of fluid statically mobilized in the tissues or body cavities will produce the same result because such fluid is no longer available to the circulating blood stream. Most modern workers in the field of traumatic shock feel that exudation into damaged tissues with its removal of large quantities of fluid at the cost of the blood volume is a potent force in causing this type of shock. There is ample experimental evidence to support this point of view.

It is apparent from the foregoing discussion that the loss of water and salt from the body may occur in a variety of ways and result from a number of different physiologic disturbances. Among these we have described loss of base and water by diarrhea, vomiting or surgical drainage, loss of serum by exudation into burnt or frozen tissues, loss of salt in the urine by alterations in the carbohydrate metabolism, loss of salt as a response to acidosis, an excessive urinary excretion of sodium in adrenal insufficiency, and finally, unusual loss of salt and water by the skin following exposure to heat. There is one common denominator to be found in all of these disease conditions when they have reached an advanced state, viz., the shock syndrome.

The train of events by which dehydration and salt depletion ultimately lead to the classical syndrome of shock requires only brief mention. One of the most striking physiologic principles of the body is expressed in its tenacious effort to maintain the salt content of the blood serum and the interstitial fluids at a constant level in the face of adverse circumstances. When salt is lost for any reason, the body sacrifices its previous water stores to protect its sodium concentration. Conversely, the extensive loss of water is almost invariably associated with a considerable loss of salt. Hence, a severe drain of salt or water or both is reflected in the circulating blood, producing in time a decrease in blood volume so great that the state of shock

ensues in much the same manner as in acute hemorrhage.

Let us next turn our attention to those situations in which the state of shock is brought about primarily by a rapid dilatation of the vascular bed rather than by contraction of the blood volume. Since the isolation of histamine by Sir Henry Dale in 1909, physiologists have recognized that large doses of this drug will cause a generalized capillary dilatation, with a drop in blood pressure and collapse. The closest clinical approach to this laboratory experiment is seen following the entry of venom into the body by the intravenous route. It was my privilege some years ago to observe the clinical effect of an intravenous rattlesnake bite. The patient, while extracting venom during his duties at the American Museum of Natural History, was bitten on the back of his hand. In spite of the immediate administration of antivenom serum the patient collapsed in twenty minutes and was brought to the Presbyterian Hospital. On admission he presented an extraordinary picture. His skin was cold and dusky red in color, he was semicomatose, his respirations were shallow, his pulse was rapid and almost imperceptible, his heart sounds were inaudible and his blood pressure was too low to be read. In spite of several saline infusions and a transfusion of 700 cc his blood pressure, which was raised by these therapeutic procedures, soon fell to a critical level again. It was not until 7200 cc of fluids had been given intravenously in the course of sixteen hours that his blood pressure remained normal. The frequently fatal outcome from an intravenous rattlesnake bite results from failure to recognize the fact that the therapeutic attack should be primarily directed against the state of shock. A recent study by Blair of the bite of the black widow spider brings to light many similarities between the effect of the spider toxin and rattlesnake venom on the peripheral vascular bed.

When Laennec, in 1826, described the weakness of the heart sounds in severe febrile conditions, he attributed this change to cardiac failure, a point of view which unfortunately, still continues to dominate medical thought. This is true in spite of the fact that Romberg and Fässler as early as 1899 wrote upon the effect of bacterial products on the vasomotor apparatus of rabbits. These authors were able to show that a state of collapse could be induced by the intravenous injection of pneumococci or other organisms. Furthermore, they pointed out that intravenous salt solution was more effective in treating these animals than was subcutaneous ether, camphor, strychnine or cognac. Romberg at that time suggested the term "toxic shock" for this complication of infectious disease. It is hardly necessary to emphasize the similarity between Romberg's

"toxic shock" and the shock resulting from intravenous injections of histamine or snake venom

A striking confirmation of the shock-producing capacity of the pneumococcus was afforded by a clinical experiment performed upon himself by a member of our staff a few years ago. This individual gave himself a large dose of pneumococcus vaccine, intravenously. There followed an immediate and alarming collapse during which his systolic blood pressure fell to 60 mm of Hg and continued below normal for three days. In conjunction with this he developed numerous petechial hemorrhages of the skin, which would lead one to infer that, in addition to dilatation of the capillaries, there had also been actual damage.

Doubtless you recall in your own experiences with severe infectious diseases, particularly pneumonia and typhoid fever, patients who have presented the picture of falling blood pressure, rapid pulse and collapse. In many instances this serious complication is a manifestation of shock, and probably results from an increase in the vascular bed due to capillary damage. Confusion of this state with cardiac failure will result in misdirected and possibly harmful therapy. The importance of this point of view was indicated by Theodore Janeway in the *New York State Medical Journal* for 1907, when he wrote on "Some Common Misconceptions in the Pathological Physiology of the Circulation and Their Practical Significance." He said, "We must in most cases abandon the idea of cardiac death at the height of acute infectious diseases such as pneumonia, typhoid fever and septic fever. In place of heart failure we must write vasomotor failure." The discussion of this complication of infectious disease in many modern textbooks of medicine offers a discouraging contrast to Dr. Janeway's enlightened attitude.

There is still another mechanism involved in the production of shock through vasodilatation. I refer to the influence of the sympathetic nervous system. Surgeons recognize this influence in the production of primary traumatic shock and it is by this route that the well-known effects of fear and cold are exerted, although the concomitant vasoconstrictor effects via the adrenals make this a complicated physiological problem. In the field of internal medicine, we have come to realize that one of the immediate effects of extensive infarction of the myocardium is a clinical picture of falling blood pressure and collapse, which is identical with shock. It is hard to believe that such a rapidly developing syndrome could result from tissue damage unless it were brought about through a reflex nervous mechanism. Fishberg has made a careful study of this type of shock and his conclusions are of great interest to the cardiologist. He be-

lieves that the development of peripheral vascular failure in cardiac infarction is a fortunate physiologic disturbance because the return flow of blood to the heart is inhibited by the capillary stasis and the contraction in blood volume decreases the burden on the heart. Therapeutic measures to combat such a beneficial complication would naturally be contraindicated. However, other clinicians disagree with this point of view and feel that shock even under these circumstances should be actively treated.

Up to this point I have dwelt upon the occurrence of shock in a variety of clinical conditions, stressing in each instance the mechanism which dominates the picture. In some of these situations shock resulted primarily from a rapid decrease in circulating blood volume, whereas in others the chief factor was vasodilatation. It is only fair to state that this is a diagrammatic visualization of processes which like other biological phenomena are more complex than I have seemed to indicate. For example, even in histamine shock, where the primary disturbance is admittedly due to capillary dilatation, nevertheless capillary dilatation is inevitably accompanied by an increase in the size of the capillary pores which permits large quantities of blood serum to escape into the tissue spaces. Thus the factor of decreased circulating blood volume also plays a part. This effect may naturally be assumed to exist in the case of snake venom and bacterial toxins, or in any other condition in which generalized capillary dilatation is marked.

In diabetic acidosis accompanied by the shock syndrome, I have indicated the importance of dehydration and salt depletion. There are occasional patients in whom the state of shock persists after adequate replacement therapy and after the ketosis has disappeared. Certain experimental evidence suggests that there may be in these cases a factor of capillary poisoning which is responsible for the persistent recurrence of the shock syndrome. Thus it has been shown that a variety of substances which have a chemical similarity to the ketone bodies, such as acetyl acetone and sodium acetate, will produce vasodilatation in animals.

I would like to digress, if it be digression, at this point and introduce briefly the subject of surgical shock. As an internist I am occasionally asked to pass on cardiac competency in relation to a projected operation. I am wholly in agreement with the work done at the Peter Bent Brigham Hospital which showed the surprisingly small effect operations had upon cardiac function. Much of the so-called cardiac and renal failure postoperative is due to shock. We have in this situation many forces leading to dehydration as well as the neurogenic factors producing peripheral vascular paralysis. At the risk of obvious triteness, I would point

out that salt solution is more often needed than digitals. In these cases, as in any others where there is a real problem of differential diagnosis between primary cardiac failure and peripheral circulatory paralysis, observation of the venous pressure is a very helpful aid to discrimination. In shock it is usually within normal limits whereas in a cardiac state severe enough to be confused with shock it is usually elevated. As an exception, I must cite the occasional occurrence of very high venous pressures in pure shock due apparently to constriction of the veins, at least they are greatly contracted wherever visible. This finding is in distinct contrast to the venous distention seen in cardiac failure.

There has been much discussion of the participation of a toxin in the production of the clinical manifestations of intestinal obstruction and indeed substances with histamine-like action have been isolated from damaged loops of gut. To what extent these substances contribute to the total mechanism in producing shock is still problematical. I have pointed out the role of dehydration and salt loss in severe burns but here too it is possible that certain toxic substances are absorbed from the necrosing tissue and may act as capillary poisons. However, one inevitably returns to the fact that the toxins are hypothetical and as yet without therapeutic possibilities, whereas the other factors are well understood and easily treated.

The treatment of shock is more or less independent of its cause. Whether it be due to trauma, toxemia, hemorrhage or dehydration the physiologic problem is the same, namely a disparity between the circulating blood volume and the vascular bed. On one hand there is primarily a decreased blood volume from hemorrhage or fluid loss, on the other, an increased vascular bed resulting from capillary dilatation. The need for immediate measures to increase the circulating blood volume is common to all types.

I think it is reasonable to say that the longer the state of shock is permitted to exist the more difficult it becomes to alleviate it and the higher is the mortality. Consequently delay in initiating therapy is dangerous. As an emergency method the intravenous injection of 50 cc of 50 per cent glucose which may be conveniently kept on hand is of some temporary value, as it will draw fluid into the blood stream from the tissue spaces. Prolonged use of glucose solutions is not only inadequate therapy but actually augments the state of shock by its tendency to cause dehydration. Glucose should be followed promptly by the intravenous injection of 1000 to 2000 cc of normal saline solution. There is among clinicians, a very general belief that the intravenous administration of fluids in large quantities tends to constitute a dangerous

stram on the myocardium. This opinion is derived largely from experiments on animals not in a state of dehydration. Experiments in our clinic by Caughey have shown that a normal man can receive 1500 cc of normal salt intravenously without altering his venous pressure. Dehydrated patients can accept many times this amount with no difficulty. If shock exists and there is no primary cardiac damage the response of the arterial blood pressure may be taken as an indication of therapeutic success. If there be any question as to the cardiac status a venous pressure manometer should be inserted into the infusion apparatus, and a rise in venous pressure used as an index of overload of the venous circulation. As I have just stated above such overload is very rare even when several liters of fluids are necessary for satisfactory replacement.

Although a normal physiological solution of sodium chloride is usually an adequate therapeutic agent, it should be remembered that in many of the conditions that I have enumerated salt depletion is relatively more rapid than fluid loss. Under such circumstances it is wise to use higher concentrations of salt such as 1 to 2 per cent or even 5 per cent, until the restoration of base is complete.

The ideal treatment for advanced shock is a large blood transfusion, and every patient likely to develop shock should have his blood grouped early in the course of his disease. When salt solution has failed, transfusion may turn the tide. The theoretical basis for the fact that blood is more effective than salt solution lies in the assumption that it contains a relatively nondiffusible substance, i.e., serum protein, which makes the influence of added blood a more permanent one. We cannot accept this suggestion without reservation, for it has been clearly proved that in histamine shock whole serum leaves the blood stream. In other words, the capillaries become readily permeable to protein. However there is no denying the greater therapeutic value of blood over all other fluids. In an attempt to find a substitute for blood other colloidal substances have been tried. The most prominent of these is aescin. During the World War, this solution was tried but given up in this country because of the severe reactions which frequently followed its administration. In the past few years, methods of preparation of aescin solutions have been improved, and enthusiastic reports of its action have appeared.

All therapy in severe shock should be intravenous rather than subcutaneous or intramuscular. The rapidity of response is much greater when the intravenous route of administration is employed because the poor peripheral circulation tends to slow subcutaneous absorption tremendously. This applies to hypodermic medication as well as to fluid administration.

The use of vasoconstricting drugs such as adrenalin is not helpful and may, in fact, be harmful. From a physiologic standpoint they are contraindicated because the blood vessels which they affect are already constricted to the disadvantage of the capillary circulation, as has been shown by studies of both the skin and visceral arterioles. Furthermore, experimental work has shown that continuous injection of adrenalin in quantities that are equivalent to the amounts produced by sympathetic stimulation can cause a 14 per cent decrease in blood volume during a two-hour period. Hence adrenalin exaggerates the state of shock, even though it temporarily increases arterial pressure.

In conclusion I would like to express my

pleasure in being offered an opportunity to review this subject before a group interested primarily in cardiac problems, for it is the cardiac consultant who most often has to assume the responsibility for differentiating peripheral circulatory failure and the condition with which it is so commonly confused, viz, cardiac insufficiency. The most satisfactory point of orientation lies in the recognition of the constantly recurring basic physiological pattern, resulting from a disparity between the circulating blood volume and the vascular bed. Although I am aware that much of the ground that I have covered is familiar to you, the lack of emphasis upon this important complication of disease in the most modern textbooks justified, I felt, my making the summary as broad as possible.

THE ECONOMIC AND SOCIAL ASPECTS OF SOCIALIZED MEDICINE*

BY IAGO GALDSTON, M.D.†

THE American medical profession is at this time confronted by a social movement which threatens to disrupt the profession's individualist relation to the public. This movement has for its objective the socialization of medicine, and while there is no agreement among its proponents as to the specific form which the socialization of medicine should take, we may assume with certainty that what is contemplated differs radically from the prevailing quid pro quo individual relationship between doctor and patient.

In an objective analysis of the movement for socialized medicine, we must begin by seeking for its origin among social and economic factors. "Why", we must ask, "is there such a strong movement for the socialization of medicine?" The answer in part is, that the movement has arisen in response to needs of an economic and social nature. There is undeniably a great need among our people for additional and more extensive medical services of a curative and prophylactic nature. There is a mountain of testimony available to the effect that this nation suffers much economic loss as well as much misery by the prevalence of preventable and inadequately treated illness.

Together with this realization there is prevalent a strong conviction that by a more effective utilization of the available resources of medical science, the average lifetime could be extended, much illness could be avoided, and much of economic loss saved. This dilemmatic situation raises the pertinent question "Why

does not more of our citizenry receive adequate medical care?"

Among the many answers given to this query, the outstanding one is, that present-day medical service is too costly. "Too costly" may have one of two meanings, either that the return received for the expenditure is of too small a value, or else that the commodity is beyond the means of the potential purchaser.

It is in this second meaning that medicine is complained of as being too costly. The average American family cannot afford to purchase for itself adequate medical care. Pushing our inquiry farther, we may ask "Why cannot the average American family afford to purchase adequate medical care?" The answer to this query is to be found in the records of the distribution of our national wealth and in the distribution of our national income. According to W. I. King*, sixty-five per cent of the people in the United States own but fifteen per cent of the wealth of the country, the maximum average wealth in this group being less than \$3,500. The remaining thirty-five per cent of the people comprising the middle and rich classes own eighty-five per cent of the national wealth, and in this group two per cent of the people own forty per cent of the total wealth of the country.

Perhaps even more significant, from our viewpoint, is the distribution of our national annual income. According to the National Bureau of Economic Research†, 66.7 per cent of our income-receiving individuals have an annual income of between \$500 and \$1,500. An additional 13.9 per cent have annual incomes ranging between \$1,500 and \$2,000. In other

†Income in the United States National Bureau of Economic Research pp 136-7

words, 88.8 per cent of the people receive but 58.7 per cent of the total income. In contrast we find six per cent of our people receiving roughly forty per cent of the annual national income.

These figures reveal why adequate medical care is too costly for the vast majority of people. These figures reveal also, though they do not tell the entire story, why there is so much preventable illness and avoidable loss of life. These figures explain why, despite the wealth of available medical knowledge and the richness of our scientific resources, so many of our people are without their benefits.

We are thus brought to the realization that the movement for the socialization of medicine arises out of the complexities and imbalances of the prevailing economic system.

Fundamentally, too, we must realize that the socialization of medicine is an attempt to secure adequate medical service for the average man and his family without going through any radical change in the distribution of national income. The only way in which this might be accomplished is by compelling the physician to render more service for proportionately less remuneration. This must be plainly evident to anyone who seriously contemplates the problem. As long as the average income of the average family remains what it is today, only a small portion of that income will be available for the purchase of medical service. No matter how this portion is collected, whether by a system of voluntary taxation, by insurance or by any other method, it will still remain a small per unit volume. By the expenditure of this collective sum only so much medical service is secured today, and by common agreement, this amount of medical service is insufficient. If more medical service is to be secured for our people for the same collective sum this can be accomplished only by lowering the price of medical service.

The problem which the medical profession faces today and which society as a whole faces with regard to medicine, is part and parcel of the larger economic and social problem which enmeshes all of mankind. Its origin is identical with that of the economic disorganization which has imposed a pall of depression upon the entire civilized world. There is little hope that any effective solution of the medical problem will be achieved until the underlying economic factors are set aright. Nor for that matter of fact, is there any hope that we may effectively escape the periodic disruption of our economic existence until a basic readjustment in the distribution of the wealth produced is accomplished.

However, as a profession we are rooted in individualism, but it is an individualism with a large social consciousness. What other communal group can match us in our free gifts

to society, of our toil, of our thought and of our genius? Where other men have exacted the utmost of their so-called due, for their discoveries, their inventions and their contributions, our ethics and traditions have taught us to make freely available to all mankind all of our finds. James Watt patented his steam engine in the same age that Jenner discovered smallpox vaccination. Edison invented and patented the incandescent lamp about the time that Von Behring discovered diphtheria antitoxin. Banting gave the world insulin in the same decade that the DeForest valve made the radio one of the major modern industries. Let history judge which were the greater gifts to mankind, and let it bear witness to the enlightened individualism of the medical man.

We have made a necessity out of a virtue. Charity is not a cabballatical practice with our profession, but our everyday performance, so ingrained in our relations to our fellow men that they largely demand it now as their due.

There is more to this problem than appears on the surface. Thus, it is not pertinent to inquire why do our people require so much medical care? We who are physicians know the effects of economic status upon physical well being. Health is affected by food, clothing, shelter, work, leisure, education and recreation. Is it not possible that the reason why our people require so much medical attention is not because they cannot afford adequate medical service, but rather because they cannot afford adequate food, clothing and shelter, because some are worked too long and too severely, while others are left to disintegrate in idleness because their education is inadequate and too poor, etc.?

It is pertinent to observe that when a man is sick, he has the powerful *vis medicatrix naturae* fending for him. He may get well without the aid of his doctor, sometimes even despite his doctor. But who fends for man in want of food in want of shelter in want of clothing?

Germany has had socialized medicine for fifty years, but the average expectation of life at birth in Germany is about ten years less than in our own country.* Evidently the socialization of medicine works no miracles.

Hence we come to a point in our consideration where we acknowledge the need for improvement in the medical care of our people, but reject the proposal to socialize, that is, to industrialize medicine, because it offers no promise to remedy the existing defect, because it would involve the disorganization of the profession of medicine, with the loss of so much that is best in it.

When the proponents of socialized medicine are harping on the alleged high costs of present-day medical care, they turn historians.

With a majestic sweep, they encompass the story of the ages and they distill the "unquestionable lesson from history" They give utterance to such generalizations as "Everywhere and always, the physician has been a product of his times, and the conditions under which he has practiced have invariably reflected the customs of the period"

The crux of the entire matter appears best expressed in the epitomic statement uttered by those favoring the socialization of medicine as if it were axiomatic, to the effect that "The physician's position in society is never determined by the physician himself but by the society he is serving"

This pseudo-historical dictum needs careful scrutiny To begin with, the question might be asked In society what professional group ever succeeds in determining outright and without opposition its own status in the communal economy? Further, the protagonists of socialized medicine use the term society in an animistic sense, as if society were a corporate thing, possessed of a unique intelligence which understands clearly the relationship of the different groups incorporated within it and is capable of assigning to each its proper rôle and position This animistic concept of society is medieval in character and was discarded more than eighty years ago *The position of medicine in this given society will be determined by whatever pressure those groups can bring to bear upon medicine in whose interest it is to purchase the services of the medical profession at the cheapest and the lowest possible rate and also by the amount of resistance that will be shown by the medical profession to such exploitation*

But disposing of this pseudo-dictum is not enough for our purpose We must pursue the subject farther There was for those that propounded it an end which the dictum served Let us follow to that end The almost syllogistic reasoning ran somewhat as follows "Medicine never determines its position in society, on the contrary, society does that for medicine Our society is determined to socialize medicine, hence, it is foolish for medicine to oppose the inevitable" In the words of Sigerist, "We can oppose the development, we can retard it, but we will be unable to stop it", or, as it is paraphrased by others, "In any final sense, the economic and professional needs of modern medicine call for group payment by the public, group practice by the profession and a conjunction of the two"

We must ask here Who is it that defines the "final sense" and who is it that determines the economic and social needs of modern medicine? Since there is no corporate state no articulate society, who is it that has been pretending to the rôle?

Undeniably the social trend is toward socialization But "trends" have no transcending warrant to exempt them from critical scrutiny Trends can be wrong, too

In this connection it is interesting to note that every age has its shibboleth, has its linguistic gilded calf to which the deluded bow and pay homage The shibboleth of our age is socialism and socialization So powerful and so narcotizing is this term, that even the most arrogant of dictators make use of it Fascism in Italy justifies itself in the name of socialization and Nazism in Germany even goes so far as to call itself National Socialism

And in truth, the word social has a fatal enchantment, for to the unthinking, whosoever is against socialization appears per force, to be for greedily and thoughtless selfishness Few constitute the opposite of socialization to be individualization Nor is it commonly recognized that one may be for the socialization of certain phases and functions of human existence and endeavor, and yet be for unconditional individualization in other respects Total and unconditional reactions are usually associated with juvenility and inexperience Few love or hate so completely as the child or childish adult, and in the widespread embrace of the idea of socialization which, like the conversion manias that swept through Europe in the early centuries, have now involved so many of our vocal thinkers, there is more hysteria than religion, more quest for refuge from perplexity than understanding Because individualism and laissez-faire have brought in their train so much suffering, therefore let us destroy individualism, let us socialize! All of mankind's history has been like the swing of the pendulum, a progression from extreme to extreme, and never has the golden mean of the Greek philosophers guided us in our affairs No man can be insensible to the sufferings for which modern capitalist society is responsible, no man can be so blind as not to see the greatness achieved by the free and unfettered enterprise of the individual entrepreneurs Now, as in all times, in Athens, in Republican Rome, in the free cities of Italy, the greatest ages have been those of individual freedom

Let me not be understood as being opposed to social endeavors, not even to much of that which is properly called socialism Many phases of human existence can best be served by social endeavor Our own profession, that of medicine, though practiced by individuals and in an individualistic manner, is in its studies, in its research, in the inter-relationship of practitioner to practitioner, and the total relationship of the profession to the people, a most highly social profession My protest against the shibboleth of socialization is that it is offered

as a panacea, as an ultimate and final cure all, as an unailing remedy. Of course it cannot be and is none of these.

The proponents of the socialization of medicine have no adequate understanding of the psychologic nature of man. Their reasoning follows the guidance of a naive materialism. Because the chain belt system of mass production has given us cheap and effective automobiles and radios, sewing machines, farm tools and mail order house products, therefore, they reason, a similar system of mass production and distribution can be as effectively applied to medicine. But they count without the nature of the beast. Man is a gregarious animal. On the least impulse he will flock with his fellow kind. He loves the group and feels strong in the company of his own. But for that very reason he is as strongly in need of periodic affirmations of his singularity of his uniqueness of his individuality. Man can toil in common but save for the ceremonial banquet he prefers to eat alone, or with those very few who are near to him. Man can, to an appreciable degree, sink his ego in the complex organism of the factory, shop, office or community, but only at his peril can he afford to abdicate his birthright of individuality as a lover, father or elder. *One might with warrant generalize that man is a social communal animal as a producer, but an individualist as a consumer.* And in relation to the physician, the patient is ever a consumer.

There is in this struggle between those who urge the socialization of medicine and those who oppose it a deeper cleavage than appears from even a careful pursuit of their arguments.

To me it seems that in this difference between the two groups, there is reflected two fundamentally divergent philosophies, as far apart as those two that motivated Athens and Sparta. It is not merely a question of the socialization of medicine but more it is a question as to which of two lines of pursuit offers economic and social salvation.

Shall it be the state, the patriarchal institution upon whose lap we shall lay the full destinies of the individual, to whom we will look for the regulation of our living manner and the provision of our multiform needs, or shall it be the individual, grown to the stature of a civilized and social being who will as a sovereign carve his own destinies, in the company of with the help of, but at the cost of none of his fellow men?

In other words, shall men rule themselves in all respects of life and be truly democratic or must we turn back to dictatorship?

There is, in the practice of medicine a saving grace which as in the case of the isolated tiller of the soil defends the practitioner against becoming brutified. That grace in both instances is intimate contact with life. The farmer is an

intimate witness of life in the things that grow about him, the physician in the human beings that claim his help. The rest of the world deals with things with goods and money, with machines and figures and books. These two, the physician and the farmer, shall we say, see life in the raw."

It is perhaps for this reason that both agriculturists and physicians are conservative. They hold to their values and are not easily persuaded to exchange them for new script. So even without a knowledge of the lessons taught by history, the physician is an individualist and a democrat, and the profession is well represented among those who fought for the rights of the individual from Servetus to the medical signatory of our Declaration of Independence.

The issue of democracy has been raised once again, and there are some who, like the benighted Athenians, are issuing a call to Philip. The medical profession in its small segment of this matter and in a stammer indeed, is sounding the Philippic warnings of Demosthenes. We distrust the tyrant, even when he comes garbed in the cloak of socialization. We claim for ourselves and for mankind the birthright of suffrage. We say the other way the way of the Caesars leads to Caligula and Nero to the dominance of the barbarians, to the yoke of the Roman Empire. We remember how man kind fought for the Magna Charta, for the Reformation, against the Louis of France and the Georges of England. Our faith then is like that of Pericles with the Demos. This Demos our philanthropist, however, does not understand, nor does he love it truly.* How simple is his reasoning! Cavalierly he lumps together all social insurance schemes unemployment, old age disability and sickness, never thinking that the first three are merely matters of compulsory savings, while sickness insurance involves the uprooting of an entire profession and a shifting of the stream bed of motivation that has for so long been fixed between patient and physician. Furthermore it means bureaucracy, that cankerous parasite that always comes into being when human relations become indirect, complicated, and achievable only through intermediaries. *What is there in our history, in our experience that warrants faith in the successful socialization of medicine?* We are a nation of people honest as individuals and often cynically corrupt in the mass. Our history is taught badly or else we would better appreciate the venality of our collective people, for this is the land of graft, collusion and dishonesty. How short is our memory! Carpet baggers, poisoned beef for our Spanish American War soldiers, Tweed Teapot Dome, the banks, nay Gustavus Meyer's history of great American fortunes the autobiography of Lincoln Steffens, and Beard's American History,

should dissuade everyone from faith in the governmental, mass or mob. To this, add our own experiences with workmen's compensation and with communal and government hospitals and the picture is complete.

Lest I be charged with misanthropy, let me hasten to add that no man is to blame who fails, when what is required of him is beyond all limits of his capacity to achieve. Man can love his kin, respect his neighbor and share in the suffrage of his town. Beyond these only the exceptional man can reach. For this reason the Government's post office pen is no one's pen and tax money is a common source of political patronage.

Despite this, there is no doubt but that the agitation for socialization is very intensive. An indication of the economic and social confusion that prevails is to be witnessed in the fact that the socialization of medicine is sponsored by two diametrically opposed economic groups. Socialized medicine is endorsed by the revolutionary groups, and it is sponsored as well by the reactionary groups. The one sees in the socialization of medicine the cutting wedge of their longed-for cooperative commonwealth. The stand-patters see in the socialization of medicine a prop for the present economic system. History, I suspect, will prove both in error.

At this point it is important that we turn the limelight of criticism upon ourselves. Because we are so bitter in our criticism of the proposed schemes for the socialization of medicine, let it not be construed, therefore, that we are without fault.

The medical profession has unquestionably shared in the predatory ideology and practices of present-day society. We may talk of the nobility of our profession and may cite, as I have, numerous individual examples of professional generosity and unselfishness. In fact, it can be argued that few professions have so many such illustrious examples in their membership as does medicine. But the public judges us, and rightly so, not by our illustrious examples, but by common denominators, and these have been confessedly none too good, at least when measured by our pretenses and by our numerous privileges, which impose exceptional obligations upon us. This has been as true of the upper group as of the lower.

Need I at this time remind you that medical education for the undergraduate was until some thirty years ago largely a commercial endeavor, carried on for the profit of the entrepreneurs? Need I point out to you that the solid-

ity and unity of medicine, culturally and otherwise, is disrupted by the existence of numerous small cliques, exclusive societies and the like? We may indulge in the orator's exaggeration and speak of our noble healing cult and of our oath of Hippocrates, and yet, a minority of fortunate physicians have for many years held on to their hospital, dispensary and other positions, concerning themselves but little with the very large number of physicians who are without such opportunities for continued study and training.

It is well to talk of spiritual enslavement and of the submergence of the individual ego, but when one is economically enslaved, when one does not know how to make ends meet, one's so-called birthright appears like a small price to pay for a mess of pottage wherewith to dull the gnawing pains of hunger. Undeniably, even among our own ranks there are many physicians who would be eager to accept the socialization of medicine precisely because therein is the promise of more than they can get out of the "dog-eat-dog" society of today. This circumstance is very unfortunate. One cannot and one must not shut one's eyes to the suffering and deprivation which is about us. We, however, who are physicians, must not "jump at" a remedy which threatens to be worse than the disease.

Whether the agitation for the socialization of medicine will prevail I am unable to say. My guess, which is no better than the next man's, is that the cards are stacked against us. However, be that as it may, if I read history aright, there is a "triumph of the defeated" no less great than the triumph of the triumphant. The effectiveness of opposition is a chapter in history which few appreciate, and the virtue of opposition as a social instrument I recommend for consideration. The Greeks were defeated by the Romans, but the satires of the later-day Roman poets (Juvenal) reveal that the Greek, rather than the Roman, prevailed. Rome was overrun by hordes of barbarians, but the invaders were Romanized. Christianity triumphed over paganism, but some of our customs are witnesses of the triumph of paganism in its defeat.

Our opposition to the socialization of medicine must therefore be persistent. We are bound to triumph even if we are defeated. Our opposition, however, must be discriminatory rather than total, and it is our eternal obligation to deflate the pomposities of the promoters of pet schemes to show up their shallow thinking and their ignorance, even as I hope I've been able to do.

MEMORIES OF A GREAT PHYSICIAN,
DR. FREDERICK C. SHATTUCK, OF BOSTON

BY JOHN D. HAWES, 2ND, M.D.*

"HALF life is memory, the other half an anticipation", says Yeats-Brown. Having reached an age when the years crowded with memories far exceed those I may rightfully anticipate, I am hereby jotting down certain very precious recollections of my early medical life and especially those years when it was my privilege to be the assistant to the late Dr. Frederick C. Shattuck of Boston. Dr. Shattuck, then at the height of his career, was professor of clinical medicine at the Harvard Medical School and chief of the Medical Staff at the Massachusetts General Hospital. He was a "doctor of the old school" as was the original of that name so vividly described by Ian MacLaren and who for forty long years gave loving care to the dwellers in Glen Drumtochty. Like him, Dr. Shattuck practiced medicine as an art, making a room brighter by his presence and trials and tragedies easier to bear for those who must bear them. The incidents I am about to describe took place during my first twenty years of practice when I as a young practitioner in Boston, was intimately associated with him first as student and later as his assistant.

Dr. Shattuck was a picturesque figure, handsome and what one might call debonaire. His face, always attractive, lit up on smiling so that it radiated cheer. Strikingly dressed his waistcoats, invariably of some brilliant plaid have gone down in song and story. A flower in his buttonhole and a cigarette that hung in some miraculous fashion from the corner of his mouth completed a picture that one always looked upon with pleasure.

It was a morning in October just thirty years ago when the shininess of a new brass shingle outside the door of my office on Marlborough Street had had no chance to become dimmed that I was called to the phone and heard Dr. Shattuck's gentle voice asking me to drop down to see him for a minute. Much impressed and filled with curiosity I started out walking—we had no automobiles in those days and I did not consider my bicycle sufficiently dignified for the purpose. His office was small but like the man sunny, warm and cheerful with a fire burning on the hearth as it always did for at least nine months of the year regardless of weather. He was sitting in his well worn leather armchair smoking as usual. "Come in", he said. "Sit down and be comfortable." I wondered what was coming next. "Hawes", with that quizzical smile I came to know so well, "I'm get-

ting very old and Smith (referring to his then assistant) is getting very busy. I wonder would you be willing to assist me in some of my work?"

Would I be willing to assist Dr. Shattuck? There was no more enviable position in Boston for a young medical man than this and right well I knew it. I do not remember leaving his office but I do recall walking up Marlborough Street on air. It was a wonder that I was not pulled in by the police! Then followed many years of hard but intensely interesting work. The practice of medicine in Boston and the life of the young physician at that time was a very different thing from what it is now. I remember very distinctly consulting two men whom I looked upon as representing all that is finest in medicine as to what I should do and where I should open my office. Each gave me the same advice "John", they said, "You must be on the staff of the Massachusetts General Hospital and have an office on either Marlborough or Beacon Street. These are the first requirements of a gentleman who wishes to practice medicine in Boston." How often have I thought of their advice with some amusement and yet with much respect. Incidentally, I followed their suggestions!

Getting started on a medical career in Boston was no easy matter for a young doctor with no money. Saturday afternoons, Sundays and holidays were religiously spent at the office hoping for a telephone call or that some medical crush would fall from the plate of those older and well established physicians whose names and reputations meant so much to us. How clearly incidents of those days stand out in my mind! A beautiful Saturday afternoon in my office to which the sun never penetrated, longing for the golf links or for a row on the Charles, I was reading with some difficulty a German medical magazine when the telephone rang and I heard Dr. Shattuck's voice "Hawes, do you care to make a three-dollar visit in South Boston?" How glad I was to break away from improving my mind! On my faithful bicycle with my doctor's bag hanging on the handlebars across the city I went to earn and well earn my precious three dollars. One of my very first patients was a charming young girl who thought she had something wrong with her chest. Being a thorough and conscientious young man I told her to strip to the waist so that I could examine her and then modestly left the room. A few minutes later I returned to find that she had misunderstood my directions

Hawes, John D., 2nd—President Boston Tuberculosis Association. For record and address of author see "This Week's Issue" page 444.

and had removed her clothing from the waist down' Blushes on the part of each of us

Again one beautiful Sunday morning I was walking down Beacon Street with an older physician, a splendid Irishman, loved by all of us and with a very large practice in the city. As we strolled along I was deeply impressed by the number of people and particularly the pretty girls to whom he doffed his hat and bowed "My word, Doctor", said I, "What a wonderful practice you must have and what a group of lovely girls you are acquainted with?" "Hush, my boy," was his reply with a wonderful Irish twinkle in his eye "Johnny, my lad, I don't know a one of them but don't you think a pretty face deserves a bow?" Joyous memories!

Another time a classmate and dear friend of mine who lost his life in Flanders—Dr George P Howe—was taking his daily exercise in a wherry on the Charles River This was before the Esplanade was built and a dam controlled the tides so that rowing at low tide was a bit precarious and one had to watch the channel pretty carefully or else pay the penalty My friend for some reason always known as "Peter" nearsighted to a great degree, had strayed from the straight and narrow path and found himself stranded on the mud flats where he had to get out and walk The shells cut his feet and he was in anything but a good humor when a short way off a fellow oarsmen resting in deeper water called out and asked if he could help To which Peter very logically but not tactfully replied "I don't see what in hell you can do anyway" He was embarrassed and chagrined when he drew nearer and found out that his would-be Good Samaritan was one of his professors and instructors at the Medical School—Dr Elbridge Cutler

Dr Cutler was a splendid example of the general practitioner of those times Once he left his practice in my care while he attended a certain medical meeting It was June so that most of his patients had moved out of town to their summer homes at the North or the South Shore "Dr Hawes", said he, "I am leaving five or six patients in your care They are all well along in years and I hope that you will make no radical changes in the treatment I have laid out for them You see, all that I am doing is to escort them pleasantly to the grave" This remark made a deep impression on me for I was young and believed in a somewhat militant and aggressive form of medicine As I grow older I realize that more and more the task of us doctors in many cases is to escort our patients as pleasantly as possible to the grave And I certainly made no changes in those that Dr Cutler left under my care

Always a gregarious fellowship we young

doctors were wont to foregather at mealtimes, there to forget for the time the dullness and trials of a medical existence For a good many years there had been at 89 Charles Street a favorite eating place known as the P O T Club which meant "Pay or Travel" One of us, I for one year, well earned the dollar a week deducted from our board by collecting it from the others We learned from experience how to carve efficiently if not elegantly Comments on any false move or failure to find the joint were loud and much to the point while vociferous demands for second helpings before the unlucky one elected to preside over the roast had had a chance to help himself stimulated speed and accuracy A bowl containing marbles marked from one to twenty-five was passed around as a regular ceremony before dinner, each man drawing a marble If he drew a low number his beer cost him, accordingly while loud indeed were the lamentations of those getting the high numbers The drawings completed and the money collected, one of us, usually my husky friend, Peter, went around to the corner grocer and returned with the case of beer Such eating clubs came and went but each left behind delightful memories

But it was with Dr Shattuck that most of my work was centered and it is of him that my memories are clearest and most cherished At that time he was constantly being called in consultation to see patients all over New England while in addition during his term of service he made daily visits at the hospital and conducted clinics twice a week for third- and fourth-year medical students These it was my job to plan and arrange for There was an immense amount of laboratory work including specimens of all kinds to be examined, reported on and mailed each night before going to bed Many evenings, tired out from a hard day's work or an equally strenuous party—for doctors do relax at times, I came home only to find a half-dozen boxes and bottles awaiting me which meant weary hours in the laboratory, painfully slow typing, sometimes half asleep, until finally the clank of a letter-box cover told me that I might go to bed It was hard but interesting work

The clinics I rejoiced in Out of his vast experience there was always some new diagnostic point or valuable therapeutic procedure to be gleaned On these mornings, Henry, Dr Shattuck's coachman and later chauffeur, a familiar figure to all of us in the Back Bay, would drive the victoria and two sleek bays to my door and for the short distance to the doctor's office (and I always wished it were longer) I was quite the King, leaning back nonchalantly in the middle of the seat with a priceless sable robe thrown carelessly over my knees, hoping that some of my friends would see me

I well remember one day when on reaching the hospital Dr Shattuck said to me, "Hawes, go to this Drug Department and bring me a five-grain capsule of quinine I have a cold." Thus I did and having done so ventured to ask why he took the quinine and what he thought it would do for his cold. I had imagined that the days of quinine, except for malaria, were past. An amused look came over his face as he replied, "I haven't the slightest idea what quinine will do for my cold but I know damn well it will make me more comfortable!" There was much sound common sense in what he said particularly in those days of therapeutic nihilism.

Dr Shattuck was eminently an honest man not only in his medicine but in every other way. He hated subterfuge and short cuts. He was firm in his belief that no special tests or signs could take the place of good thorough work that covered every detail followed by a serious consideration of all the facts in the case. In this way alone was it possible to arrive at a correct diagnosis. John Buchan expressed his feelings very well when one of his characters said, "The peril is that men may be tempted to seek short cuts and the good God does not permit of short cuts in this life of ours." At one clinic the subject of exophthalmic goitre, now called hyperthyroidism, was under discussion. Now in every medical school class there are always at least one or two so-called "bright boys." They occupy front seats listen intently and appear to be and perhaps are deeply interested. They are always ready with some question they believe to be pertinent and resemble the Bandarlog in the Jungle Stories in their desire to attract attention. They constitute a harmless but not a particularly admirable group. This is common knowledge to any doctor. On this occasion while the salient diagnostic points of the case were being demonstrated one of these students leaned forward and asked, "Dr Shattuck is not 'exophthalmos' a pathognomonic sign of this condition?" This was rather in the nature of a red rag to a bull. I waited breathlessly for his answer. Looking at him pityingly, Dr Shattuck replied "Young man Christ said 'An evil and adulterous generation seeketh after a sign and there shall no sign be given to it.'" The student collapsed and was heard from no more.

Dr Shattuck believed in speaking the truth but not so as to hurt the patient if it were humanly possible to avoid so doing as shown by the following incident which likewise shows why he was so loved by all who came in contact with him. This occurred when I, as his senior house officer was escorting him through the hospital on his daily visit. On entering one of the wards his pointed to a very pale and evidently extremely sick woman in a nearby bed and asked "Hawes what is the matter with

that patient?" Now the position of senior house officer is a very exalted one and the individual occupying it takes great pride in any rare or unusual case that he is able to demonstrate to his chief. He has not yet learned his lesson. Accordingly, I replied, loud enough for all to hear, "That, sir, is a case of pernicious anemia." A pained look came across his face. "Come here," and he led me across the ward out of, hearing "Primary anemia, please, Hawes, 'pernicious' has a horrid sound to the patient!" I have never forgotten that incident and then and there resolved that for the rest of my life I would deal with human beings and not with "cases" no matter how interesting they might be.

Another time I accompanied him to one of the surgical wards where his opinion was requested concerning a man who had been doing very badly after his operation. He read this history, studied the chart and very briefly looked at the patient who was evidently dying. Every effort in the way of injections of salt solution under the skin and other equally painful procedures as was customary in those days was being made to help him although the case must have been hopeless from the start. I handed him the consultation slip and again looking gravely at the sick man he wrote briefly on it and gave it back to me. "I should put no obstacle in the way of his peaceful departure," is what I read.

Dr Shattuck was always intensely interested in the health and welfare of those associated or working with him. Various times and indeed once in my own case he prescribed vacations for his house officers when even to think of such a thing was the rankest kind of heresy. Rules and regulations were all very well but they held no fear for him and at times were meant to be broken. One of the important duties of an assistant such as I, was to "camp" on certain very sick patients who could afford it and for whom it was felt that the constant attendance of a young doctor on the case in addition to the nurse might be helpful. For three or four days I had been on duty at the bedside of a very prominent man, an intimate and dear friend of my chief who was dying of pneumonia. It had been a constant but a losing battle trying in vain, by subcutaneous doses of morphia, digitalis or strychnia to carry him past the crisis. I had thrown myself into this case most intensely and had just about reached the breaking point myself when Dr Shattuck entered the room carrying a bundle done up in a newspaper. Looking at the patient and then at me, he beckoned toward the bathroom, a favorite consultation place for all doctors. Closing the door softly, he carefully unwrapped his package. "This Hawes is a bottle of Pol Roger, a favorite brand of your patient here. I think it will do him good."

Lovingly he undid the wire, uncorked the bottle and without saying a word took the bathroom glass, filled it to the brim with the champagne and handed it to me "Drink that," he said. Decidedly taken aback I murmured, "No, thank you, sir, not while I'm on duty here." At once he replied, "Hawes, you're working for me and I'm paying your salary. You'll be of no use to me if you break down. Do as I say." And I did. Other camping incidents had their lighter side especially when the patient got well. Once I spent five days and nights in the cellar of a famous Boston banking concern where one of the firm had been taken suddenly sick and could not be moved. In wandering around at night, for there was not much to do, I found a cupboard containing a set of massive silver-mounted hair brushes for each partner with the owner's name engraved—and very awe-inspiring names they were! I amused myself each morning using in turn the brushes of this or that well-known financier until finally my patient was taken home through an opening they made in the wall so that he could be carried out on the level! I learned a great deal about high finance while on duty on this case. Again, late one night when in evening clothes at a party of my own, Dr Shattuck sent me to a club in Boston where a Christmas celebration was being held at which a certain very delightful but somewhat frail old gentleman had collapsed, the cause of which I saw no reason to inquire. A holiday play was being given by the members and directly back of the stage was the bedroom where I found my patient sound asleep. There was high festival held that night with song and laughter accompanied by the popping of what seemed to me innumerable corks, all of which grew louder and louder, finally reaching a magnificent climax with voices not quite so clear and songs less steady, after which gradually the noise died down, leaving only a clatter of dishes as waiters cleared away and then silence. I had been very envious of those who had been having such a good time in front and quite bored with my somnolent patient and was glad when morning came when I took him to his home, both of us still in evening clothes.

Another time Dr Shattuck gave me the somewhat unenviable job of taking a well-known citizen with marked suicidal tendencies by train to a certain institution an hour's ride or so away from Boston. The parlor-car seats were all taken so we sat down together in a crowded day coach. I did not enjoy the trip. Once he tried to escape from me and to jump off the train and again in a very loud whisper he asked me, "Dr Hawes, do you really think I'm going insane?" At this a nice old lady seated directly in front of us got up hastily and scuttled into another car. I was quite relieved when I finally deposited him at the door of the

institution to which he was going. Not a pleasant task but good training.

Dr Shattuck's clinics and lectures were a delight to listen to. For the latest advances in science and the laboratory side of whatever subject he took up he depended on his assistant but the clinical aspect of the case was presented as none but a master could do it, based on years of thorough and thoughtful observation at the bedside of sick patients. A week or so before a given clinic on heart disease, for instance, the telephone would ring and I would hear his distinctive voice saying, "Hawes, I'm talking to the fourth year men on hearts next week. Look up all the latest work on the subject and let me have it, will you?" And up to the Medical Library I would go and wade through all the latest literature on the subject in English, French, German and sometimes Italian until I had collected for him what I knew he needed. Then it all had to be boiled down, typed out and handed in to him. When the time for the clinic came he would use this material as he saw fit but would invariably make it subservient to the clinical and human side of the problem. The comfort of the patient, whether sitting up in a wheel chair or lying in bed, was always his first consideration. No patient ever went back to the ward utterly exhausted and tired out as I have seen happen various times at clinics elsewhere. There was no perfunctory dealing with cold scientific facts. Always in his teaching he dealt with human beings who happened to have this or that disease and never with cases.

After the clinic came the hospital visit which was quite a ceremonial affair. Three or four house officers, senior, junior, "pup" and sometimes the externe, the head nurse, often some visiting physicians and always his assistant accompanied the doctor on his rounds, and—I nearly forgot—most important of all, there was Hans, a very elongated and rather pink dachshund, whom the patients loved to see. Always in some way or other, Dr Shattuck cheered up the ward when he entered it. There was a greeting for every patient and a fund of stories that seemed to fit each case, some proper and some not quite so but always very much to the point. Many times I have watched him regarding with great amusement the mounting blush on the nurse's face as he told one of his stories which was a bit off color, and likewise the smile that lit up the patient's face.

House officers came and went but year after year these visits of Dr Shattuck's continued and left an indelible impression on those of us who were lucky enough to be on his service. One of my cherished memories of this man happened late in his life shortly after I had moved into a little house in Brookline not far from Dr Shattuck's own home where he lived after he

had retired from active practice. A wonderful basket of peaches from his own trees was left at my door with a note, "I don't believe that your own trees have had a chance to grow yet so I am sending you some of my own." A little thing but characteristic of the man.

The science of medicine has made wonderful strides forward since the days of those men for whom I worked and knew so well, but the art of medicine which came from the heart as well as the brain as practiced by those men is rare if ever, equalled today.

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

FOUNDED BY RICHARD C CABOT, M.D.

TRACY B MALLORY, M.D., *Editor*

CASE 21441

PRESENTATION OF CASE

A ten months old baby girl was admitted because she had passed a bloody stool two weeks previously

The patient was born at full term. There were no convulsions or any other postnatal disturbances. The child was breast fed for two months and since then had been on an adequate diet. She had received cod liver oil and orange juice every day since the second month, and cereals and puréed vegetables since the sixth month.

Approximately two weeks before entry the patient passed a large dark red stool. Tarry stools were passed that day and the following day, but the feces were not increased in amount. Following this incident she became irritable, weak and appeared to lose her appetite. She became quite pale. There was no history of vomiting, diarrhea, foreign body ingestion or jaundice.

Physical examination showed a well-developed and nourished, extremely pale infant who was quiet and observant. The skin had a slight icteric tint. There were no purpuric spots seen on the skin or mucous membranes. There were no hemangiomas apparent. The mucous membranes were very pale. The lungs were negative. The heart was not enlarged, the sounds were strong and there was a loud blowing systolic murmur over the entire precordium. The abdomen was soft. The liver edge could be felt just below the costal margin. The spleen was palpable but not very large.

The temperature was 100.8°, the pulse 160. The respirations were 34.

Examination of the urine was negative. The blood showed a red cell count of 1,760,000, with a hemoglobin of 30 per cent. The white cell count was 14,950. A smear showed achromia and variation in the size and shape of the red blood cells. The bleeding time was normal. The clotting time by capillary tube method was normal. Six stool examinations showed strongly positive guaiac tests. The stools were fairly well formed and brownish in color. There was

little or no mucus present. No amebae could be found.

On the evening of admission she was given a transfusion of 150 cubic centimeters of citrated blood following which she showed marked improvement in spite of a mild transfusion reaction. Iron ammonium citrate 25 per cent, two drams twice a day, was given. On the third day she had a large formed stool, the center was gray and was surrounded by reddish black material. For the next two days the stools were tarry. Iron by mouth had been discontinued. Proctoscopic examination was negative. She was given another blood transfusion on the fourth day after her second hemorrhage. Her red blood cell count on the sixth day was 4,100,000, with a hemoglobin of 52 per cent. The white cell count was 29,500. The child at no time seemed to have acute pain. At times she seemed to be suffering from mild abdominal discomfort, to judge from her irritability and crying. She did not vomit while in the hospital. Her temperature was normal throughout the preoperative course in the hospital, except on admission and for a few hours following each of the two transfusions.

X-ray examination of the gastro-intestinal tract after a barium feeding was negative. A flat abdominal film was negative.

Approximately two weeks after entry, operation was performed.

DIFFERENTIAL DIAGNOSIS

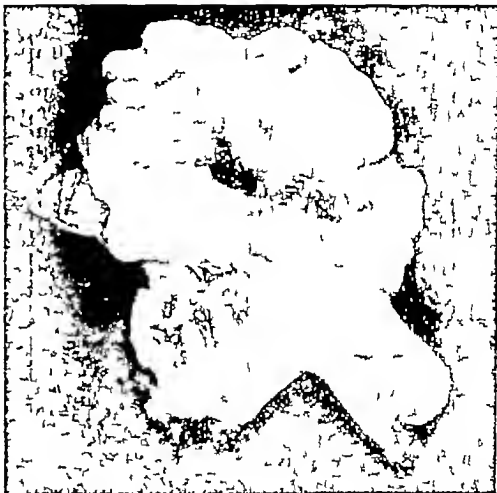

DR THOMAS H LANMAN* A discussion of bleeding by rectum in this age group must include a number of conditions. From the history and physical examination we can rule out anything of an inflammatory nature such as ulcerative colitis which is rare, although we have seen cases under a year in our hospital. I think that tuberculosis can also be ruled out. There is, also, the question of some blood disease—one of the purpuras. That again I think can be ruled out by the normal clotting and bleeding time, the absence of purpuric spots and also to some degree by the suddenness of the onset. Another cause would be polyps in the intestinal tract. These are commonly found in the region of the rectum and it is unusual for them to give evidence of such massive hemorrhage as this child has had, or to produce a red count as low as that, although we have seen cases of long duration in which the red count dropped pretty low. Intussusception high in the intestinal tract does occur, but is quite rare and also is quite unlikely to give signs of sudden and massive hemorrhage. A large amount of blood loss such as she had on the first occasion is against intussusception. She is in the age group when the so-called idiopathic type of intussusception occurs. In our cases of this type of intussusception about 90

*Associate Visiting Surgeon Children's Hospital Boston.

per cent occur under a year. A point against its being a polyp is the fact that the rectal type of bleeding is much more likely to result in blood on the outside of the stool rather than mixed with it. In intussusception it would be very unusual for her to have as massive hemorrhage as this without the clinical symptoms characteristic of acute intestinal obstruction. We do get subacute or chronic forms of intussusception in this age group, but here while bleeding does occur it is usually small in amount. Bleeding in the acute type is a result of marked interference with return of circulation. I do not believe you can get as much

cause I do not find any sign of peritonitis or of any obstruction. The discomfort that she complains of may be due to blood in the bowel itself. We have had cases where the blood was known to give a palpable mass. It is not uncommon for a Meckel's diverticulum to be the advancing point of an intussusception, but if intussusception were present in this case I should expect it to be incidental. I should expect to find a bleeding Meckel's diverticulum.

DR. HAROLD L. HIGGINS: We felt quite definitely that the blood was not coming from the large bowel because of the absence of mucus. We also were inclined to feel that the child

bleeding as this without pretty obvious signs of obstruction. It would be extremely unusual for intussusception to go on for the two weeks with that amount of hemorrhage and not have pretty obvious signs. The x-ray moreover is against it.

I think my guess would be that she probably bled from a Meckel's diverticulum. This occurs much more frequently than we formerly thought. We have seen a large number of cases in the past two years; the youngest two months of age, where bleeding by rectum was a presenting sign. In our series of forty-five Meckel's diverticula we have seen bleeding in seventy per cent of the cases, and in a great many of these the hemorrhage has been quite massive in amount. Recently we have found the red count below two million in a case where there was a perforation of an ulcer in a Meckel's diverticulum. I doubt if this case was perforated. The white cell count was 30,000, which might suggest diverticulitis associated with it. I doubt if there was perforation be-

cause I do not have a duodenal ulcer. Babies do get duodenal ulcers and I have seen several such cases. They usually are in undernourished children, and the bleeding is scant rather than profuse.

PREOPERATIVE DIAGNOSIS

Ulcer of Meckel's diverticulum

DR. THOMAS H. LAMMAN'S DIAGNOSIS

Bleeding from Meckel's diverticulum

PATHOLOGIC DIAGNOSIS

Ulcer of Meckel's diverticulum

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY: At operation a typical Meckel's diverticulum was found. The two clamps in the photograph are placed upon the ends of the resected segment of ileum and the short and rather fat diverticulum projects between them. The second picture shows the inside

of the diverticulum after it had been opened. The deeply punched-out linear ulcer is very evident and also the difference between the thick velvety mucosa lining the diverticulum and the thinner, glossier mucosa of the ileum can be distinguished. The reason for this difference in gross appearance became at once evident when the microscopic sections were examined. The mucosa in the diverticulum was very complicated in structure showing an irregular intermixture of gastric and upper intestinal types of epithelium, the latter, however, predominating. The ulcer could be easily shown to have formed in the areas of intestinal mucosa rather than of gastric.

This case is very typical of many that have been reported. When ulcers are present in Meckel's diverticulum gastric mucosa of the fundic type can always be found, but the ulcers occur in the neighboring islands of intestinal epithelium. The interpretation of the pathogenesis as true peptic ulcer formation from the erosive action of gastric secretion unneutralized by bile, pancreatic juice, the secretions of Brunner's or pyloric glands can hardly be questioned and the evidence presented by these cases has, of course, been used by Lindau* and others as a strong inferential argument for the theory of hypersecretion as the basis of ulcer formation in the stomach and especially the duodenum.

The ulcer in this case was histologically typical of the active stage of peptic ulcer as one sees it in either stomach or duodenum or in the jejunum following gastroenterostomy. The so-called "fibrinoid necrosis" a brilliantly eosinophilic hyaline layer at the base of the ulcer which Buchner has emphasized was particularly well marked. At its deepest point the ulcer had penetrated the muscularis and only a millimeter of slightly thickened serosa lay between the base of the ulcer and the peritoneal cavity.

DR LANMAN: When Dr Henry Hudson looked up our cases he found gastric mucosa in seventy per cent, which was quite striking to us. I suppose we must have missed a lot. They go into collapse with sometimes a very massive hemorrhage, like a gastric ulcer. I was interested in looking it up and found that frequently in the last two or three years the red cell count had been below three million.

DR HIGGINS: I referred to Abt's System of Pediatrics, published about 1927 and found there no mention of bleeding from a Meckel's diverticulum. The recognition of this condition is recent, certainly within the last fifteen years.

A PHYSICIAN: Is this condition ever seen in adults?

DR MALLORY: Yes, several have been reported by Lindau.

*Lindau, A. and Wolff, H. The peptic genesis of gastric and duodenal ulcer. Surg. Gyn. Obst. 53: 621 (Nov.) 1931.

CASE 21442

PRESENTATION OF CASE

A fifty year old white married American attorney entered complaining of pain in the left lower quadrant, and constipation.

Six years before entry he became ill with a vague aching pain in his left lower quadrant, localized for the most part midway between the left anterior superior iliac spine and the umbilicus. This was accompanied by loose watery stools. An x-ray at this time was reported as showing a large diverticulum which was causing obstruction. An operation was done following which there remained a fecal fistula. This healed spontaneously after about three months but one year later it reopened. Because of a suspected chest condition no surgical intervention was advocated. He was hospitalized, however, and with palliative care the fistula again healed. The suspicion of pulmonary disease was not confirmed. One and a half years later the patient went to his physician voluntarily for instruction in bowel management and a general check-up. Thereafter he remained quite well with only slight abdominal distress concomitant with upper respiratory infections. Four months before admission he again developed rather constant dull aching pain in the left lower quadrant, somewhat more severe than that of the initial episode. A protrusion of the operative scar appeared and gradually increased in size. Two months later he began to have pain in the region of the bladder and also in the right upper quadrant. This discomfort became progressively greater in intensity and particularly sharp just prior to bowel movement. One month previous to his entry he became nauseated and vomited everything ingested. This continued for two days and thereafter he remained well for three weeks, when he had another attack of vomiting which again persisted for two days. His bowel movements throughout his illness were irregular to the extent that he frequently went one or two days without going to stool. At times he had one or two scanty movements consisting of hard formed stools which were followed by a large soft formed stool. His appetite became quite poor during the last part of his illness. He had a great deal of flatus and complained of feeling "gurgling" in his abdomen.

At twenty years of age a septal operation was performed and five years later a double hemorrhaphy was done. He had "chronic bronchitis" for years which became much worse during the winter.

His father died at seventy-eight of prostate trouble. His mother died of liver disease at the age of fifty-five. One brother died of tuberculosis.

Physical examination showed a well-developed

and nourished middle-aged man who seemed to be quite comfortable. There was pyorrhea of the lower teeth and the upper teeth were absent. The heart and lungs were negative. The blood pressure was 130/80. In the left lower quadrant there was a small scar two centimeters in diameter which protruded so that a projecting mass about the size of a tennis ball was formed. This mass was very tender and loops of bowel were felt within it. The abdomen was held moderately rigid and tenderness was elicited generally with deep pressure. In the left lower quadrant only moderate pressure produced pain. The remainder of the examination was negative.

The temperature was 99.6°, the pulse 96. The respirations were 23.

Examination of the urine was negative. The specific gravity was 1.028. The blood showed a red cell count of 5,390,000, with a hemoglobin of 80 per cent. The white cell count was 18,900. The stools gave a positive reaction to the guaiac test. A Hinton test was negative. The non-protein nitrogen of the blood was 45 milligrams per cent.

The patient remained quite comfortable for the first few days in the hospital. On the fourth day he began to vomit everything ingested. The tenderness in the lower abdomen increased and the temperature rose to 101.5°. He improved somewhat after this but since a mass was then palpated in the region of the old operative scar a surgical approach was deemed advisable. One week after admission under gas and ether anesthesia a partial repair of the incisional hernia and incision and drainage of a peritoneal abscess were done. On the following morning the patient went into profound shock with a thready pulse of 160 and a blood pressure of 88/70. Despite intravenous injections and a whole blood transfusion the patient did not rally and died on the ninth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. HORACE K. SOWLES: "An x-ray was reported as showing a large diverticulum which was causing obstruction." That is what we might expect from the clinical symptoms.

We presume that operation was a laparotomy with drainage of an abscess or drainage of the inflamed area due to perforation of a diverticulum.

We have as yet no indication whether the protrusion of the operative scar was a hernia, or possibly a recurrence of an abscess, except that he did not give any story of increased temperature at that time.

Pain in the bladder of course is consistent with an inflammatory process in the pelvis. The pain in the right upper quadrant is not so easily explained except that it is well known that obstruction of the left colon often causes

extreme distention in the cecum and in the right colon.

"He had a great deal of flatus and complained of feeling 'gurgling' in his abdomen." I think that particular sort of complaint is pathognomonic of interference in the lumen of the intestinal tract. It is consistent with chronic obstruction.

The examination of the protruding mass in the left lower quadrant seems to rule out a superficial abscess since it contained loops of bowel.

Our findings still seem to point to an inflammatory process more in the pelvis and left lower quadrant but somewhat throughout the rest of the abdomen.

The temperature is not high, but the pulse is abnormally high and here we might bring out the point that the pulse in acute abdominal conditions or in intestinal obstruction is often a much better indicator of the patient's reaction or toxic condition than the temperature.

The white blood count is exceedingly high, which would seem to be evidence of inflammatory reaction.

Evidently it was felt now that it was necessary to drain what I assume to be an abscess. Of course we cannot rule out malignancy even though he had a diverticulitis six years ago. He may have continued to have an inflammatory process in his sigmoid since that time but we cannot absolutely rule out a malignant disease. He has had no gross bleeding although the guaiac test is positive at the present time.

Twenty-four hours is a little late for what we consider acute surgical shock. Rapid pulse and low blood pressure might suggest hemorrhage but it is hard to conceive of a massive hemorrhage from this condition. I should think it would be more apt to indicate a fulminating and acute peritonitis secondary to the drainage of the pelvic abscess.

Although we cannot rule out malignant disease I think this patient had a primary diverticulitis with intermittent intestinal obstruction and an inflammatory process in his pelvis, or that secondary to malignant disease he developed a pelvic abscess which was drained, and I should assume that as a result of the operative procedure he developed acute fulminating peritonitis which was the cause of his pronounced shock.

DR. TRACY B. MALLORY: Dr. McKittrick, will you tell us what you found at operation?

CLINICAL DISCUSSION

DR. LELAND S. MCKITTRICK: We assumed that he had a recurrence of an old diverticulitis. He had a perfectly definite hernia in the old scar with the palpable loops of bowel as described here, moderate obstruction clinically, and he had obviously a fairly extensive inflammatory process. We were disturbed about

the recurrence of what we assumed to be his diverticulitis in relation to his old hernia because that made it pretty complicated to get at. He quieted down pretty well at first but when he flared up again it seemed imperative that we drain what we assumed to be an abscess. We went in medially to the old scar, not because we wanted to but because that was the point where he persistently had his maximum tenderness. Posteriorly there was very little tenderness that one could make out. While the desire was to go in lateral to the scar and posteriorly, we went in medially because we could not overlook his maximum tenderness. That took us directly into the abdominal cavity. Why he had the tenderness there, I do not know. We had gone over him a number of times and it had persisted. The abdomen was then carefully walled off and a large abscess lateral to the old scar and pointing at its posterior margin was drained from behind. It was simply necessary to break the adhesions posterior to the hernia, where we drained a large abscess. Nothing else was done but approximate the wound to a slight degree and he was given what was considered to be ample drainage.

DR SOWLES: You did not do what was suggested here, a left hernia repair?

DR MCKITTRICK: No, to close the wound it was necessary to free the edges up a little bit.

CLINICAL DIAGNOSES

Diverticulitis of the sigmoid with abscess
Peritonitis?

DR HORACE K. SOWLES' DIAGNOSES

Diverticulitis with abscess or malignant disease with abscess
Acute peritonitis

ANATOMIC DIAGNOSES

Multiple diverticula of the descending colon and sigmoid
Acute diverticulitis
Peritonitis, acute, generalized
Pulmonary congestion and edema
Atelectasis, partial, lower lobes
Cyst of the right kidney, solitary, congenital
Abscess, left flank
Operative incisions Exploratory laparotomy, incision and drainage of flank abscess
Operative scar Bilateral hernioplasty

Arteriosclerosis, aortic, moderate
Perisplenitis

PATHOLOGIC DISCUSSION

DR TRACY B. MALLORY: What was found at postmortem was a very extensive diverticulosis of the descending colon and sigmoid. The great majority of the diverticula were entirely free from any inflammatory change, but in a localized zone at just the upper end of the sigmoid there were numerous obviously inflamed diverticula on all sides of the gut. The omentum had become firmly adherent to the exposed peritoneal surfaces of some of these and this mass of thickened omentum about the large bowel formed a pretty considerable tumor mass in the left lower quadrant.

I presume the point of tenderness overlay one of these diverticula which had been successfully walled off by the omentum. Another diverticulum on the posterior surface had actually perforated and a frank abscess was found in the retroperitoneal tissues, into which led the drain which Dr McKittrick had inserted. We found a very slight but diffuse general peritonitis. All of the serosal surfaces were reddened and covered with a very thin film of fibrin. There was nothing else that could account anatomically for death, so I am inclined to agree with Dr Sowles' assumption that a very acute peritonitis was probably the most significant immediate factor at death. It would not be possible anatomically, of course, to rule out an element of shock.

A PHYSICIAN: When the first exploratory incision was made was the possibility considered of closing that and making a second incision laterally?

DR MCKITTRICK: Because of the hernia the wound could not be closed without freeing the bowel and omentum laterally and thus brought us into the abscess.

DR SOWLES: I should like to ask if he had anything to account for the right-sided pain?

DR MCKITTRICK: No, I was not over on the right side at all.

A PHYSICIAN: Is it possible to drain them by a retroperitoneal operation rather than opening the peritoneal cavity?

DR MCKITTRICK: Yes. I think frequently you can get in from behind but you have to have some lead. You cannot go in unless there is tenderness or something there that would lead you to make that incision.

STERILIZATION AND THE PSYCHOSES

The rapid increase of mental disease in this country has been the subject of many recent articles. It has been stated that the birth rate of people with subnormal intellects is so much greater than that of normal people that racial degeneration is inevitable. One way of solving this problem is to sterilize the unfit. Is such a procedure to be advised?

This question has been studied by a committee appointed in May 1934 by the American Neurological Association, assisted by a grant from the Carnegie Foundation. The committee, consisting of Doctor Abraham Myerson, Chairman, Doctors J. B. Ayer, Tracy J. Putnam, Clyde E. Keeler and Leo Alexander, has recently published a preliminary report. The conclusions are at such variance with the popular ideas on this subject that they deserve careful consideration.

The committee states, to begin with, that there is no valid evidence that mental disease

and mental defects are on the increase. Commitment to hospitals and asylums is increasing, but this, as the committee points out, is a factor which operates against propagation. The mentally sick, diseased and defective show less tendency to marry and among those who do marry the birth rate is low.

The contributions bearing on heredity made by the study of genetics do not support the contentions of the eugenicists for research has shown, according to Riddle, that "the specific conditions under which a gene or factor operates and develops have an equal value with the germinal factors in the appearance of anything that can be called heredity. Heredity is controlled whenever and wherever an aspect of development is controlled." The committee goes on to state "Its whole thesis, which seems to us to be extremely pertinent to the problems of psychiatry, is that by manipulating both the external environment and the internal environment of the individual, first, the characters of the individual may be altered from their otherwise normal hereditary pattern, more importantly, that there is work to show that the germplasm itself may be modified."

Only two psychoses have a hereditary significance—manic-depressive and dementia praecox. Of the two, the former is more definitely hereditary. Factors of heredity exist in feeble-mindedness but it is not a simple recessive Mendelian character.

Interesting experiments have been carried out as to the relative values of heredity and environment in relation to intelligence. Some of these experiments, summarized in the committee's report, appear to prove quite conclusively that environment especially in the early years of life plays an important part in the development of the child's intelligence.

As regards the inheritability of epilepsy, the committee accepts the statement that epilepsy occurs more frequently in the descendants of epileptics than in the descendants of non-epileptics, but does not believe that there is any single recessive Mendelian character which can explain its incidence.

The committee comments favorably on Lange-Eichbaum's study of genius and heredity. "Enough evidence is adduced to indicate that sterilization might readily cut off from the race some of its most valued and valuable members." Concerning the inheritance of criminal tendencies most writers agree that while there may be a constitution, the effort to breed it out by any eugenic measures is in the present state of our knowledge not to be recommended.

In concluding its study of sterilization, the committee expresses its views as follows:

"First Our knowledge of human genetics

has not the precision nor amplitude which would warrant the sterilization of people *who themselves are normal* in order to prevent the appearance, in their descendants, of manic-depressive psychosis, dementia praecox, feeble-mindedness, epilepsy, criminal conduct or any of the conditions which we have had under consideration. An exception may exist in the case of normal parents of one or more children suffering from certain familial diseases, such as Tay-Sachs amaurotic idiocy.

Secondly Particularly do we wish to emphasize that there is at present no sound scientific basis for sterilization on account of immorality or character defect.

Thirdly Nothing in the acceptance of heredity as a factor in the genesis of any condition considered by this report excludes the environmental agencies of life as equally potent and, in many instances, as even more effective."

As a result of these conclusions, the committee recommends that any law concerning sterilization passed in the United States under the present state of knowledge should be voluntary and regulatory rather than compulsory, and should apply to patients in private institutions and at large as well as to those in State institutions. Other recommendations are made concerning the machinery for administering sterilization laws, after which the committee states that it can recommend sterilization only in selected cases of certain diseases and with the consent of the patient or of those responsible for him. These diseases, arranged in the order in which sterilization would appear to be indicated, are as follows:

"(1) Huntington's chorea, hereditary optic atrophy, familial cases of Friedreich's ataxia, and certain other disabling degenerative diseases recognized to be hereditary

- (2) Feeble-mindedness of familial type
- (3) Dementia Praecox (schizophrenia)
- (4) Manic-depressive psychosis
- (5) Epilepsy"

The report emphasizes the need for further research along this line, and recommends the appointment of a permanent committee for this purpose. The concluding paragraph summarizes the views of the committee on the present status of sterilization:

"Furthermore, it is to be emphasized that no great or radical change in the complexion of society can be expected from any such sterilization program as we recommend, nor from any justifiable legislation. We do not believe that society needs to hurry into a program based on fear and propaganda. Although the problem of mental disease and defectiveness is enormous, there is no new social or biological emergency."

NUTRITION AND DEPRESSION

A STUDY of 5,000 city children between the ages of six and nine years, made during five years of depression by the United States Public Health Service, shows that the weight of those from depression-poor families has inclined definitely downward.

These children were divided into three groups: those whose families had remained in comfortable economic circumstances, those whose families remained poor, and those whose families, originally comfortable in 1929, had become poor during the depression. The relative weight line for the first group remained approximately level; the line for the second group inclined definitely downward, and the line for the third group inclined somewhat upward—which reminds one of the old saying that God takes care of the poor and the rich take care of themselves.

THIS WEEK'S ISSUE

CONTAINS articles by the following named authors:

DAYTON, NEIL A. M.D. Ohio State University College of Homeopathic Medicine 1915. Director, Division of Mental Deficiency, Division of Statistics, Rockefeller Research Project in Mental Diseases and Defect, Massachusetts Department of Mental Diseases. Instructor in Psychiatry, Tufts College Medical School. His subject is "A New Method of Calculating Discharge Rates in Mental Diseases with Special Consideration of the Age Factor." Page 841. Address: Room 167, State House, Boston, Mass.

GOLDWATER, LEONARD J. A.B., M.D. New York University, University and Bellevue Hospital Medical College 1928. Instructor in Medicine, New York University College of Medicine. Clinical Assistant Visiting Physician, Third (N.Y.U.) Medical Division, Bellevue Hospital. Director, Student Health Service, New York University College of Medicine. Address: 53 East 82nd Street, New York City. Associated with him is:

STEINBERG, ISRAEL. A.B., M.D. Harvard University Medical School 1928. Assistant Visiting Physician, Third (N.Y.U.) Medical Division, Bellevue Hospital. Instructor in Medicine, New York University College of Medicine. Address: 103 East 84th Street, New York City. And:

MOST, HARRY. B.S., M.D. New York University, University and Bellevue Hospital Medical College 1931. Clinical Assistant Visiting Physician, Third (N.Y.U.) Medical Division, Bellevue Hospital. Assistant in Medicine, New York University College of Medicine. Address: London School of Tropical Medicine, Keppel Street, London, W.C.1 England. And:

CONNERY, JOSEPH E. M.D. New York University, University and Bellevue Hospital Medical College 1914. Associate Professor of Clinical Pathology, New York University College of Medicine. Visiting Physician, Third (N.Y.U.) Medical Division, Bellevue Hospital. Address 75 East 55th Street, New York City. Their subject is "Hemoptysis in Trichinosis." Page 849

KING M. K. M.D. Medical College of Virginia 1930. Passed Assistant Surgeon, United States Public Health Service. In charge of Surgical Service, United States Marine Hospital, Savannah, Georgia. His subject is "Uncinariasis and Appendicitis." Page 851. Address: United States Marine Hospital, Savannah, Ga.

COGAN, DAVID G. A.B., M.D. Harvard University Medical School 1932. Clinical Assistant in Ophthalmology, Massachusetts Eye and Ear Infirmary. Assistant in Ophthalmology, Harvard University Medical School. Address 61 Phillips Street, Boston, Mass. Associated with him is

COGAN, FRANCES C. A.B., M.D. Johns Hopkins University School of Medicine, 1934. Address 81 Phillips Street, Boston, Mass. Their subject is "Cataracts and Dimetrophenol." Page 854

WEITAKER, LESTER R. M.D. Harvard University Medical School 1923. F.A.C.S. First Assistant Visiting Surgeon, Massachusetts Memorial Hospitals, Boston. Associate Member Evans Memorial for Clinical Research and Preventive Medicine. Instructor in Surgery, Boston University School of Medicine. His subject is "Electrosurgical Appendectomy." Page 856. Address 41 Bay State Road, Boston, Mass.

FRENCH, RALPH W. A.B. M.D. Harvard University Medical School 1910. F.A.C.S. Surgeon, Truesdale Hospital, Fall River, Mass. His subject is "Primary Abscess of the Omentum." Page 857. Address 151 Rock Street, Fall River, Mass.

ATCHLEY, DANA W. S.B., M.D. Johns Hopkins University School of Medicine 1915. Associate Professor of Medicine, Columbia University College of Physicians and Surgeons. Associate Visiting Physician, Presbyterian Hospital, New York City. His subject is "The Role of Peripheral Circulatory Failure in Clinical Medicine." Page 861. Address: Presbyterian Hospital, 620 West 168th Street, New York City.

GALDSTON, IAGO B.S., M.D. Fordham University School of Medicine 1921. Secretary, Medical Information Bureau, New York Academy of Medicine. Consultant in Health Education, National Tuberculosis Association. His

subject is "The Economic and Social Aspects of Socialized Medicine." Page 868. Address 2 East 103rd Street, New York City.

HAWES, JOHN B., 2ND. A.B., M.D. Harvard University Medical School 1903. Formerly, Assistant Visiting Physician, Massachusetts General Hospital, Director, Pulmonary Clinic and Non Pulmonary Clinic, Massachusetts General Hospital, Consultant, Diseases of the Lungs, New England District, United States Veterans Bureau, and Secretary, Massachusetts Tuberculosis Commission. Now, President, Boston Tuberculosis Association, Director, Massachusetts Tuberculosis League, Rutland Cottage Sanatorium and National Tuberculosis Association. Consultant, Beth Israel Hospital, Jordan Hospital, Plymouth, and Henry Heywood Memorial Hospital. His subject is "Memories of a Great Physician, Dr. Frederick C. Shattuck, of Boston." Page 873. Address 330 Dartmouth Street, Boston, Mass.

SECTION OF OBSTETRICS AND GYNECOLOGY*

C. J. KIRKHAM, M.D., Chairman 524 Commonwealth Ave., Boston, Mass.	R. S. TITUS, M.D., Secretary 473 Commonwealth Ave., Boston, Mass.
---	--

THE TREATMENT OF VOMITING OF PREGNANCY

There is probably an underlying physiologic disturbance as a basis for all vomiting of pregnancy, although the importance of superimposed psychic disturbances in many cases is not to be denied. So-called "toxic" vomiting probably does not differ from "non toxic" vomiting except as regards the severity and persistence of emesis. The pathology of the disease may be adequately accounted for on the basis of starvation alone, provided one includes deficiency of vitamins with the water, mineral, and other food deficiencies of starvation.

For the purpose of outlining treatment, patients who vomit may be arbitrarily divided into three groups as follows:

I "Physiologic" vomiting

The nausea and morning vomiting which frequently occur for a few weeks after the first missed period require no especial treatment other than reassurance, mild doses of sedatives in apprehensive patients, and the suggestion that the patient take a glass of milk or cup of coffee some twenty minutes before arising in the morning.

A series of short selected articles by members of the Section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the Section.

II *Mild Hyperemesis* includes patients who persistently vomit a significant portion of the normal food and fluid intake. However, they retain enough food so that clinical dehydration, marked weight loss, and acidosis (i.e., persistent acetone and diacetic acid in the urine) are absent.

In the treatment of these patients, intelligent management of the frequent causes of psychic disturbances in the home is often an important factor. Disturbing elements in the environment should be removed when possible. It is advantageous temporarily to dispose of "helpful" friends and relatives. Excitement should be avoided, and the mind occupied with matters other than the vomiting. Moderate doses of barbiturates (i.e., phenobarbital gr $\frac{3}{4}$ to $1\frac{1}{2}$ B.I.D.) aid in the control of nervousness and seem to allay nausea. The bowels should be kept open with mild catharsis or enemata. The nausea often seems to be brought on or aggravated by hunger, hence six small meals daily instead of the three usual ones are helpful. The elimination of fats from the diet temporarily is also helpful. The diet should be easily digestible, rich in vitamins and minerals, as well as adequate in carbohydrate and protein. Empirically, many patients seem to improve after liberal doses of vitamin B complex. Coated tablets of Brewer's yeast concentrate are made by several pharmaceutical houses.

Most patients will respond to these measures. Those who do not improve promptly should be watched daily for signs of dehydration and acidosis.

III *Severe Hyperemesis*

This group includes patients who retain less than half of the normal diet and show marked weight loss, dehydration and acidosis. Mild cases of patients who vomit but who fail to respond to a few days' treatment as outlined above, and those whose vomiting is severe when first seen should be removed to a hospital.

On admission the patient should be isolated, and no visitors allowed until vomiting has been controlled. She should be left alone except for strictly necessary visits of physician and nurse. No emesis basin or equipment reminiscent of vomiting should be visible. The T.P.R. should be recorded every four hours, and the twenty-four hour urine volume measured. Admission and daily urine specimens should be examined routinely, particular attention being given to testing for acetone, diacetic acid and bile.

The initial physical examination should include careful inspection of the mouth for sore tongue and search for evidence of peripheral neuritis, findings which suggest vitamin B complex deficiency.

On admission the patient should have an enema following which a liberal dose of a bar-

biturate may be given by rectum (i.e., pentobarbital gr iv ss). The deficient water, salt and carbohydrate should be corrected immediately by hypodermoclysis of normal saline (2000-3000 cc) and 10 per cent glucose solution, 500 cc given slowly intravenously. Rectal taps sometimes aggravate nausea and vomiting. Saline clyses and intravenous glucose are repeated at frequent intervals in sufficient quantities to maintain a daily urine volume of over 1200 cc free of acetone and diacetic acid. The pentobarbital is repeated in 3 grain doses at intervals of six to twelve hours. Nothing is offered the patient by mouth until vomiting has ceased for eighteen to twenty-four hours. She is then given fluids hourly, such as milk, ounces VI, orange juice ounces VI, and water ounces VI alternating for fourteen hours of the day. When the hourly fluids have been taken for two days without significant vomiting, the patient is offered frequent small meals of attractive easily digestible solid food. A daily bowel movement is important throughout treatment, and should be secured if necessary by enema.

An occasional patient will continue to vomit in spite of this régime. The responsibility for such patients, as well as for those whose condition is poor when first seen, should be shared with a competent obstetrician before the condition becomes desperate. Of particular significance in evaluating the state of affairs are the following signs: persistent pulse of 110 or over, persistence of acidosis, the appearance of bile in the urine, early signs of peripheral neuritis, mental confusion, and other peculiarities of behavior.

If by any means, a well-balanced nutritious diet with large doses of vitamin B complex can be given to such patients, therapeutic abortion is seldom indicated. Feedings through the duodenal tube by constant drip of a liquid diet reinforced with large doses of vitamin B complex have been successful in a group of such patients in whom other methods had failed. A Levine tube is passed through the nose after liberal sedation with a barbiturate, and manipulated into the duodenum if possible. The stomach is washed with dilute bicarbonate solution and a liquid diet is fed at body temperature through the tube by drip. Feedings are given hourly for twelve hours daily and the rate of the drip is regulated so that each feeding runs in in thirty minutes. The diet consists of milk ounces IV with a heaping teaspoon of Brewer's yeast concentrate (Harris), orange juice ounces IV sweetened with corn syrup, and eggnog ounces IV, alternating for twelve hours daily. The tube is withdrawn an hour after the last feeding, to be replaced the following morning. A small amount of the feeding is sometimes regurgitated at first but all patients as yet so treated have retained the bulk of the food. Feedings are continued through

the tube from two to five days depending upon the severity of the condition

However, if a patient is encountered who is refractory to all measures, and therapeutic abortion is considered, it is important to get obstetrical consultation before the condition is desperate. Of patients who have progressed to the point of persistent rapid pulse, mental aberration or signs of peripheral neuritis the mortality is high regardless of whether therapeutic abortion is performed

It is advisable in the after care of severe vomiters to give a rich source of vitamin B complex in addition to a well balanced low vitamin diet for some weeks after vomiting has ceased. Also, although hemoglobin and red blood cell estimations are high during the vomiting due to blood concentration many of these patients on recovery have a relatively severe secondary anemia for which the exhibition of iron is beneficial

THIRD ANNUAL POSTGRADUATE MEDICAL EXTENSION COURSE

The following sessions have been arranged by the Committee for the week beginning November 3

Barnstable

Sunday November 3, at 4 00 P.M. at the Cape Cod Hospital Hyannis. Subject Lung Diseases (a) Differential Diagnosis and Treatment of Lobar Pneumonia. (b) The Surgical Problems of Empyema. Instructors J H Pratt and J W Strieder J L B Vail Chairman

Bristol South (Fall River Section)

Monday November 4 at 4 00 P.M., at the Stevens Clinic of the Union Hospital Prospect Street, Fall River Subject Pediatrics The Neonatal State and Its Diseases Medical and Surgical Aspects Instructors W R Sisson and P J Mahoney Eugene A. McCarthy Chairman

Essex North

Friday November 8 at 4 00 P.M., at the Hotel Bartlett 95 Main Street, Haverhill Subject Neurological Aids in the Diagnosis and Treatment of Disease from the Medical Viewpoint. Problems of History and Examination with Special Reference to (a) Neurosyphilis Multiple Sclerosis and Other Degenerative Conditions. (b) Diseases with Acute Onset, such as Meningitis and Cerebral Accidents Instructor J B Ayer Francis W Anthony Chairman

Essex South

Tuesday November 5 at 4 00 P.M. in the Nurses Home of the Salem Hospital Salem. Subject Immunology Latest Developments in Immunization Smallpox Typhoid Measles,

Scarlet Fever Diphtheria, Whooping Cough and Infantile Paralysis Instructor R F Feemster Walter G Philppen Chairman.

Hampden

Thursday November 7 at 4 00 P.M., at the Academy of Medicine, Professional Building 20 Maple Street, Springfield, and at 8 00 P.M. at the Holyoke City Hospital Holyoke. Subject Cancer of Breast and Uterus Sarcomas of Bone Lymphoma and Leukemia, Their Early Diagnosis Discussion of Life History of Cancer and Grades of Malignancy Instructors E M Daland and G G Smith. George L Sebald and George D Henderson Chairmen.

Hampshire

Wednesday November 6 at 4 15 P.M., in the Nurses Home of the Cooley Dickinson Hospital Northampton Subject Immunology Latest Developments in Immunization Smallpox, Typhoid Measles, Scarlet Fever Diphtheria, Whooping Cough, and Infantile Paralysis Instructor W W Lee Robert B. Brigham Chairman

Middlesex East

Wednesday November 6 at 4 00 P.M. at the Melrose Hospital Melrose. Subject Psychiatry Management of Psychic States in the Care of General Diseases, Especially Chronic Disorders Subpsychotic States. Instructors G C Caner and Maurice Fremont-Smith. Joseph H Fay Chairman

Middlesex South

Tuesday November 5 at 4 15 P.M. at the Cambridge Hospital, Cambridge. Subject Kidney and Bladder Diseases, A (Surgical) Hematuria Its Significance in Surgical Diseases of Kidney and Bladder Instructor F H Colby Edmund H. Robbins Chairman

Norfolk South

Monday November 4 at 8 30 P.M. at the Quincy City Hospital Quincy Subject Pediatrics Abdominal Disease in Childhood Medical and Surgical Aspects Instructors P H Sylvester and H W Hudson Jr David L. Belding Chairman.

Plymouth

Tuesday November 5 at 4 00 P.M. at the Brockton Hospital Brockton. Subject Pediatrics Abdominal Disease in Childhood Medical and Surgical Aspects. Instructors J L Morse and W E. Ladd W H Pulsifer Chairmen

Worcester North

Friday November 8, at 4 30 P.M. at the Burbank Hospital Fitchburg Subject Kidney and Bladder Diseases. B (Surgical) Prostatism and Related Diseases. Cystitis and Pyelitis. Instructor B C Wheeler Edward A. Adams, Chairman.

 Lewis C. Donahue 3 Marshall Street, Needham Mass

NOTICES

LECTURES BY DR. S J THANNHAUSER

Dr S J Thannhauser formerly Professor of Medicine and Director of the Clinic of the University of Freiburg, Germany is giving a course of clinical lectures on Saturday mornings at 9 A M at the Boston Dispensary The subjects for November are as follows

November 2—Diabetes
 November 9—Diabetes.
 November 16—Liver Disease
 November 23—Peptic Ulcer

Practitioners in any part of New England are cordially invited. This course is made possible by a grant from the Bingham Associates Fund for the Advancement of Rural Medicine.

MEDICAL CLINIC AND STAFF ROUNDS AT THE PETER BENT BRIGHAM HOSPITAL

At 3 30 P.M. on Thursday November 7 in the amphitheater of the Peter Bent Brigham Hospital, Dr Henry A. Christian, Physician-in-Chief, Hersey Professor of the Theory and Practice of Physic in the Harvard Medical School, will give a medical clinic. To it are cordially invited practitioners and medical students

On Saturdays in the wards of the Peter Bent Brigham Hospital from 10 to 12 staff rounds will be conducted by Dr Christian.

HARVARD MEDICAL SCHOOL COLLOQUIUM

Luncheon meetings of the Harvard Medical School Colloquium will be held again this year in the Bowditch Room of Vanderbilt Hall on Thursdays at 1 P.M. These meetings are for the purpose of bringing medical students and teachers into closer con-

tact with their own several departments and also with the University as a whole The meetings in November will be as follows

November 7—Studies of the Circulation of Pregnant Women Dean C S Burwell

November 14—The Ethiopian Situation Dr C S Coon

November 21—Where Medicine is Going Assistant Professor D V Brown

MASSACHUSETTS DEPARTMENT OF EDUCATION

UNIVERSITY EXTENSION COURSE

Mental Hygiene for Adults

Gardner Auditorium, State House, Boston

This course offers an unusual opportunity to hear outstanding leaders in the mental hygiene movement discuss in simple nontechnical language principles and mechanisms of mind that control our everyday lives Rich in stimulating suggestions and valuable advice for better and wiser living, these lectures appeal universally All, regardless of age, position, financial standing, or education, will be interested in the personal applications of these lectures The course will be particularly suggestive for nurses, teachers, social workers, doctors and parents,—those directly responsible for the welfare of others

The course is offered in cooperation with the Massachusetts Society for Mental Hygiene It may be taken either (1) as a series of lectures which entails no class work but simply attendance at meetings, or (2) as a credit course which requires class work, collateral reading, and a final examination Certificates will be awarded by the Massachusetts Department of Education to those who complete the requirements for the credit course

PROGRAM

Course Leader

Henry B Elkind, M D, Medical Director,
Massachusetts Society for Mental Hygiene

November 5 Keeping Mentally Fit—Joseph Jastrow, Ph D, formerly Professor of Psychology, University of Wisconsin.

November 12 The Management of Disease in Childhood in Relation to Mental Health — Bronson Crothers, M D, Assistant Professor of Pediatrics, Harvard Medical School

November 19 The Child and the Modern World—Lawson G Lowrey, M D, Director, Institute for Child Guidance, New York City

December 3 How Psychiatry Can Aid in Meeting Problems of Modern Life—Donald Gregg, M D, President, Massachusetts Society for Mental Hygiene

December 10 Current Ethical Trends — James J Walsh, M D, Professor of Physiological Psychology, Cathedral College, and Extension Lecturer, Fordham University, New York

December 17 Adult Problems "The Blues" and Fatigue States—Karl M Bowman, M D, Associate Professor of Psychiatry, Harvard Medical School

January 7 Psychoanalysis and Mental Health—Jacob Kasanin, M D, Clinical Director, State Hospital for Mental Diseases, Howard, R I

January 14 Adults in Difficulty — A. Warren Stearns, M D, Dean, Tufts College Medical School

Register now

This class will meet weekly on Tuesday evenings at 7 45 P M, beginning November 5, 1935 Enrollment may be made at the University Extension Office, Room 217, State House, or at the first meeting of the class Charge \$4 for auditors, \$6 for credit students, text material extra

NOTICES OF MEETINGS

BOSTON UNIVERSITY SCHOOL OF MEDICINE SURGICAL CLINIC AT THE BOSTON CITY HOSPITAL

Friday, November 1, 12-1, Cheever Amphitheatre
Dr Irving J Walker, Clinical Professor of Surgery, Harvard Medical School, will talk on "Jaundice"
Physicians and medical students are invited

Friday, November 8, 12 1, Cheever Amphitheatre
Dr William R Morrison, Associate Professor of Surgery, Boston University School of Medicine, will present the following cases

- 1 Ileosigmoidostomy
- 2 Resection of Stomach for Adenocarcinoma,
Using Von Petz Sewing Clamps
- 3 Femoral Hernia

Physicians and medical students are invited

BOSTON DISPENSARY

ASSEMBLY HALL, 25 BENNET STREET

Medical Conference Program

9 10 A M, November, 1935

November 1, Friday—Ward Cases Dr S J Thannhauser

November 2, Saturday—Diabetes Dr S J Thannhauser

November 4, Monday—Nephritic Clinic Dr R W Buck

November 5, Tuesday—"Diagnosis of Spinal Conditions" Dr J D Adams

November 6, Wednesday—Ward Cases Dr S J Thannhauser

November 7, Thursday—"Revision of Interpretation of Laboratory Tests for Syphilis" (Continued)
Dr W A Hinton

November 8, Friday—Ward Cases Dr S J Thannhauser

November 9, Saturday—Diabetes (Continued) Dr S J Thannhauser

- November 12, Tuesday—Report on the Results of Short Wave Therapy in the Past Year Dr P Hoefler
- November 13 Wednesday—Ward Cases Dr S J Thannhauser
- November 14 Thursday—Recent Observations on the Functional Properties of the Vascular System and on the Hemodynamics in Arterial Hypertension Dr Soma Weiss
- November 15 Friday—Ward Cases Dr S J Thannhauser
- November 16 Saturday—Liver Disease Dr S J Thannhauser
- November 18 Monday—Blood Clinic. Dr William Dameshek.
- November 19 Tuesday—Back Strain—Sciatic Dr P R Ober
- November 20 Wednesday—Ward Cases Dr S J Thannhauser
- November 21 Thursday—"Interviewing a Patient" Prof Elton Mayo
- November 22, Friday—Ward Cases Dr S J Thannhauser
- November 23 Saturday—Liver Disease (Continued) Dr S J Thannhauser
- November 25 Monday—Heart Clinic Dr S H Proger and Mrs O Janeway
- November 26 Tuesday—X Ray Demonstration Dr A. Ettinger
- November 27 Wednesday—Ward Cases Dr S J Thannhauser
- November 29 Friday—Ward Cases Dr S J Thannhauser
- November 30 Saturday—Peptic Ulcer Dr S J Thannhauser

HARVARD MEDICAL SCHOOL

THE GEORGE W GAY LECTURE ON MEDICAL ETHICS
Amphitheatre C at 5 P.M.
Thursday November 7—Dr James B Herrick of Chicago

LECTURES ON "THE CARE OF THE PATIENT"

Amphitheatre C at 5 P.M.
Thursday November 14—Dr Arthur R. Crandell of Taunton.
Thursday November 21—Dr David D Scannell of Boston.

FAULKNER HOSPITAL CLINICAL MEETING

The next clinical meeting at the Faulkner Hospital will be held on Thursday November 7 at 5 00 P.M. In addition to the usual clinical pathological conference Dr Chester M Jones will talk on "Enteritis Symptomatology and Diagnosis". All physicians are invited.

ESSEX SOUTH DISTRICT MEDICAL SOCIETY

The regular meeting of the Essex South District Medical Society will be held Wednesday November 6 1935 at the Beverly Hospital
Clinic at 5 P.M. Dinner at 7 P.M.

Speaker Dr Charles E Mongan of Somerville President of the Massachusetts Medical Society who will talk on "Matters of Interest to the Medical Profession."

HATFORD CARVILL, M.D., *President*
R. E. STONE, M.D. *Secretary*

BARNSTABLE DISTRICT MEDICAL SOCIETY

THURSDAY NOVEMBER 7 1935

Business Dinner 12 30 at Bill Cox's Sea Grill Hyannis Park.

Scientific Meeting 2-4 P.M. at Cape Cod Hospital
Dr Henry Pinkerton—Results of Tumor Research at Falmouth Institute

Mr Walter Hughes—The Sex Factor in Cancer
Dr Samuel M Beale—Clinical Experiences

Discussion opened by Dr Shields Warren.

J L B VAIL, M.D., *Secretary*

WILLIAM HARVEY SOCIETY

The next meeting of the William Harvey Society will be held Friday November 8 in the Auditorium of the Beth Israel Hospital Boston at 8 00 P.M.

PROGRAM

Speaker Dr Harold E. B. Pardee Assistant Professor of Clinical Medicine, Cornell University Medical School.

Subject "Arteriosclerotic Heart Disease."

Chairman Dr Cadis Phipps, Professor of Medicine Tufts College Medical School

THE ATLANTIC DERMATOLOGICAL CONFERENCE

This meeting will be held in Boston, Mass. Saturday November 9 1935

Clinical Meeting at the Boston City Hospital

1 30 P.M. Luncheon at the Boston City Hospital in complement to the conference by the Board of Trustees

2 15 P.M. Demonstration of 30 cases

4 00 P.M. Discussion of the cases with complete freedom of thought guaranteed under the Constitution of the Conference which is revered by all has been preserved by none

Dinner at the Hotel Keamore 490 Commonwealth Avenue

7 00 P.M. "Be large in mirth when we'll drink a measure the table round" Macbeth III 4

7 30 P.M. Sit down and feed and welcome to our table As You Like It, II 7

Newell Bent, Jr., Explorer Naturalist and Photographer will show motion pictures and chat of his trip which he made alone from Cape Town to Cairo. He climbed the snow-capped volcano Kilimanjaro he hunted big game with his camera and he consorted at times with cannibals

The conference is limited strictly to its members.

J HARMON BLAIRDELL, M.D., *Secretary*

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held in the Peter Bent Brigham Hospital Amphitheatre (Shattuck Street Entrance), Tuesday evening, November 12, at 8 15 P M

PROGRAM

Presentation of Cases

Recent Studies in Yellow Fever—A Virus Disease
By Dr Frederick F Russell, Lecturer in Preventive Medicine and Hygiene, Harvard Medical School

NUMBER 19

THE MODERN TREATMENT OF CRANIOCEREBRAL INJURIES WITH ESPECIAL REFERENCE TO THE MAXIMUM PERMISSIBLE MORTALITY AND MORBIDITY*

BY DONALD MUNRO, M.D.†

INTRODUCTION Ever since John Abernethy¹ protested 125 years ago against the "propriety and necessity of trephining the cranium under various circumstances consequent upon injuries of the head" as then advocated by "the members of the Academy of Surgery in France and Mr Pott in England" the treatment of craniocerebral injuries has been under dispute. At that time the pathological background was provided by the terms "concussion" or "commotio cerebri," "contusion" and "compression." These were still the diagnostic criteria 100 years later² at which time operation in the form of a subtemporal decompression was again the therapy of choice. A major step in the comprehension of the physiology involved had been taken, however, by virtue of Cushing's completion of Koerber's work³. This led directly to the division of the old stage of "compression" into four parts and a demonstration of the fact that the symptoms produced at that time were caused by varying degrees of failure of the cerebral circulation⁴. Treatment, aside from the subtemporal decompression still included venesection. Lumbar puncture though new and therefore dangerous was being mentioned. Compound and depressed fractures and meningeal hemorrhage were then and had been for fifty years legitimate excuses for operative interferences⁵.

After the World War this further and final steps elucidating the physiology of the cerebrospinal fluid were taken by Weed⁶ and Dandy⁷. These led directly to the introduction of a new method of treatment, dehydration⁸, and the renewal of interest in and finally the adoption of an older one, lumbar puncture⁹.^{11, 12} This subtemporal decompression was reserved for use in those cases whose intracranial pressure could not be lowered by repeated lumbar punctures and the other old indications for operative interference were confirmed^{13, 14}. The pathological rather than the physiological

changes associated with head injury were coming to be recognized as the proper basis for treatment^{11, 14}. The old terms "concussion," "contusion" and "compression" like the newer and more popular all inclusive "fractured skull" began to be abandoned.

This phase also is now coming to an end. Cerebral physiology as a whole rather than as a function of the cerebrospinal fluid mechanism or the individual corticospinal connections is more comprehensible thanks in great part to the work on cerebral circulation from Cobb's laboratory¹⁵. Exploratory trephino for diagnosis has been introduced and has justified its use^{16, 17}. Today methods of treatment of craniocerebral injuries should be fairly standardized and for the most part beyond further discussion at present. Yet there are still those who refuse to heed the experience of others. Decompression operations are still being advocated¹⁸, the degree of unconsciousness of the patient on admission to the hospital is still being used as an exclusive diagnostic and prognostic indicator¹⁹.²⁰ the efficiency of increased intracranial pressure as a method of controlling traumatic cortical hemorrhage is still stated as a fact^{21, 22, 23}, and morphin is still used as a method of treating impending respiratory paralysis²². It is not surprising therefore that, in the face of these disagreements among those who write as experts, the general surgeon should be confused. Being confused he refuses to adopt new methods until the entire situation has been clarified further. As Abernethy wrote in 1811 "many material points seem to us to require still further elucidation".

In this paper I propose to present for your consideration what I believe to be the rational pathologic basis for the detailed diagnosis of craniocerebral injuries to indicate the justifiable methods of treatment arising therefrom, and to set up a series of maximum mortality rates in accordance with the pathology under consideration. These figures are based on recent personal experience with about 900 cases of craniocerebral injury extending over a period of five years. They do not apply in any sense to other

*Read before the Clinical Congress of the Connecticut State Medical Society on September 15, 1935.

than the acute injuries. Consideration of late so-called posttraumatic effects seems to me to be futile until the earlier diagnoses are standardized and the treatment of the acute stage is based upon a pathologic rather than a symptomatic or emotional background. As well attempt to predict the number of five year cures in a series of tumors of the breast without knowledge of either the percentage of malignancy or the methods used in the treatment of them.

Diagnosis. It is universally acknowledged that the only reason for making a diagnosis is to provide a foundation upon which a rational method of treatment can be based. As an aid in establishing such a knowledge of the normal anatomy and physiology of the diseased part is essential. Destructive organic lesions with resultant variations from this physiological norm constitute the pathology of the disease or injury under consideration. From this point of view it is obvious that the diagnosis of a given injury must be a word picture which shall describe the damage done to all the organs immediately involved. The physiologic abnormality, per se, indicates only necessary variations in the technique of treatment after the diagnosis is established. For example a diagnosis of increased intracranial pressure is equally applicable to both a lacerated brain and a cerebellar tumor. Yet reduction of this pressure by lumbar puncture may be curative in the former and fatal in the face of the latter pathologic entity. So, too, the incompleteness of "fractured skull" as a diagnosis intended to cover craniocerebral injuries in general is obvious when the medical examiner demonstrates an untreated subdural hematoma which has been an unrecognized and unmentioned companion of the break in the bone. Nor should the surgeon consider his pathological diagnosis complete enough to justify treatment until he has made use of all available and practical methods of investigation at his command. It is as handicapping to be without accurate data on the variations in cerebrospinal fluid pressure in a given case as it is to be without an x-ray examination. Both may well be immediately essential in the recognition of a rupture of a middle meningeal artery. In a compound fracture of the skull with possible involvement of a frontal sinus, however, the result of an

x-ray examination is infinitely more important therapeutically than the information obtainable by lumbar puncture. Furthermore in the presence of surgical shock neither examination can be carried out, nor is either one immediately practical or essential. Finally it must be constantly borne in mind that in craniocerebral injuries similar symptoms may be produced by widely divergent or overlapping pathologic changes. It is therefore safer for the patient if the surgeon, in the interests of accuracy, will be always ready to supplement the simpler diagnostic methods by actual operative exploration.

Treatment based on such a diagnostic background must of necessity be fundamentally correct. What variations there are will come in the technical aspects. Ultimate tests of its success will depend upon adequate statistical studies. These, to be of any value, must be founded upon a sufficiently large series of cases and must propound end results in mathematical terms rather than as individual opinions. "Ex cathedra" statements condemning or criticizing in "glittering generalities"^{18, 20} any therapeutic procedure cannot be too strongly condemned. On the other hand any method of treatment that is soundly conceived and that can produce a mathematically improved mortality or morbidity rate must supersede all previous methods.

Non-Operative Treatment Group. Craniocerebral injuries can be properly divided into three groups in accordance with the operative or non-operative requirements of treatment and as complications of the fundamental conditions which have been already classified. The first of these is made up of the injuries whose pathology is such that non-operative treatment is indicated. It includes cases of concussion, edema and congestion, and contusion and laceration of the brain (Table 1). As a group these form about 70 per cent of all craniocerebral injuries. Under the methods of treatment outlined below the immediate mortality has been kept at about 12 per cent. This is figured on the entire group without regard to the time of death after admission. It tends to be high rather than low because with the formation of a specialized service in a general hospital the drift of severely injured or obscure

cases admitted on the general surgical or medical sides is toward this service. This is evidenced by the fact that in 1930, which was the first year of the formal organization of the neurosurgical service at the Boston City Hospital, there were twenty-two compound fractured skulls admitted to the hospital. One half or eleven were treated on the general surgical side. In 1934, however, out of the same number (twenty-two) of the same injury admitted throughout the hospital, only two were treated on the general surgical side, the remaining twenty being either admitted directly for neurosurgical care or transferred there for treatment immediately after admission on the general surgical services.

Concussion. The primary and simplest form of craniocerebral injury is true concussion. The term has been widely used to cover all forms of brain injury regardless of the pathology present. It should be restricted solely to those cases in whom a blow on the head has produced some degree of unconsciousness but who on recovery present no residual symptoms or signs whatsoever. Upon it as a foundation are built the complicated and more serious succeeding brain injuries. It is probable that the primary unconsciousness practically always associated with craniocerebral injuries is due to this concussion.

The pathology of concussion is unknown and as a diagnosis it has to be made after the fact. Many theoretical explanations of it have been advanced however. Kral¹⁴ quoting Hauptmann summarizes them as follows. First, the molecular disintegration theories with a negative anatomical background, secondly, the theories that predicate anatomical changes as the cause and thirdly, the theories that circulatory damage is the underlying factor though these last fail to answer the questions as to whether reflex or direct mechanical stimulation is the fundamental process and whether in its turn anemia or hyperemia is produced. The first of these is obviously impossible of proof or disproof. I merely wish to draw attention to the fact that since it was originally promulgated in the second half of the 18th century (Pettit by Kral¹⁴) there has been a considerable advance in physics beyond the molecular stage and any such theory today must include a disposition of not only molecules but also of ions and electrons. Chief among the second group must be classed Cassanova's¹⁵ theory of damage to subcortical vessels by pressure from a fluid wave. This is supposedly set up in response to a change in shape of the skull. It involves a movement inward by cerebrospinal fluid from the subarachnoid space along perivascular to perinuclear spaces with resulting hemorrhages and cell damage. It has been popularized by Martland¹⁶ as the explanation of the condition known as 'punch drunk'. A violent histological insult to the

brain must be predicated to produce such changes. This is not compatible with the requirements of the definition that residual signs and symptoms must be absent after recovery of consciousness. Furthermore Cobb¹⁷ states that the flow of cerebrospinal fluid is normally toward the subarachnoid space and is limited in its freedom of entrance therein by the tight collar of pia arachnoid which surrounds each vessel at the point of its entrance to or emergence from the surface of the brain. A reversal of this flow must include tearing of this collar with the strong probability of surface hemorrhage and cortical damage. These would prove to be adequate causes of post-concussion symptoms. It must be admitted, however, that as far as we know the compression malformation of the skull caused by severe blows may of itself produce the alterations associated with loss of consciousness. Here, however, microscopic and macroscopic changes are evident and post-concussional symptoms are frequent. The third or "vascular change group" of theories finds more support. A usual cause of syncope or unconsciousness is a dilatation of the arterial side of the peripheral intra-cortical vascular bed. This is associated with a drop in blood pressure, pallor, sweating, nausea, etc. These vessels have been shown by Cobb¹⁸ and others to be all interconnected and are not end arteries. They are moreover provided with vaso-dilator and vasoconstrictor nerves. This dilatation has been shown to result from the so-called "vasovagal reflex"¹⁹ in which stimuli reach these vessels along the vasodilators. Such a reflex can be set up by pressure on the abdominal carotid sinus²⁰, as an accompaniment of surgical shock²¹, by direct experimental stimulation of the vagus nerve²² as the result of experiencing great pain suddenly²³ and by an increased carbon dioxide content of the blood²⁴. More recently in association with Faulkner and Maddock I have shown that a direct blow on an experimental animal's head will duplicate these signs and symptoms²⁵. These experiments are as yet unfinished, however. Finally Weiss²⁶ has postulated a "centre of consciousness," damage to which produces unconsciousness in nontraumatic syncope, and Kral¹⁴ adduces considerable inferential evidence to show that the mechanism controlling sleep is the seat of the changes which produce the primary unconsciousness in all cases of craniocerebral injury. On purely theoretical evidence then it seems to me to be probable that the original unconsciousness of craniocerebral injuries may be due in part to a "vagal" reflex set up in response to the blow on the head. This dilates the arterial side of the intra-cortical capillary bed, produces anoxemia and throws out of gear the cerebral mechanism that keeps intact the state we know as consciousness. This mechanism may be in Weiss's seat of consciousness or in

the region given over to the initiation of sleep or in some other at present unknown point. If this abnormal reflex activity is corrected at this point, consciousness is regained, the patient complains of no symptoms and searching examination reveals no signs of residual cerebral pathology. Under these conditions and only under these can the patient be said to have suffered from *concussion*.

The pathology being unknown, treatment must be inefficient and inaccurate. Fortunately patients do not need treatment to recover. If any were indicated it should be at present such as would cause a contraction of the dilated arteries, interrupt the vagal reflex and raise the blood pressure. Cases of true concussion occur in about one per cent of the hospital type of craniocerebral injuries. In the population at large the occurrence is doubtless much greater. True concussion is probably never fatal.

The following histories illustrate true concussion.

No 1167. A child of four years tripped and hit her head on the pavement. She was unconscious and dazed for twelve hours. There was no vomiting, paralysis, seizures or bleeding externally. She was brought to the hospital at the end of eighteen hours for checkup although she complained of no symptoms. Neurological and physical examinations were normal. Lumbar puncture showed clear, colorless fluid with a pressure of 150 mm. water, a protein of 22 mg. per cent and a negative gold sol and Wassermann. The patient was kept under observation for two weeks and was discharged well.

No 1755. A child of eleven years was struck by an automobile and knocked unconscious twenty minutes before admission. On admission he complained of no symptoms and neurological and physical examinations were completely normal except for a puncture wound in the centre of a right parietal hematoma. Lumbar puncture done at once showed a pressure of 90 with clear, colorless fluid with normal chemistry. X-rays showed a fracture of the squamous portion of the right temporal bone. The wound was healed and the patient discharged well fourteen days after admission.

Edema and Congestion.—The next more serious type of craniocerebral injury that responds to non-operative therapeutics is edema and congestion or, as it is commonly referred to, cerebral edema. In it the pathology peculiar to this lesion is superimposed upon a concussion although the more primary condition is not usually included in the diagnosis. The pathology is well understood when it is present as an accompaniment of the more serious succeeding brain injuries but is not commonly seen as an entity because it rarely proves fatal per se. In its pure form it consists of an increase in brain volume caused by an overdilatation of the perivascular and perineuronal spaces. This is due to leakage from the arterial side of the intracortical capillary bed. In addition the absorption of the cerebrospinal fluid is impeded due

to the venous congestion which, in its turn, may go on to the point of rupture of the intracortical veins and the formation of perivascular hemorrhages. From the descriptions and photographs it is probable that Cassasa's²⁵ and Martland and Beling's³³ cases of perivascular hemorrhages belong in this category. When the dilation of the cortical arteries set up in response to the theoretical "vagal" reflex described above or as the result of some at present unknown factor continues beyond an indeterminable critical point, the normal relationship existing between the capillary arterial hydrostatic pressure and the colloid osmotic pressure of the perivascular and perineuronal fluid is altered.⁴⁵ The intravascular hydrostatic pressure is raised³⁴, fluid escapes into the tissue spaces and the perivascular colloid osmotic pressure there is lowered in relation to that of the blood plasma. As this perivascular pressure drops the amount of fluid escaping from the capillaries increases. As a result the venous limb of the capillary loop becomes compressed.³⁴ This elevation of intravenous pressure interferes with the normal absorption of the tissue fluids which back up and thus make more pressure on the veins. Tissue anoxemia and further alterations from the normal colloid osmotic relationships between blood plasma and tissue fluids ensue.³⁴ This process is one that quickly influences the whole venous side of the cerebral vascular tree.²⁷ It will rupture small veins with resultant intracortical and subpial hemorrhages^{35, 36} even without any preexisting injury. As a side effect, and because the absorption of the cerebrospinal fluid depends upon an essentially equal pressure in both ventriculoarachnoidal and cranial venous systems, the intracranial pressure may be raised. Through this lack of absorption in the face of continued production the cerebrospinal fluid backs up into the ventricles and cisternae until finally the majority of the cerebral subarachnoid reservoir is closed off by direct pressure of the surface of the swollen brain against the overlying dura. Recently Connors and Wright²¹ have stated that such edema does not occur within forty-eight hours of the injury and are even skeptical of its late occurrence. They reason that they have never seen it at autopsy and further debar themselves from recognizing it in non-fatal cases by the inadequacy of their diagnostic criteria. On this basis and in consideration of an abundance of other evidence⁴⁵ their contention can be dismissed as incorrect.

The diagnosis of edema and congestion in addition to concussion and possibly including perivascular hemorrhage is made on the following evidence. There is a history of a blow on the head sufficiently severe to produce some degree of unconsciousness. This is followed on return to consciousness by either subjective symptoms

such as headache, dizziness or nausea or objective signs varying from a single cranial nerve palsy to hemiplegia with convulsions. The cerebrospinal fluid will be normal as to cell count and chemistry and free of blood. If the intracranial pressure is measured during the period of congestion it will be found to be above normal providing the patient is not dehydrated. Having in mind the pathology it is evident that treatment directed either toward shrinking the brain by dehydration or looking to removal by lumbar drainage of the excess backed up cerebrospinal fluid will be successful. Dehydration may be obtained by hypertonic glucose solution intravenously, magnesium sulphate by rectum or according to the method of Fry.³ Its efficacy and indication should be checked by measurement of the intracranial pressure while it is being used however. Lumbar drainage is obtained by the removal at lumbar puncture of enough cerebrospinal fluid to reduce an abnormally high pressure to normal limits. Such a procedure should be repeated every twenty-four hours until two successive normal pressure measurements have been obtained previous to the withdrawal of any fluid.

Cases of edema and congestion make up about 23 per cent of all hospitalized craniocerebral injuries. This as in concussion, is probably low when considered in relation to its occurrence among the population at large. The mortality should never exceed $\frac{1}{2}$ of 1 per cent. The associated presence of a bony injury alters neither the diagnosis nor the prognosis.

The following synopses illustrate different types of traumatic edema and congestion.

No 1267. A child of twelve years was struck by a sled while coasting and rendered unconscious for at least thirty minutes. On recovering consciousness she complained bitterly of a severe headache. Physical examination revealed a swelling over the left parietal region and neurological examination slight vertigo and pointing of the left hand. Lumbar puncture on admission showed a pressure of 165 with clear colorless fluid and negative chemistry. Six days later the pressure was 200 mm. water and five days after that 140. The first lumbar puncture completely relieved her headache and she was discharged well sixteen days after admission.

No 1351. A forty year old man complaining of severe headaches and dizzy spells especially when active was admitted two and one half weeks following a head injury sustained during a homicidal attack. At that time he was unconscious for two hours with subsequent amnesia for twenty-four hours. He was in the hospital for one day and then home in bed except for meals for the balance of the time. His headaches which were severe were his only symptom. On admission his physical and neurological examinations were entirely negative. Lumbar puncture that day and the two following showed clear colorless fluid with a protein of 34 mg per cent and negative gold sol. Fifteen cc. of fluid was removed at each puncture. The pressures were respectively 200, 250 and 190

mm water. His headache was relieved at this time. Check up punctures six and eleven days after admission were normal. The patient was discharged well twenty days after admission.

No 1550. A forty three year old man was admitted one week after an injury to the head sustained in an automobile accident. This injury was superimposed on a shrapnel wound of the head sustained seventeen years before, another automobile accident fourteen years before some type of epileptic seizure with convulsions of the head one year before, multiple sclerosis and drug poisoning. Following the last accident he was unconscious one hour and during the following week took almost no fluids or food. On admission both legs and arms showed marked weakness with Babinski on the right, absent abdominal reflexes and a divergent squint all antedating his last accident. New signs were extreme emaciation and dehydration difficulty in swallowing urinary incontinence and drowsiness. Lumbar puncture showed a pressure of 60 mm. water or less with clear colorless normal cerebrospinal fluid except for a chloride of 600. In spite of fluids by vein and parenterally his coma increased his temperature rose to 103 and he died twenty-four hours after admission. An autopsy performed through the courtesy of the medical examiner demonstrated multiple minute perivascular hemorrhages of the brain with no other recent pathology and in addition to the clinical condition of advanced toxic dehydration.

Contusion and Laceration. If the cerebral pathology resulting from a relatively slight blow on the head as described above is complicated by the addition of a bruise of the surface of the brain with a rupture of one or more cortical vessels there is contusion of the brain. If the severity of the injury is sufficiently great actually to tear the cortical surface in addition, the condition is spoken of as a lacerated brain. These merge one with the other and any distinction except in the extreme cases is a purely arbitrary personal one. They are both associated with concussion with edema and congestion and almost certainly with subcortical hemorrhages. They both have free blood in the cerebrospinal fluid varying in amounts from a few hundred cells in the mildest contusion to pure blood in the most severe laceration. The increased intracranial pressure that is basically present because of the edema and congestion associated with interference with the absorption of cerebrospinal fluid from the high cranial venous pressure is further increased. This additional increase is from backing up of spinal fluid which is prevented from escaping by the mechanical plugging of the normal outlets in the arachnoid villi by the free red blood cells.⁴ This latter will be least marked and of little effect in the mild contusion case but on the other hand will be the chief cause in the bad laceration. In the severely injured patients anemia of the medulla follows the development of high intracranial pressure to be succeeded in its turn by a spread of the cerebral edema to this region with resultant respiratory failure and death.

The diagnosis of contusion or laceration is made on the following data. There is a history of a severe blow on the head which has in most cases produced a definite period of unconsciousness. In the more severe injuries this period may be prolonged for days and is as has often been stated^{19, 23} an indication of the severity of the injury. With the coma may go loss of sphincter control, and especially in moribund cases a general flaccidity with absent tendon reflexes. Respiratory irregularity, sudden dilatation of the pupils, sudden increase in pulse rate and temperature occur just prior to death. If the injury is less severe the unconscious period will be succeeded by a varying degree of disorientation often accompanied by active delirium. Nausea and vomiting, particularly at first, are common. Headache and retrograde amnesia are almost invariable while any degree or form of somatic or cranial nerve palsy can

make up approximately 50 per cent of all hospitalized cranio-cerebral injuries. This is probably abnormally high when applied to the population at large. Under proper treatment the group mortality should not exceed 18 per cent. The presence of an associated bony injury tends to decrease the patient's chances of survival, not because the break in the bone is of itself necessarily lethal, but because the blow that produced it must have been applied with greater force. Either contusion or laceration or both may or may not be associated with any of the specialized forms of bone injury or any type of meningeal hemorrhage. These latter conditions, however, will be characterized by their own additional pathological peculiarities and must therefore be considered as separate diagnostic and therefore therapeutic entities.

Operative Treatment Group (Table 2) The group of cranio-cerebral injuries whose path-

		Total Series	724	156	880	17.72	

occur. Surgical shock is an invariable accompaniment of the more seriously injured. The intracranial pressure is high providing the patient is neither dehydrated nor in surgical shock. The cerebrospinal fluid contains free blood, the amount varying in accordance with the severity of the damage to the brain surface. Because of the multiplicity of signs and symptoms the diagnosis is finally made on the history together with the cerebrospinal fluid findings as outlined.

Treatment is best carried out by a judicious combination of dehydration and lumbar drainage. However the surgeon should never lose sight of the fact that dehydration alone in these cases is inefficient in exact ratio to the amount of free blood in the cerebrospinal fluid. This is due, as pointed out above, to the mechanical blockade of the arachnoidal villi by the free red blood cells. The technique of both types of treatment is the same as described under the previous heading. Operative decompression as a therapeutic measure is contraindicated. Exploratory trephination however, can be properly employed as a diagnostic measure whenever the patient fails to improve after a suitable interval of properly executed non operative treatment such as outlined above.

ology is such that treatment must be through operative interference includes the cases of sub- and extradural hemorrhages and compound and depressed fractures of the skull. As a group they make up about 30 per cent of all cranio-cerebral injuries. Their mortality is high, 31 per cent, but doubtless will be lowered as we become more willing to operate earlier and as our operative technique improves. These injuries are all associated with, and complicate by their presence, the fundamental brain pathology that has been discussed above. In general, treatment must be such as will properly care for this latter condition as well as being so carried out as to avert sepsis, control otherwise fatal hemorrhage and obviate later epilepsy without undue risk to the patient. Ordinary diagnostic methods should be supplemented by bilateral exploratory trephinement without hesitation.

Subdural Hemorrhage The commonest member of this group is not as might be supposed from the textbooks the extradural hemorrhage but rather the subdural hemorrhage. These are practically always associated with one of the forms of brain pathology noted above when there has been an antecedent injury to the head. The exception under these conditions occurs in connection with trivial injuries which produce

Cases of contusion and laceration of the brain

no concussion even, but which do rupture a "bridging vein" as it crosses the subdural space. There are, of course, other sources for these clots unassociated with any injury as, for example, in the presence of curvity or as an extension from a subarachnoid hemorrhage originating in cerebral vascular disease. Hous-ton Merritt and I¹⁰ have shown that the clots are formed from a mixture of blood and cerebrospinal fluid incarcerated within the subdural space. These divide themselves into three groups. The first and classical group is made up of those collections that consist of pure blood. These are completely encapsulated lesions, that may remain unrecognized for years and can be accurately placed as to age up to two to four months. The diagnosis may be made before operation but ordinarily the clot is found in the course of an exploration for tumor, after a ventriculogram, or while investigating the etiology of some previously unexplained epilepsy. This type is non-expandable. The second group is made up of solid clot mixed with blood dissolved in cerebrospinal fluid. Expansion takes place by dialysis up to three months after formation. After that they remain fixed in size as a freely movable collection of subdural fluid. They can be accurately placed as to age up to four months by a study of the protein content of the fluid portion and in my experience are finally diagnosed only by exploration. This is usually carried out for the purpose of determining why the patient is not improving under adequate non-operative treatment. The third group contains those that originate as a solution of blood in cerebrospinal fluid and that have no solid clot. They also slowly expand by dialysis up to one month after formation, and the diagnosis is again made only at exploratory craniotomy. They can be placed accurately as to age only up to three weeks but are known to remain for as long as seven years. The later stages of these second and third groups have been shown to be associated with symptomatology which is at present classed under the general heading of posttraumatic syndrome or neurosis. The early symptoms are those of the associated brain lesion. The cerebrospinal fluid is usually but not necessarily bloody. The intracranial pressure will be high in the early cases and during the expansion of the hematoma. After this process is completed, however, adjustments within the skull are gradually made and the intracranial pressure returns to normal levels. This is particularly true in groups two and three.

All types of clots are prone to be bilateral. As a result the major symptomatology may apparently appear as either ipsi or contralateral to the lesion. They are diagnosable only by bilateral exploratory temporal trephinement or other exploratory operative procedure. This is indicated whenever a patient suffering from

the varied pathology caused by a blow on the head fails to improve under adequate non-operative treatment such as outlined above. As a class subdural hematomas occur in about 12 per cent of all craniocerebral injuries. The present mortality of this group should not be over 35 per cent and probably can be reduced still further. For descriptive case reports the reader is referred to the paper on subdural hematomata by the writer.¹¹

Compound Fracture of the Skull Compound fracture of the skull may be linear, comminuted or depressed. It may involve cranial venous sinuses or the frontal air sinuses. It often is associated with a severe type of brain pathology leading in the worst cases to actual loss of brain substance by extrusion onto the scalp. Whether considered from the point of view of mortality or immediate morbidity a compound fractured skull is a problem in sepsis and nothing else. All other considerations must go by the board. A detailed study of eighty-nine such cases has been recently completed¹² and demonstrates that if principles looking toward, on the one hand the avoidance of the spread of infection and on the other, toward the surgical excision of those bacteria already present, are followed the operative mortality and morbidity can be kept within reasonable figures. These principles include a diagnosis by palpation through the scalp wound, rigid avoidance of any cleansing of the scalp or scalp wound until just before starting the major operative procedure, operation after twenty-four hours and before forty-eight hours after the receipt of injury in an adequately equipped operating room, 100 per cent debridement including all layers and especially the bone and brain elimination of packs or drains in the wound except where the frontal sinus or supra-orbital ridge is involved, and complete closure of the scalp with two layers of fine silk sutures followed by scarification in the regions adjacent to the suture lines. Complicating sub or extradural hematomata may occur and should be dealt with as required. In the same way the associated brain injury should be appropriately treated. Depressed portions of the fracture should be considered therapeutically only from the point of view that regards them as possible harborers of infection. The symptomatology is that of the underlying brain injury and may be modified by signs of an early meningitis or other type of cerebral infection. The cerebrospinal fluid findings are also those commonly seen in association with the uncomplicated cases of cerebral pathology. The gross mortality of this group of cases is about 32 per cent but if properly handled should be about 21 per cent. The present morbidity (largely from sepsis) is 23 per cent. This can and should be reduced to not over 5 per cent. Compound

fractures make up about 11 per cent of all craniocerebral injuries

It is significant that if the surgeon will assume the care of the cases of uncomplicated brain pathology together with those cases of subdural hematoma and compound fractures that go with them he will be treating 92 per cent of all craniocerebral injuries. Furthermore if this therapeutics is founded on diagnoses made from a pathologic point of view his mortality should be between 17 and 18 per cent. It is probable also that as he becomes more skillful in his operative work, he can even reduce this figure to the neighborhood of 15 per cent.

Depressed Fractures of the Skull Depressed fractures of the skull uncomplicated by any additional scalp, bone or meningeal injury occur in about 5 per cent of all craniocerebral injuries. It should not be forgotten, however, that such a fracture is invariably accompanied by some type of brain injury. The pathology of the bony injury itself is simple and varies from the "celluloid ball" type of depression in the soft skull of the infant, to the immovably locked fragmented depression seen in the adult. The symptoms and signs are those of the associated brain injury. The diagnosis is best made by stereoscopic x-rays. Palpation is notoriously inaccurate. It is impossible to differentiate a true depression and a subperiosteal hematoma. All depressed fractures except those in the region of the foramen magnum require operative elevation. This must usually be combined with a wide opening of the dura beneath the depression so that the surgeon can be sure that there is no subdural hemorrhage present. As little bone as possible, consistent with a complete elevation and exploration locally, should be removed. Particular care should be exercised to see that such a pure depressed fracture is never operated upon until the increased intracranial pressure resulting from the associated brain pathology has been permanently reestablished at normal. There is no necessity inherent in the bony deformity itself that calls for an emergency operative procedure. If operative interference is undertaken before the congestion of the cranial venous circulation is corrected, the technical aspect of the procedure is made infinitely more complicated. This is on account of the free bleeding. Under such circumstances a fatality from air embolus or operative hemorrhage may occur, particularly if a large venous sinus has been involved in the injury. The mortality rate certainly should not exceed 4 per cent and if the cases are properly handled ought to be zero.

Extradural Hemorrhage Extradural hemorrhage is the last of the ordinary craniocerebral injuries that requires treatment by operation. It is the classical example and has served for

years as the model upon which the symptomatology of all brain injuries were based. It is almost always an expanding lesion with a constantly growing blood clot lying between the skull and the dura. The source of the clot is found in a rupture of any part of the middle meningeal artery or one of the large cranial venous sinuses. The clots are commonly unilateral and cerebral though they may occur simultaneously on both sides of the cerebrum or singly over the cerebellum. They are always associated with some degree of brain injury. This latter is the cause of the primary period of unconsciousness in the typical history. If the original brain injury is relatively mild—as for example, concussion or mild edema and congestion—the patient regains consciousness and may even be subjectively normal before the slowly forming extradural clot has reached a size large enough to produce coma on its own account. Such a period of consciousness represents the second stage of the typical history. As the clot increases in size more and more brain deformity takes place, and the patient slowly gets confused and drowsy. Paralysis and convulsions may or may not be present. The final period of unconsciousness now appears. This will terminate in death if the condition is not promptly relieved. This so-called pathognomonic succession of events is not by any means constant. It does not occur for example, when the associated brain pathology is so severe as to keep the patient unconscious until the clot has reached such a size as to produce coma of its own accord. If the dura is loosely attached to the inner side of the skull, so the spread of the bleeding is little if at all impeded, such an enlargement of the clot may proceed at a very rapid pace indeed, and induced coma becomes a question of minutes rather than one of hours.

Blood in the cerebrospinal fluid may or may not be present, again depending upon the degree of brain injury. The intracranial pressure will be high. Roentgenological examination of the skull of these patients is extremely important. Although lateral stereoscopic films are preferable, a single film of the suspected side is better than none. The suspected presence of a clot will be sufficiently verified to justify operative interference if a fracture line can be shown to cross any part of the middle meningeal artery or a cranial venous sinus. It should be mentioned in passing that the x-ray films are useless unless they show both the fracture line and the vascular groove. The general symptomatology in these cases is extremely variable and cannot be depended upon from a diagnostic point of view except as confirmatory evidence which supports a suspicious history, positive x-ray films or adequate cerebrospinal fluid data.

The making of this diagnosis presents in my opinion the most difficult problem of any associated with the entire group of craniocerebral injuries. A pathognomonic history with a positive roentgenogram in the presence of a hemiplegia with or without aphasia or convulsions, and verified by clear cerebrospinal fluid at a high pressure can mean only one thing. This fortunate combination is, however, contrary to the general opinion, extraordinarily rare. Histories are more apt to be completely absent or at best inadequate or grossly inaccurate. Hemiplegias and convulsions occur only when the clot is thickest over the motor cortex and mathematically the chances are against the clot being commonly centered at that point. Furthermore it is not unknown in the late stages of the slowly developing clots to have a shift of hemiplegia to the ipsilateral side with a complete reversal of the ordinary expected reflex responses. In children hemiplegia and convulsions may also be associated with uncomplicated cerebral edema. The added presence of a severe cerebral contusion or laceration or surgical shock will completely alter the cerebrospinal fluid picture. In deed, I am convinced that the final diagnosis in many of these cases, just as in subdural hemorrhages, can be made only after exploratory trephination.

Treatment is operative at the earliest possible moment. At operation three things should be done in any event. The clot completely removed, the bleeding point identified and either ligated or clipped if arterial, or closed with muscle stamp graft if venous, and the dura opened sufficiently to provide a decompression. Postoperative transfusion will frequently be necessary not only to combat shock but also to correct actual blood loss. Postoperative malignant edema as in the subdural hematomas is prone to occur and must be rigorously combated by active dehydration, lumbar punctures, etc. Extradural hematomas occur in about 25 per cent of all craniocerebral injuries. They carry, in spite of earliest treatment, far and away the highest mortality. The rate in my series is 59 per cent and is exceeded only by that of complicating meningitis.

Complications. Complications of craniocerebral injuries fall into three great classes

The first covers associated general bodily conditions and includes surgical shock and toxic dehydration. The second group is made up of conditions that are associated with infection in the cranial cavity other than compound fractures, and the third consists of non-specific linear fractures of the vault and base. From a practical point of view it has been impossible in this series of cases to determine the occurrence rate of any except toxic dehydration and intracranial sepsis, thus last in the form of meningitis. These conditions occurred either singly or together in a total of 31 per cent of the cases with a mortality of 28.5 per cent.

COMPLICATIONS DUE TO ASSOCIATED GENERAL BODILY CONDITIONS

Surgical Shock. The most important complication of a craniocerebral injury when it is present is surgical shock. This differs in no way from the surgical shock seen in other major surgical injuries except for an increased preponderance of associated coma. It is either actually or potentially present in all the major craniocerebral injuries. It is ordinarily characterized by a falling systolic or persistently low pulse pressure, pallor, cyanosis, sweating, subnormal temperature, high pulse and rapid respiratory rate. If unconscious the patient will have absent reflexes and often relaxed sphincters. If conscious, moderate disorientation associated with apprehension will frequently manifest itself. The cerebrospinal fluid pressure except in the cases of massive injury will be well below normal and may be zero. The fluid will usually be bloody because of the associated contusion or laceration of the brain. The diagnosis is provisionally made in the presence of any severe craniocerebral injury and confirmed by blood pressure, pulse and temperature readings and if necessary by the measurement of the cerebrospinal fluid pressure. The best treatment in my hands has been repeated small transfusions of blood (125-250 cc), and absolute prohibition of any diagnostic or therapeutic procedure that might or dinarily be used to treat the associated injury or injuries. If compatible blood is not available for transfusion (and it usually is not) 50 per cent glucose given intravenously in 100 cc. doses for adults is a satisfactory substitute until a donor can be obtained. Luminal in

small doses by mouth and caffeine sodiobenzoate intravenously are also of aid. In addition, of course, the customary general therapeutic measures are used.

Toxic Dehydration Toxic dehydration is commonly unrecognized as a complication of craniocerebral injuries. I know of no test which will accurately demonstrate its presence or absence, the diagnosis depending upon clinical evidence only. It characteristically occurs within the first three or four days or between the tenth and fourteenth days of the receipt of the accident. It should be suspected whenever the patient becomes more and more stuporous with a rising temperature and at the same time can be shown to have a subnormal intracranial pressure. This suspicion will be strengthened if one can ascertain that there has been vomiting, profuse sweating, overheating from too many blankets and intentional or accidental limitation of fluid intake especially in unconscious patients. Its presence will be confirmed when the patient's symptoms improve after the administration of 12,000 cc of fluid over a period of forty-eight hours. This is particularly true if coincidental with the improvement, the intracranial pressure rises to normal or over, and a fluid intake and output chart demonstrates an approximation rather than a separation of the two graphs. In the ten to fourteen day type the dehydration will usually be found to have a therapeutic basis. I have seen it develop at this time in association with too vigorous use of intravenous hypertonic glucose, magnesium sulphate solution by rectum and injudicious restriction of fluid intake. It is particularly apt to occur in young children and after ether anesthesia in operated cases. Here, too, symptomatic relief follows adequate hydration and is associated with a normal or rising intracranial pressure. This condition occurred in this group of cases twenty-three times or at the rate of 26 per cent. It is not necessarily a serious or fatal complication but it may prove so if unrecognized or if allowed to go on untreated. The mortality in this series was 17.8 per cent. The case history below is one of a typical case of toxic dehydration.

No 1675. This sixteen year old male was injured on January 16, 1935. He was in severe shock, vomited, had two convulsions and was treated with intravenous hypertonic glucose during four days. On January 20, a lumbar puncture showed bloody fluid under 120 mm of pressure. He was incontinent of urine, mildly irrational at times and for the rest unconscious and without localizing signs. His fluid under 120 mm of pressure. He was in compound fracture of the jaw and many contusions and had bled from his ears, nose and mouth. On January 22 his cerebrospinal fluid pressure was 60 mm water and the following day it was zero. His pulse remained as before as did the other signs. His fluid intake was raised to 5,600 cc on the 21st, 5,420, 9,040, 7,900, 9,000, 10,080, 10,090, 10,050, 7,700, 7,400, 7,100, and 6,200, respectively,

for the succeeding ten days after which it was kept at this level until discharge ten days later. On January 25 he was explored on account of a persistently slow pulse. A shrunken dry brain with an empty subarachnoid space $\frac{1}{2}$ to $\frac{3}{4}$ inch below the inner surface of the skull was demonstrated. On the 29th his pulse rose to 70 and his lumbar puncture showed a pressure of 30 mm water with xanthochromic fluid. On February 3, ten days after operation and with his fluid intake stabilized between 6,000 and 6,500, his cerebrospinal fluid pressure was 100, he was rational and cooperative and, except for his fractured jaw, was normal on examination. X-rays showed no fracture of the skull but a positive fracture of the jaw, his pulse ranged between 70-80, an electrocardiogram was normal and he was out of bed. He was discharged to the dentist, well of his cerebral complaints on February 14, 1935, twenty-three days after admission.

Intracranial Sepsis In this group are gathered those cases of intracranial sepsis—all as meningitis—that were neither associated with compound fractures as described above nor with any other operative procedure. They occurred in the course of the routine treatment of the cases of pure brain pathology. They differed in no way from purulent meningitis from any other cause. There were five cases in all, one of which survived,—a mortality of 80 per cent. This ratio of occurrence was slightly over $\frac{1}{2}$ of 1 per cent. The case that recovered had a contusion of the brain with a complicating fracture of the middle and anterior fossae and localized meningitis. The other four were as follows, all being associated with contusion and laceration of the brain.—A fracture into the temporal bone with extension of infection from the ear, a fracture of the cribriform plate with extension from the nose, a fracture unspecified with influenzal meningitis and pneumococcus meningitis with no demonstrable fracture.

COMPLICATIONS DUE TO NON-SPECIFIC LINEAR FRACTURES OF THE VAULT AND BASE

Non-Complicating Linear Fractures Non-complicating linear fractures are perhaps the most common associate of craniocerebral injuries. They still serve as the focal point of medicolegal attention in the litigated portion of these injuries. It is only recently that there has been any inclination on the part of the medical profession to abandon their use as a diagnostic yardstick. Indeed I fear that the much beloved classical but useless distinction drawn between fractures of the vault and fractures of the base will never be given up. In general they may be distinguished from the complicating linear fractures by the fact that they are so located as to be completely outside the accessory para-nasal sinuses and the cavities of the ear and mastoid. Aside from the fact that their presence constitutes objective evidence that the bone containing the fracture has come forcibly in contact with some stationary or moving object, their significance lies in the damage they cause to vessels and nerves.

which have been in direct contact with them at the time of their formation. Of course it is also fair to assume that such a fracture in the base of the skull will have been caused by a greater application of force to the head than a comparative one in the vertex. The most commonly involved of those vessels and nerves is the middle meningeal artery followed in point of frequency by any one of the cranial venous sinuses. Such involvement practically always results in either sub or extradural hemorrhage and has been sufficiently discussed above. Other structures that may be damaged in this way are certain of the cranial nerves including the optic, the trigeminal and in certain instances the facial. The diagnoses in these cases are all too obvious and the treatment purely symptomatic. Finally the internal carotid artery and cavernous sinus may be torn in association with a plain linear fracture. This may produce an arteriovenous fistula. One such case occurred in this series and has been relieved of the worst of his symptoms by fractional ligation of the ipsilateral carotid arteries.

It should never be forgotten that the certain presence of a linear fracture can never be determined short of a postmortem examination. X rays are notoriously inexact even under the best conditions and it is well known that venous markings in the skull may at times mimic fracture lines to a remarkable degree. For these various reasons no attempt has been made in this series of cases to determine the ratio of occurrence of linear fractures of the skull.

Complicating Linear Fractures. Those linear fractures that involve the region of the ear and mastoid or the para nasal sinuses and cribiform plate present a different problem however. Perhaps the most common are the fractures of the temporal bone which extend into some part of the ear either with or without involvement of the mastoid also. Their presence permits communication between the sterile meningeal spaces and the possibly infected ear cavities. This communication is certain if cerebrospinal fluid escapes from the ear and is probable if there is any amount of bleeding from the same source. There may be associated damage to the 7th and 8th cranial nerves, the drum or the labyrinth. Symptoms may include dizziness, nystagmus, loss of hearing, facial palsy and loss of the sense of taste. Any one of these may be either transitory or permanent. Meningitis by direct extension is a possibility at any time up to two weeks. Treatment is to avoid all treatment of the ear and especially to avoid plugging or irrigating the canal. If there is an escape of cerebrospinal fluid it is vital to provide enough drainage by early and frequent lumbar punctures. This permits collapse of the subarachnoid space adjacent to the menin-

geal tear. It is a fallacy as any one can demonstrate for himself, to suppose that these acute cerebrospinal fistulae exist except in the presence of and on account of a higher than normal intracranial pressure. These patients do not decompress themselves. It has proved impossible to determine the number of such fractures as well as the number of patients who had a temporary flow of cerebrospinal fluid from the ear. In one case, however, the flow did last long enough to justify the belief that a fistula had formed. This case recovered, the fistula closing of itself. Meningitis also occurred only once as the result of this type of fracture.

Fractures involving the cribiform plate or para nasal sinuses while less common are much more serious. In either case communication with the nose is established. The diagnosis is made by x ray, by the escape of cerebrospinal fluid from the nose with or without blood or by the demonstration of air inside the skull. By far the most dangerous cases are those with the cerebrospinal fluid rhinorrhea. The chances of successfully treating this by repeated lumbar punctures are extremely remote. Yet if it is not stopped promptly, meningitis is an inevitable certainty. The best opinion today seems to be that an early operative exposure of the fracture and upper end of the fistulous tract followed by plastic closure of the dural tear is essential. This should be undertaken as soon as the patient's condition warrants and with a full appreciation of its magnitude. I have done this three times with only one recovery. Of the other two, one, a child in whom the rhinorrhea had been present a year, died of surgical shock and another three days after the operation. The other died, as proved by autopsy, of exsanguination from the rupture of an aberrant artery in the sphenoidal sinus, the cause for which could not be determined. There was one other case which died unoperated as the result of a pneumococcus meningitis.

The abnormal presence of air in the skull is extremely rare and associated usually with a fracture of one frontal sinus. The air may not appear for some days and then only after a sneeze or an attempt by the patient to blow his nose. Its presence indicates a communication between the nose and the meninges and as such in all probability calls for operative interference. My personal experience is limited to two cases, however, both of which recovered completely with non operative therapeutics.

Comment. I cannot leave this detailed discussion without commenting on certain pernicious habits of thought and practice that seem to be immortal. I have discussed them in some detail in previous papers¹¹ and have shown that they arise from ignorance of the fundamental well recognized principles of cerebral physiology.

The first is the assumption that a decreased intracranial pressure will cause more cortical or intracortical bleeding. Such an assumption is obviously false when the close relationship between intracranial and intravenous pressure is realized. It is indisputable that increased intracranial pressure in craniocerebral injuries leads directly to cortical and intracortical hemorrhage. The way to prevent or lessen this hemorrhage is to lower—not raise—the intracranial pressure. Ignorance or disregard of this fundamental physiopathological fact is inexcusable on the part of any surgeon that accepts the responsibility of treating craniocerebral injuries.

The other matter that calls for emphatic discussion is the use of morphin in craniocerebral injuries. This procedure has been denounced over and over again but still persists. As is well known to anyone with experience in this type of case the cause of death following cerebral damage is respiratory paralysis. It should be equally well recognized that morphin is or may be a respiratory depressant. The folly therefore of treating an individual who is already in grave danger of dying from depressed respiration by the administration of a respiratory depressant is all too obvious. Morphin in any form should never be used where an increase in the intracranial pressure is either suspected or proved.

Methods of Treatment While methods of treatment of the fundamental pathology of craniocerebral injuries vary greatly in the hands of each individual surgeon, there are certain fundamental facts that stand out. The first is that subtemporal decompression as a method of relief of increased intracranial pressure per se is practically universally disapproved. Dandy¹⁸ and in certain instances Coleman⁴² are among the few who still insist on its efficacy. Extradural hemorrhage, depressed fractures and most compound fractures are generally agreed upon as imperative indications for operative interference. Subdural hematomas are neither generally recognized nor treated in the acute form nor will they be until the principle of exploratory transtemporal trephination as advocated by Coleman⁴⁶ and me⁴⁷ is more generally accepted. When recognized in the so-called chronic state their presence is also considered an indication for operation. For the rest, methods of treatment in general revolve around three principles. The first and simplest is that which advocates leaving the patient thoroughly alone except for keeping him in bed. This is no more than an overdone negativistic reaction to the indiscriminate operating that characterized the first part of this century. It is being rapidly abandoned as surgeons in general arrive at a better understanding of the problems involved. The second would have as a basis of

treatment, and, in most cases as the only treatment, the principle of dehydration. Fay is the chief exponent of this principle and has recently published a summary of his methods and results⁸⁷. Despite his protestation to the contrary it is apparent that even in his hands dehydration alone cannot be depended upon and on p. 157 and following in his reprint he gives full directions for the treatment of his patients by "daily lumbar drainage" for from seven to ten days. To be sure, dehydration is carried out up to three months after discharge in an attempt to obviate posttraumatic syndromes, so-called, but this should constitute an entirely separate problem. In any event his "dehydration treatment" is only partly dehydration and his early results may as well be due to the "associated daily spinal drainage" as to the predicated shrinkage of the brain. The third general principle involves the use of decompression by lumbar drainage as the prime requisite. This may or may not be associated with added dehydration. It is not yet universally accepted as either safe or adequate^{21, 20, 19} although it is by no means without authoritative supporters^{48, 22}. I have shown by a study of parallel series of cases that its use definitely lowers the mortality rate⁴¹. It is generally conceded that the fear of causing a herniation of the cerebellum through the foramen magnum, previously justly ascribed to it on the basis of experience with tumors, is unjustified in these acute injuries. The most outspoken of its opponents is Dandy¹⁸ who condemns it completely and utterly but quotes no figures to support his contention.

If one summarizes these apparently diverse views it is now becoming apparent that, in general, treatment of the acute craniocerebral injuries is coming to be based upon the pathology present and not upon the preconceived notions of any one surgeon. The dehydrationists are using lumbar puncture and the advocates of lumbar puncture use dehydration, while the "do nothings" as Fay has aptly called them are rapidly disappearing by way of "delayed glucose injections with insulin" or delayed lumbar drainage after 6 days²¹. While I do not for a moment contend that this "combination treatment" as outlined above is the final word, it is a long step beyond universal subtemporal decompression, and an equally long step beyond masterly inactivity. Furthermore it can be expected to lead to even greater efficiency through the more universal adoption of the exploratory transtemporal trephination.

The General Surgeon's Responsibility in Craniocerebral Injuries Swift⁴⁴ states that the approximate number of fractures of the skull which occur annually in the United States is around 112,000. Such figures emphasize what is well known, that the problem of

the craniocerebral injury belongs to the general surgeon. That does not mean that the specialist whether neurologist, or neurosurgeon, will not frequently prove indispensable to him, nor does it mean that in accepting these privileges the general surgeon can ignore the responsibilities that go with them. The first and most important of these responsibilities is as pointed out above, to acquire the habit of making a diagnosis on the pathology present rather

cotton and above all, an efficient suction machine. Without these minimum requirements the surgery of these accident cases is fraught with too much danger to the patient and it is safer in the long run to move him to a more fortunate community regardless of the urgency of the surgery and the dangers of transportation.

The Maximum Permissible Mortality Rate in Craniocerebral Accidents (Table 4) Mor-

TABLE 4
MAXIMUM PERMISSIBLE AND COMPARATIVE MORTALITIES

	All Cases		Non-Operable		Operable		Complications		
	Total	Mor- tality	Total	Mor- tality	Total	Mor- tality	Mor- bidity	Total	Mor- tality
Permissible Maximum		15.17%		10-12%		25%	5%		84%
Average from those below	119,784	24.1%							
Swift ¹⁴	112,000	26%							
Munro ¹⁵	1,450	17.5%	1211	11.6%	239	47.3%			
Hospital A ¹⁶	1,178	39.5%							
Kennedy and Wortis ¹⁷	1,000	37.8%			37	62%			
Munro	880	17.7%	621	12.0%	259	30.8%	23.4%	88	84.2%
Collected ¹⁸	800	26.0%

Coleman ²⁰	590	18.5%							
Fay ²¹	528	20.0%	363	18.4%					
Munro ²²	505	15.6%	376	10.9%	129	29.4%			
Dandy ²³	?	20%							

than on any presenting symptom. If this is done as accurately and completely as possible the efficiency of the appropriate treatment will depend only on the surgeon's knowledge of normal craniocerebral anatomy and physiology. Secondly, sufficient records must be kept and reviewed often enough to prove that treatment as instituted will keep the mortality rate below the maximum permissible limits. I am well aware that no such limits are at present available and propose therefore to set up an arbitrary but not necessarily final standard in the last section of this paper. It is sufficient to state here that at present the mortality of any numerically worth while all inclusive series of craniocerebral injuries should under no circumstances exceed 17 per cent.

If the general surgeon elects to treat only the non-operable type of craniocerebral injury his only other duty is to see to it that a competent trained surgeon is at hand to take over the care of the odd 30 per cent that do require operation. If on the other hand he should elect to treat all cases whether operable or not, he assumes the further duty of seeing that the hospital in which he works provides him with essential and proper equipment. This will include an adequately trained operating room force, such special instruments as a Handerson drill, a De Vilbiss forceps, a silver clip on-fit, ventricular needles, rongeurs, fine silk, fine curved needles and appropriate needle holders, adequate supplies of bone wax and sterile

tality rates for this type of injury have varied the past seven years between 39.5 and 15.6 per cent. I have taken the sum of ten series of 500 or more cases each as a basis for the average rate as it exists at present. This is in the neighborhood of 24 per cent on nearly 120,000 cases. Although published much less frequently, there are certain other data also available which demonstrate that a large share of this mortality lies among the operated cases or those that should have been operated upon and were not. It is in this group that the greatest improvement in the mortality rate can be looked for. Fortunately such a decrease will involve greater accuracy of diagnosis all around which will tend to improve the figures in the other group also. However, no change of any kind can be looked for unless an arbitrary standard of excellence is set up. Being arbitrary it can be lowered for cause at any time. Being a standard, figures that do not approximate its levels point inevitably to the fact that something has been wrong with the work in back of them. This should lead to frequent wholesome revision of methods of diagnosis and treatment. Such an arbitrary standard maximum permissible mortality is offered in the accompanying table. The figures are divided in accordance with the grouping suggested in the body of this paper. They apply only to the acute cases of craniocerebral injury and include all cases regardless of the time of death after admission to the hospital or

the onset of treatment They are in no sense final and I have reason to believe that they will be easily surpassed in the near future Until they are, however, opinions in regard to the efficacy of any given treatment that are not backed up by as good or better statistical evidence must be looked at askance

SUMMARY

- 1 Fourteen out of twenty craniocerebral injuries do not require operation as a method of treatment
- 2 Of these fourteen, one will die
- 3 Of the remaining six, two will die—but *all* should be treated by operation
- 4 One case out of forty will be sufficiently dehydrated to be toxic from that cause
- 5 One out of 200 unoperated cases will have complicating intracranial sepsis almost certainly in the form of meningitis
- 6 One out of twenty operated cases will have justifiable postoperative sepsis either in the form of meningitis or cortical abscess
- 7 Modern treatment of the acute stages of craniocerebral injuries requires that both the diagnosis and therapeutics must be based on the pathology present
- 8 Any method of treatment based on these requirements is suitable providing the mortality and morbidity rates are kept within the permissible maximum limits arbitrarily set up as described above
- 9 A method of treatment combining dehydration, lumbar decompression, exploratory trephination and appropriate reparative operative procedures is outlined

THE PROGNOSTIC SIGNIFICANCE OF A SPONTANEOUS
DIURESIS IN ACUTE OR SUBACUTE
DISEASE OF THE LIVER*

BY CHESTER M. JONES, M.D.† AND FRANCES B. EATON, B.S.†

IT has been known for some years that there exists an intimate relation between the movement of water in the body and hepatic activity. Until recently a disturbance of this relationship has been recognized largely as occurring in cases of portal cirrhosis and rarely in biliary cirrhosis, with the production of free fluid in the peritoneal cavity. The explanation of the formation of such collections of ascitic fluid has largely concerned itself with the existence of a mechanical portal vein obstruction. Textbook articles dealing with diseases of the liver have paid scant attention to such a disturbance in body fluid except when dealing with chronic diseases of the organ although occasional mention has been made of the appearance of ascites during the course of acute yellow atrophy. In recent years scattered case reports have appeared in the literature directing attention to the fact that in the presence of acute or subacute liver disease not only may the formation of ascites be observed but also the abnormal accumulation of fluid in the subcutaneous tissues and in the pleural cavities. With rare exceptions however, attention has been directed mainly to the existence of ascites and only casual mention has been made of the abnormal collection of fluid elsewhere in the body.

Among the earlier observations, Jones and Minot¹ described the occurrence of ascites in a patient suffering from a severe, prolonged case of catarrhal jaundice. Similar cases were reported by Baner², Meyer and Learner³, Root and others⁴. Ascites and edema were noted by Umber⁵, Adler⁶, Halbit⁷, Vossin⁸, Fiesinger and Walter⁹ and others, in cases of acute yellow atrophy of unknown origin. An interesting group of cases was reported by Lederer¹⁰ in which jaundice and anuria were associated with what appeared to be an acute pneumococcus infection. Scattered clinical observations have mentioned oliguria in simple jaundice occasionally resulting in the collection of water in the tissues and Adler⁶ has commented on the concentration of the urine and oliguria occasionally seen in cancer of the liver and hepatic cirrhosis. Weiss¹¹ noted that the administration of salyrgan to a group of normal individuals produced a much smaller urinary output and a much less marked loss of weight

than in patients suffering from liver disease. Baner², Weir¹², Butsch¹³, Poindexter and Greene¹⁴ and others report cases of toxic damage to the liver from arsenic, carbon tetrachloride, eucalyptol, and other toxic substances, again reporting ascites as one of the significant findings. For the most part observers have paid less attention to the occurrence of edema than to the presence of ascites although a few authors, such as Damany¹⁵, have pointed out the fact that even in cases of cirrhosis peripheral edema may appear long before the appearance of ascites. We have had frequent examples of this clinical fact. Experimentally, Bollman and Mann¹⁶ have reported the production of ascites in animals where liver injury was produced by toxic agents or by operative procedures, and the subsequent use of a diet rich in meat or meat extractives.

In addition to the above observations, attention has been paid to the beneficial results following the production of diuresis by one or another drug in the presence of liver disease. In an apparently forgotten textbook article Van Noorden¹⁷ in 1888 described the increased secretion of urine seen in patients recovering from catarrhal jaundice. Joslin¹⁸ also noted such an occurrence following the use of large amounts of bile salts in cases of biliary obstruction. For the most part, however, such interest has been directed toward patients suffering from chronic diseases of the liver and therapeutic measures have attempted to bring about a diuresis only when ascites existed. The successful production of diuresis following the use of such drugs as the mercurial or caffeine diuretics has been considered of good prognostic significance in most instances. There is little doubt that in such chronic cases the occurrence of ascites has been properly interpreted as evidence of disturbed liver function and the successful establishment of diuresis by one of various methods usually has been associated with at least a partial restoration to normal function. It has long been known by experienced clinicians that even in cases of severe chronic liver disease, ascites may disappear spontaneously without the use of diuretics. In such instances this occurrence has almost always been followed by a return to normal hepatic function. It has been obvious in such cases that the establishment of a collateral circulation offered a logical explanation for the disappearance of a mechanically produced ascites and edema in a certain proportion of cases. What has been less obvious is the fact that other factors were involved if one would attempt to explain sat-

From the Medical Clinic of the Massachusetts General Hospital and the Department of Medicine, Harvard Medical School, Boston.

*Jones, Chester M.—Physician, Massachusetts General Hospital. For records and addresses of authors see "This Week's Issue," page 935.

isfactorly the disappearance of ascites and edema, not only in the chronic cases but in the more acute conditions affecting the liver. One important factor which is receiving attention at present is the level of serum protein and the ratio of serum albumin and serum globulin. It is frequently true in the more chronic forms of liver disease that this ratio is seriously disturbed with an associated tendency to the abnormal accumulation of fluid in the tissues and serous cavities. Other factors such as a reduced liver glycogen content, increased capillary permeability, possibly the low blood urea and interference with proper bile salt absorption, are probably operative in the production of edema, ascites, or hydrothorax, as these conditions occur in the more acute liver diseases. As yet no satisfactory explanation has been offered which adequately correlates the abnormal physical findings and the known physicochemical changes which take place in the presence of disturbances in liver physiology.

In the present paper we wish particularly to stress the prognostic importance of a spontaneous diuresis occurring in acute or subacute diseases of the liver in the presence of obvious ascites, edema, or hydrothorax, and even in cases where there is no demonstrable evidence of an abnormal accumulation of fluid in the body. Case reports such as those referred to above have paid little attention to minimal accumulations of fluid in the tissues in hepatic disease and little or no attention has been paid to the prognostic significance of diuresis occurring in patients with such disease in the absence of specific drug therapy.

CLINICAL OBSERVATIONS

The clinical material forming the basis of the observations recorded in this communication was for the most part collected from the records of ward patients in the Massachusetts General

Hospital. The cases were selected only in so far as we attempted to procure records in which there was a fairly adequate measurement of fluid intake and urine output as noted on the hospital chart. Fifty cases seen in recent years were thus selected and included patients suffering from infectious (catarrhal) jaundice, acute or subacute toxic jaundice due to arsenic or cinchophen, one case of subacute liver injury due to antimony poisoning, acute and subacute yellow atrophy of unknown origin, cases of obstructive jaundice due to mechanical blocking of the common bile duct and finally, cases of cirrhosis with an acute exacerbation of jaundice, presumably due to excessive amounts of alcohol. All of the cases included in this group were definitely jaundiced inasmuch as it was felt that this symptom, except in cases of mechanical common duct obstruction, indicated definite parenchymatous hepatic disturbances which probably involved the function of the entire organ. The diagnosis in each instance was an obvious one or was substantiated by operation or by necropsy. For the most part they represented instances of acute or subacute liver injury due either to infection or to specific toxins. In practically every instance the usual laboratory studies were made but are not reported here. Table 1 indicates the duration of jaundice, and the presence or absence of ascites, edema, or hydrothorax. Treatment in every instance consisted of complete bed rest, a diet high in simple carbohydrates, and intravenous glucose injections in the patients who were most severely ill. Obviously any specific toxin known to be associated with the condition was withdrawn. Salyrgan was used in an attempt to produce a diuresis in a few cases which we will comment upon. The majority of the patients were seriously ill and in a certain number of cases a fatal outcome ensued as a direct result of the hepatic insufficiency. (See table 1.) For

the purposes of this communication we shall content ourselves with commenting upon the presence or absence of abnormal accumulations of fluid in the individual patients and the occurrence of a spontaneous diuresis during the course of the disease. It will be noted from table 1 that ascites was present in ten of the fifty patients. Peripheral edema was noted in fifteen cases and hydrothorax, unilateral or bilateral, in four cases. Spontaneous diuresis was observed in more than two-thirds of the patients studied.

Some explanation is needed at this point concerning the expression, spontaneous diuresis. With the exception of a few patients who were followed on the metabolism ward, routine measurements of fluid intake and urine output by student nurses were accepted as accurate figures. Such an assumption of accuracy is obviously unwarranted as anyone who is familiar with routine ward work will testify. At best the figures are only approximations of actual values, inasmuch as the estimations are made by different individuals during the course of a patient's illness and by nurses of varying degrees of ability. It is the purpose of the paper to point out that even with such approximate measurements there was a frequent finding of increased urinary output which took place at some point in the course of the disease in those cases which progressed favorably. For purposes of practical clinical use it seems justifiable to emphasize the importance of such gross estimations of changes in water content of the body as a simple method of determining hepatic function. In a few instances patients were observed on the metabolism ward where extremely accurate measurements were made and these were found to agree consistently with the observations made in the general wards. It was considered that a diuresis occurred when the twenty-four hour volume of urine appeared to be at least eighty per cent of the estimated fluid intake. In many instances the urinary output was far in excess of fluid taken by mouth and administered by clysis. In patients suffering from milder forms of liver damage, evidence of diuresis might be observed only for a matter of one or two days but in the more severe cases, particularly in the presence of ascites, edema or hydrothorax, it persisted for a much longer period of time and was associated with the disappearance of the abnormal accumulation of fluid. It was an interesting clinical fact that in many instances a very marked diuresis occurred in patients showing no clinical evidence of edema or ascites. With the exception of four patients who were suffering from an acute exacerbation of a long-standing cirrhosis any diuresis noted occurred without the use of salyrgan or other diuretic drugs. It was present just as frequently in those patients who were treated with a high carbohydrate diet

alone as in those patients who received glucose intravenously as an additional therapeutic measure. Progress in the individual cases was determined by observation of the patient's symptoms, the appearance or disappearance of an abnormal accumulation of fluid, the presence or absence of a mousy breath (due to acetamid), variation in the intensity of the jaundice, with corresponding changes in the color of the urine and stools, relief of various gastrointestinal symptoms, such as nausea and vomiting, and improvement in appetite, as well as by periodic laboratory tests such as the quantitative estimation of serum bilirubin and the excretion of bromsulphalein. Routine notes by interns stating that the patient was improved were accepted in many instances as the first evidence of clinical improvement although many of the patients were observed by us personally throughout the course of the disease. With rare exceptions the occurrence of a spontaneous diuresis was associated with definite improvement in the patient's condition. Frequently it preceded any noticeable clinical improvement by several days and at times the patient remarked that he was beginning to feel better even though there was no measurable diminution in jaundice or other evidence of improvement in hepatic function. In practically every instance where a spontaneous diuresis of any degree was noted the case progressed to a favorable outcome as far as the immediate attack was concerned. Those patients failing to show a diuresis fall into two distinct groups—the first, those who were only moderately ill and who from the day of admission to the hospital failed to exhibit signs of extreme liver insufficiency, secondly, those who died as a result of the disease involving the liver. Where ascites, edema, or hydrothorax existed these invariably disappeared as clinical improvement progressed. Some of the more striking observations are given below as illustrating the findings in the group under discussion.

CASE 1 Female Aged fourteen years Diagnosis Catarrhal Jaundice

Present Illness Four days before admission acute onset of headache, malaise, nausea and vomiting. Two days later the urine became dark and stools light colored. There was some epigastric pain associated with meals.

Past History Irrelevant.

Physical Examination Moderately jaundiced, palpable liver and spleen, tenderness along the edge of the liver, no ascites or edema.

Laboratory Tests Urine contained bile for seventeen days. Bile present in stools throughout course of the disease. Quantitative van den Bergh 25 mgm bilirubin per 100 cc serum on admission, rising to 30 mgm per 100 cc and subsequently falling to 12 mgm per 100 cc on discharge.

Treatment. High carbohydrate diet and intravenous administration of glucose daily for the first ten days in the hospital.

Progress. Fluid intake and output measured after the tenth day. Marked diuresis noted on the sixteenth and twenty-fifth days after admission. Steady

improvement in clinical condition throughout the course of the disease. Fluid intake and urine output are shown graphically in chart 1.

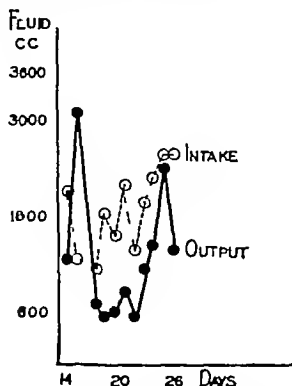

CHART 1. Catarrhal Jaundice.

CASE 2. Male. Aged twenty years. Diagnosis: Catarrhal Jaundice.

Present Illness. Five weeks before admission acute upper respiratory infection with otitis media. Twelve days before admission dark urine and clay

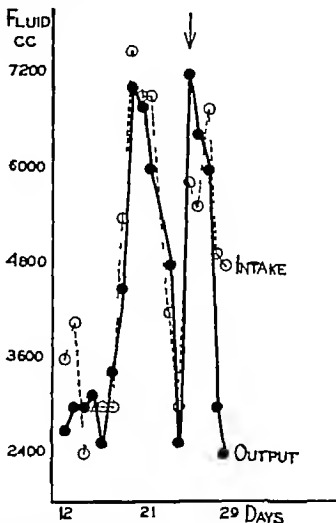

CHART 2. Catarrhal Jaundice.

Arrow indicates appearance of obvious clinical improvement.

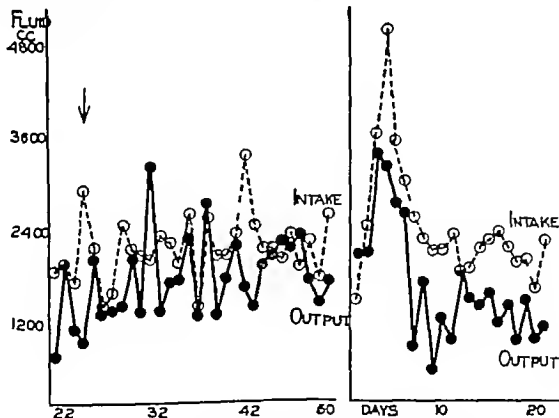

CHART 3. Catarrhal Jaundice, Diabetes Mellitus.

Arrow indicates appearance of obvious clinical improvement.

Left hand graph represents findings made on patient during course of catarrhal jaundice. Right hand graph represents findings made on second admission when patient was completely free of any hepatic disorder.

colored stools associated with anorexia and mild epigastric pain. Jaundice noted eight days before admission.

Past History. Irrelevant.

Physical Examination. Very deeply jaundiced in divisional liver edge just felt, tip of spleen palpable two fingers below left costal margin in the anterior axillary line. No evidence of ascites or edema.

Laboratory Tests. Urine showed large amounts

of bile throughout stay in hospital. Stools began to show brown for the first time the day after admission but returned to a clay color the next day and continued so for eleven days returning gradually to normal from that point in the disease. Quantitative van den Bergh on admission 23 mgm per 100 cc., at peak of jaundice 37 mgm per 100 cc., on discharge 54 mgm per 100 cc.

Progress. Anorexia continued for about two

weeks after admission at which time the patient remarked that he was feeling definitely better. Diuresis was first noted on the sixth, seventh, and eighth days after admission (see chart 2) and continued to recur during the next two weeks. A striking diuresis was noted about twelve days after admission. At no time was there evidence of any abnormal accumulation of fluid. Treatment consisted entirely of rest and dietary measures. Patient discharged practically free of jaundice and with no untoward symptoms.

CASE 3 Female Aged sixteen years Diagnosis Catarrhal Jaundice, Diabetes Mellitus

Present Illness Known diabetes for five years. Three weeks before admission cramp-like pain in lower abdomen with anorexia, nausea, vomiting. Treated in another hospital for acidosis for five days. Three weeks before admission acute respiratory infection with chills, cough and fever. Jaundice noted day before admission to hospital.

Past History Irrelevant.

Physical Examination Well developed and nourished girl, with moderate jaundice, acidotic breath, liver edge felt three fingers below right costal margin in midclavicular line and slightly tender. Spleen just palpable, tender abscess on left thigh (following insulin administration).

Laboratory Tests Urine showed positive tests for bile for fifteen days after admission. Stools clay colored for same period. Quantitative van den Bergh on admission 8 mgm per 100 cc. Sixty per cent retention of bromsulphalein one-half hour after intravenous administration of dye. CO₂ combining power on admission 59 volumes per cent. Fifteen days after admission, van den Bergh 17.5, twenty-five days after admission van den Bergh 15 mgm per 100 cc.

Treatment High carbohydrate diet with sufficient insulin to care for the excessive amount of carbohydrate.

Progress Patient improved rapidly although clearing of the jaundice was relatively slow. The abscess in the groin healed with moderate rapidity and on discharge the liver had returned to practically normal size and the spleen was not palpable. Sharp diuresis occurred on the twelfth, eighteenth and twenty-sixth days although it will be noted that there was a very high urine output throughout the course of the patient's stay in the hospital. It is of interest to compare the fluid intake and urine output as shown graphically in chart 3 with similar determinations made at a subsequent admission of the patient to the hospital, at which time there was no evidence of a striking diuresis such as was noted when the patient came into the hospital with catarrhal jaundice. It is of interest to note that in this group of fifty cases there were four instances of catarrhal jaundice associated with diabetes mellitus.

CASE 4 Female Aged thirty-nine years Diagnosis Arsphenamine Jaundice, Tertiary Syphilis, Cystitis

Present Illness Four weeks preceding admission, nausea and vomiting, epigastric distress. Jaundice noted one week before admission.

Past History Acquired syphilis ten years before admission. No treatment until ten months before admission. Usual antisyphilitic therapy with arsphenamine followed by bismuth and later followed by a second course of arsphenamine.

Physical Examination Deep jaundice with right upper quadrant tenderness and a palpable liver two fingers below costal margin.

Laboratory Data On admission stools clay colored, urine dark during first week in hospital. Bromsulphalein retention 100 per cent. Quantitative van den Bergh 20 mgm bilirubin per 100 cc.

Treatment Rest in bed, cessation of arsenical treatment, and a high carbohydrate diet.

Progress Diuresis noted second day after admission and again eight days after admission (chart 4). Complete disappearance of nausea with improvement in symptoms after five days. Patient discharged symptom free after two weeks with slight residual jaundice. During the following two weeks

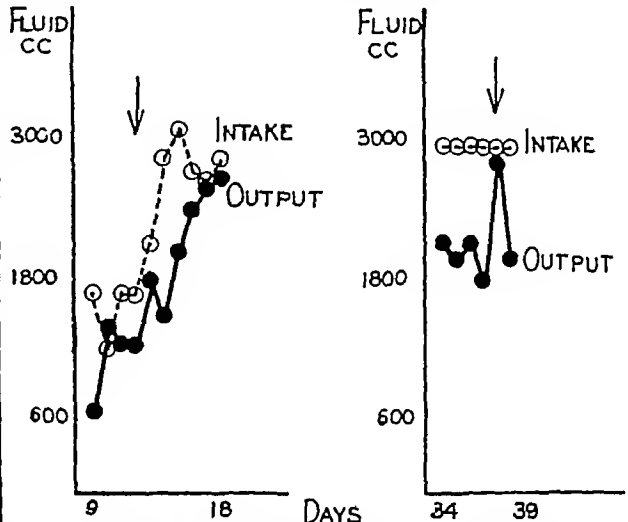

CHART 4 Arsphenamine Jaundice. Arrow indicates the appearance of obvious clinical improvement.

Left and right hand graphs represent first and second admissions respectively. Right hand graph represents readings made on the Metabolism Ward.

did not adhere to diet and did not rest. Nausea and vomiting returned in association with fainting attacks and jaundice deepened. Returned to hospital, again placed on high carbohydrate diet and given one intravenous injection of 1000 cc 10 per cent glucose on the second day. Diuresis noted on the fourth day with associated disappearance of

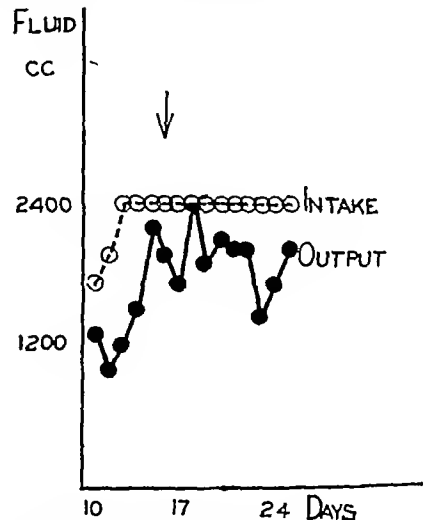

CHART 5 Arsphenamine Jaundice. Arrow indicates the appearance of obvious clinical improvement.

symptoms. Uninterrupted improvement from this point. No abnormal accumulation of fluid noted at any time.

CASE 5* Male Aged thirty-six years Diagnosis Arsphenamine Jaundice Congenital Syphilis

Present Illness Intensive bismuth therapy start

*Metabolism ward

ed one and one-half years before admission. Weekly injections of arsphenamine for one month up to ten weeks before admission. Dark urine, clay colored stools, anorexia, epigastric burning.

Past History Negative except for congenital syphilis.

Physical Examination. Deeply jaundiced. Liver edge felt 8 cm. below costal margin in midclavicular line, very tender, spleen felt easily. Mousy odor to breath. No edema, ascites or hydrothorax.

Laboratory Data. Van den Bergh on admission 28 mgm. bilirubin per 100 cc. Six days later 12 mgm. per 100 cc. On discharge 4.0 mgm per 100 cc.

Treatment. High carbohydrate diet and rest.

Progress. Beginning diuresis noted on sixth day after admission (chart 5) with associated improvement in appetite and freedom from nausea. Diuresis continued with uninterrupted improvement in all clinical symptoms.

Case 6 Female Aged forty-seven years. Diagnosis Subacute Yellow Atrophy Due to Cinchophen.

Present Illness Joint pains for some months preceding admission with intermittent cinchophen (Parastan) therapy for about four months. Acute respiratory infection four months before admission. Two months before admission, malaise weakness

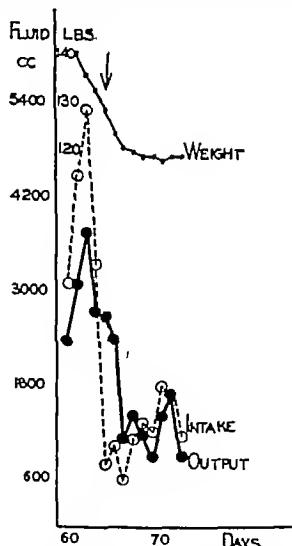

CHART 5 Subacute Yellow Atrophy—Cinchophen. Arrow indicates the appearance of obvious clinical improvement.

and nausea followed one week later by jaundice with clay-colored stools and dark urine. Slight elevation of temperature and in bed for a few days. For six weeks before admission up and around with increasing loss of strength increasing jaundice and intense itching. For at least three weeks before admission, edema of feet and swelling of the abdomen. Cough and pleuritic pain in left chest some weeks before admission.

Past History Unimportant except for mild attack of catarrhal jaundice twenty-eight years before.

Physical Examination. Well-developed, fairly nourished deeply jaundiced woman. Purpuric spots over body and excoriations from scratching. Signs of bilateral hydrothorax, obvious ascites and edema of the legs. Edge of liver felt by careful palpation about three fingers below costal margin and tender. Spleen just palpable.

Laboratory Data. Stools brown. Urine showed a trace of bile. Bromsulphalein test showed 85 per cent retention at the end of one-half hour. Van den Bergh 5.5 mgm. bilirubin per 100 cc.

Treatment. Rest in bed removal of cinchophen high carbohydrate diet, intravenous glucose 1000 cc. 10 per cent daily for first four days.

Progress. Marked diuresis throughout fifth to eighth days inclusive with a relatively high urinary output and again marked diuresis on the twentieth day (chart 6). Loss of twenty-four pounds in body weight in ten days with associated improvement in symptoms and rather rapid disappearance of edema and ascites. At the end of three weeks liver and spleen not palpable. On discharge van den Bergh showed 3.5 mgm. bilirubin per 100 cc., bromsulphalein test showed 25 per cent retention at the end of half an hour. Subsequent course was one of gradual but continuous improvement as determined by symptoms and laboratory data.

Case 7 Female Aged forty-six years. Diagnosis Subacute Yellow Atrophy—Cinchophen.

Present Illness Five years before admission painful swollen knees following an acute infection

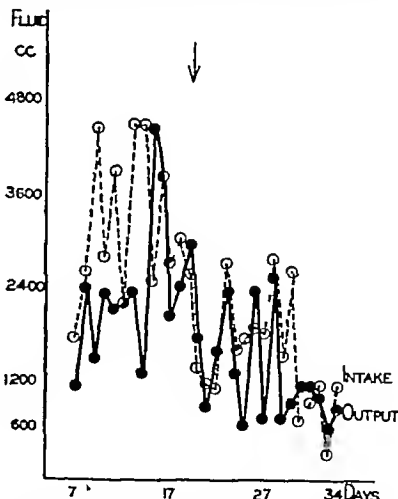

CHART 7 Subacute Yellow Atrophy—Cinchophen. Arrow indicates the appearance of obvious clinical improvement.

Treated by local applications and an "expensive medicine" nature unknown. Six weeks later developed nausea, vomiting and jaundice and lost weight. Entered another hospital and after six weeks of rest and a high carbohydrate diet was discharged relieved. Apparently in good health until one month before admission when patient complained of right shoulder pain. In three days she took Atuphan tablets followed in three weeks by

Probably a cinchophen derivative.

dark urine, anorexia, weakness, nausea and vomiting and obvious jaundice

Past History Irrelevant.

Physical Examination Deeply jaundiced, liver edge palpable, slightly tender Tip of spleen just felt No edema, ascites or hydrothorax

Laboratory Data Stools light brown. Urine contained bile on admission examination Van den Bergh 125 mgm bilirubin per 100 cc, gradually increasing over a period of three weeks to 42 mgm. per 100 cc

Progress One week after admission moderate diuresis noted (chart 7) Twelve days after admission marked diuresis associated with gradual improvement in symptoms, return of appetite, diminution of vomiting, and gradual but steady improvement from this point on, although no decrease in the jaundice was noted until one month after admission

CASE 8* Female Aged fifty six years Diagnosis Granuloma Inguinale Subacute Yellow Atrophy due to Antimony

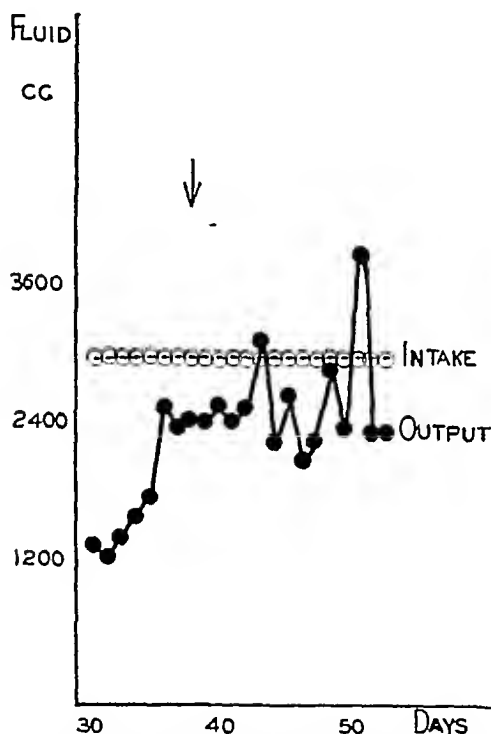

CHART 8 Liver Damage Due to Antimony Poisoning
Arrow indicates the appearance of obvious clinical improvement

Present Illness Admitted to Skin Service five months previously with a diagnosis of granuloma inguinale, semi-weekly injections since admission. One month prior to admission to the medical ward, anorexia, nausea and dizziness following medication. One week later dark urine with jaundice appeared, nine days before transfer to medical ward

Past History Essentially negative

Physical Examination Well developed and nourished, deeply jaundiced Granuloma inguinale lesions and liver easily palpable

Laboratory Data Urine contained a large amount of bile Stools light brown Van den Bergh on admission 23 mgm per 100 cc At discharge 25 days later 64 mgm per 100 cc

Treatment Rest, omission of tartar emetic treatment, high carbohydrate diet.

Progress Disappearance of nausea and vomiting and return of appetite one week after admission in

*Metabolism Ward

association with the appearance of moderate diuresis Marked diuresis noted on the thirteenth day and this persisted with a still more striking increase up to the nineteenth day (chart 8) Continuous and rapid improvement in symptoms At no time was there any evidence of abnormal accumulation of fluid in the tissues or serous cavities

CASE 9 Female Aged thirty nine years Diagnosis Acute Yellow Atrophy, cause unknown.

Present Illness Insidious onset of anorexia for some weeks before admission Much more marked two and one-half weeks before admission with actual distaste for food Five days before admission painless jaundice with dark urine and clay-colored stools

Past History Negative

Physical Examination Well developed and fairly nourished woman with deep jaundice Liver edge felt two fingers below right costal margin in mid clavicular line and slightly tender Spleen just palpable

Laboratory Data Van den Bergh on admission was 16 mgm bilirubin per 100 cc, six weeks after

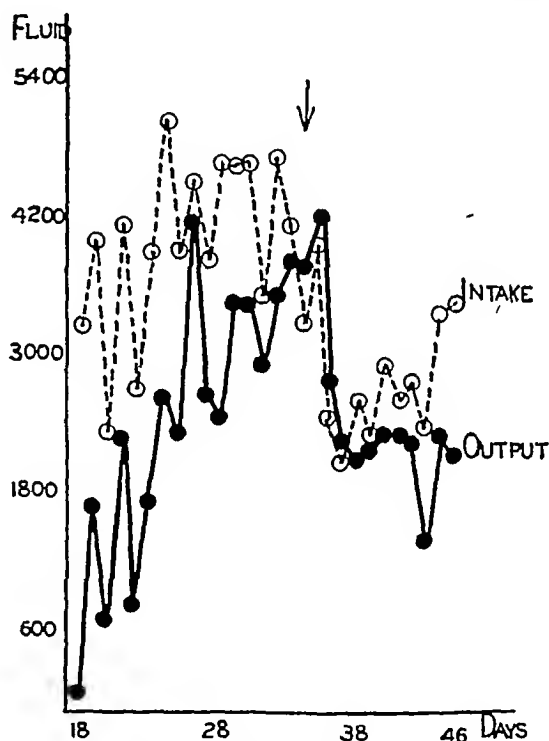

CHART 9 Acute Yellow Atrophy
Arrow indicates the appearance of obvious clinical improvement

admission (at discharge) 14 mgm per 100 cc. Stools clay colored for first ten days Urine continued to show very slight quantities of bile at discharge

Treatment Continuous rest in bed, moderately high carbohydrate diet which patient was practically unable to take until real clinical improvement set in, constant intravenous glucose for sixteen days, after which it was discontinued because of thrombosis of all available veins High carbohydrate diet from then on

Progress Patient became rapidly more jaundiced and anorexia, nausea and vomiting increased Liver diminished in size and her condition was steadily becoming worse during the first two weeks on the ward Ascites thought to be present toward the end of this period and definite pitting edema of the ankles At about the time that further intravenous treatment became impossible because of throm

basis of the veins a definite diuresis occurred (chart 9) and coincidentally the patient's appetite began to return and the nausea commenced to disappear. From this point on it was possible to feed the patient adequate amounts of food by mouth and within five days there was a complete disappearance of edema and all signs of ascites had vanished. At this point the patient began to improve strikingly her appetite was good and there was no difficulty thereafter from any gastrointestinal symptoms. Two months after admission patient was discharged, still jaundiced but apparently progressing favorably. Patient subsequently had a complete return to normal health so far as could be ascertained by the usual clinical measures or by any liver function tests.

CASE 10 Male Aged forty three years. Diagnosis ? Cirrhosis of the Liver Acute Yellow Atrophy

Present Illness. Two months before admission patient was operated on because of sharp right lower quadrant pain and the appendix was removed. At the time it was noted that there was much free

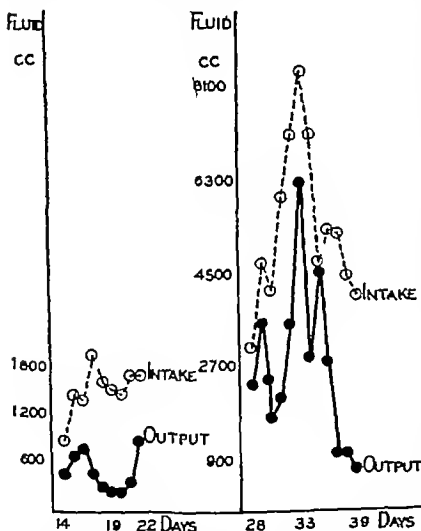

CHART 10. The above graphs illustrate the findings in two fatal cases of acute yellow atrophy.

fluid in the abdomen. Rise in temperature, day following operation and constant fever until present admission to the Massachusetts General Hospital, associated with great weakness. Swelling of the abdomen was noted followed by jaundice and clay colored stools. The patient complained of dull aching pain over the entire abdomen.

Physical Examination. Deeply jaundiced individual with obvious ascites and a few distended veins on the abdominal wall. Slight pitting edema of the lower extremities. After abdominal paracentesis it was possible to palpate the left lobe of an enlarged liver just above an epigastric hernia and in addition the tip of the spleen was felt two centimeters below the left costal margin.

Laboratory Data. Van den Bergh on admission was 16 mgm. per 100 cc. five days later 23 mgm

eight days after admission 30 mgm. Bromsulphalein retention on admission 100+ per cent. Tyrosin crystals found in urine a few days after admission.

Treatment. Rest in bed. High carbohydrate diet during the first days of stay in hospital and daily intravenous injections of ten per cent glucose.

Progress. Jaundice and ascites increased rapidly. Patient went downhill steadily became irrational after a few days finally sank into a deep coma and died thirteen days after admission. No diuresis noted.

It is of incidental interest that sharp abdominal pain associated with acute yellow atrophy may simulate an acute surgical emergency and only at operation may the underlying condition be determined.

CASE 11 Male Aged sixty three years. Diagnosis Acute Yellow Atrophy cause unknown.

Present Illness. Four weeks before admission joint pains lasting for one week with onset of constipation occasional vomiting after meals, marked anorexia and weakness. For three weeks before admission dark urine clay-colored stools and clinical jaundice.

Past History. Unimportant.

Physical Examination. Very sick underweight deeply jaundiced individual with money breath liver edge not palpable. Ascites and edema.

Laboratory Data. On admission the urine contained bile. Stools were light colored. Admission van den Bergh showed 22 mgm bilirubin per 100 cc. which on the following day increased to 26 mgm per 100 cc. Bromsulphalein retention 100+ per cent at the end of one-half hour. Further determinations not made.

Treatment. Patient was obviously extremely ill from the day of admission and intravenous glucose was administered daily 1000 cc. 10 per cent glucose a day for nine days. In addition an attempt was made to feed him a high carbohydrate diet by means of a nasal catheter.

Progress. Patient became comatose after about the third day and went steadily downhill and died thirteen days after admission. It will be noted from the graph shown on the right side of chart 10 that with the exception of a transient rise in the output of urine on the ninth day there was no diuresis during the patient's stay in the hospital.

The following case (chart 11) is presented as an example of chronic liver disease (alcoholic cirrhosis) with a superimposed acute exacerbation of liver injury which probably could be termed acute yellow atrophy. The acute phase of the disease was treated by the use of all the various measures indicated in the treatment of serious liver disease. Diuresis was obtained after the repeated administration of salyrgan and was in contrast to the spontaneous diuresis noted in the preceding cases. With the excretion of larger amounts of urine following each administration of salyrgan there was clinical improvement in the condition of the patient but not until a marked spontaneous diuresis occurred did consistent improvement take place.

CASE 12 Male Aged thirty-eight years. Diagnosis Alcoholic Cirrhosis of the Liver and Subacute Yellow Atrophy Due to Excessive Alcohol.

Past History. Essentially negative except for a mild attack of catarrhal jaundice twenty years before. Patient has been an exceedingly heavy drinker using at least a quart of alcohol daily. Two years before present illness he developed a crippling per

ipheral neuritis which incapacitated him for a year, during which time he stopped drinking. At the end of a year he resumed his accustomed alcoholic intake which he maintained until the beginning of the present illness.

Present Illness Without any particular warning, after an unusually large intake of distilled liquor, the patient became sick with marked malaise and the rapid onset of jaundice. This persisted for one week and was followed by the rapid development of coma and sudden increase in the size of the abdomen and legs due to ascites and peripheral edema. For two weeks there was slight elevation of temperature. Patient practically unconscious for the first two months of his illness. During this time tyrosin and leucin were found in the urine on many occasions. There was a marked acidosis with the CO_2 combining power dropping to 30 vol per cent and remaining at that level for two months.

cites, pitting edema of the hands, sacrum, thighs, legs, and some apparent edema of the face, bilateral pneumothorax, splenic friction rub and purpura. Ballottement revealed an extremely hard, nodular liver, the edge of which was demonstrable one hand breadth below the costal margin from the right axillary line to the left midclavicular line. After tapping, the spleen was easily palpable four fingers below the costal margin.

Laboratory Data Red count 2,990,000. Bromsulphalein retention 40 per cent. Van den Bergh 25 mgm bilirubin per 100 cc. Urine bile +. Stools clay color. Because of the difficulty of intravenous medication no further attempts were made to study liver function by laboratory tests.

Treatment. Rest in bed, as high a carbohydrate diet as patient could take, limitation of fluid to 1200 cc, repeated injections of salyrgan, transfusion and intravenous glucose therapy and one abdominal

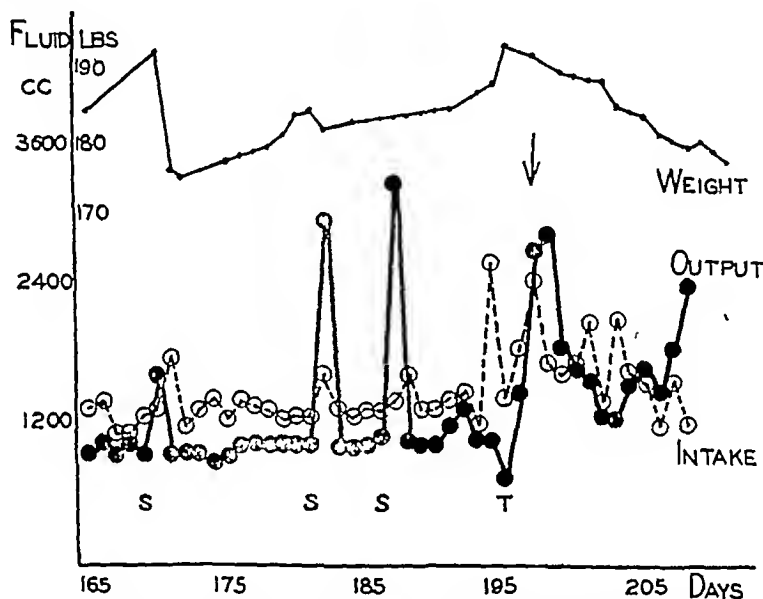

CHART 11. Alcoholic Cirrhosis—Subacute Yellow Atrophy
At the points marked S on the chart 2 cc. of salyrgan was given intravenously with a striking temporary response. A severe transfusion reaction occurred at the point marked T and was followed by a period of anuria. Two large injections of 25 per cent glucose were given at this point with the production of a marked diuresis which persisted for many days in sharp distinction to that following the use of salyrgan.

Abdominal drainage by paracentesis was necessary at intervals of about ten days. Jaundice increased rapidly for one month and then very gradually dropped to a lower level where it continued for the following three months. An anemia ranging between two and three million red cells per cubic millimeter was encountered after the end of the first month.

Treatment was persistent and heroic and consisted in almost daily intravenous injections of glucose totaling between 100 to 200 grams a day. Bicarbonate of soda was given intravenously in addition to the glucose at the time of the most profound acidosis. Transfusions were employed on several occasions during the first four months of the illness. Salyrgan with and without the use of ammonium chloride was tried on several occasions without any response. At the end of two months the patient showed definite signs of improvement, became oriented and was able to take moderate amounts of food by mouth. At the end of five months he had improved sufficiently so that he was moved to Boston, where he came under our care.

Physical Examination (Five and one-half months after onset of present illness). An emaciated, moderately jaundiced individual with tremendous as

paracentesis. It will be noted from the accompanying chart that each administration of salyrgan was followed by an increasingly marked diuresis. The abdominal paracentesis was performed when the patient was first seen and although there was a definite return of ascites over the course of a month no further taps were performed. Because of the existing anemia it was decided to transfuse the patient again, one month after he was first seen. A citrate transfusion was given followed by an immediate unexplained transfusion reaction with resulting increase in jaundice and complete anuria. The patient's condition became very critical although he had been gradually improving up to this point. Two injections of 25 per cent glucose were administered within twenty-four hours and were followed by a sharp diuresis which persisted for a period of three days with rapid disappearance of the ascites and drop in weight. His appetite returned at this point and steady improvement continued without interruption. Another period of spontaneous diuresis was noted about ten days later and from then on the patient made an uninterrupted recovery from the point of view of acute liver insufficiency. His jaundice practically disappeared, the ascites and hydrothorax completely disappeared and there was

no further peripheral edema. The purpura had previously passed. Hepatic and splenic enlargement and a pleural friction rub persisted but the patient was able to be up and around and led a fairly active existence for one year. At the end of this period while he was still showing gradual clinical improvement he contracted an acute respiratory infection and died in a few days.

A graphic description of fluid intake and urine output with corresponding changes in weight is shown in the accompanying chart. It will be noted from the chart that there is a striking difference between the diuresis obtained after the use of salyrgan and that observed as a spontaneous occurrence after the transfusion reaction. Lasting clinical improvement did not occur until a prolonged spontaneous diuresis had occurred.

DISCUSSION

It is obvious from the preceding charts that a definite diuresis occurred in a group of patients suffering from severe acute and subacute liver disease due to various causes. As previously noted (table 1) a similar diuresis was observed in three-fourths of a group of fifty patients seen at the Massachusetts General Hospital during recent years. Absence of an increased urinary output was seen only in the relatively mild cases which improved rapidly or in those cases which did not respond to treatment and which came to a fatal termination. The degree of diuresis varied in individual cases and as a rule was less in those patients who presented no clinical evidence of edema, ascites, or hydrothorax. Such a finding was obviously to be expected but it is of extreme interest to note that in many individual cases a pronounced and prolonged increase in urinary output occurred during the period of clinical improvement, even in the absence of any evidence of an abnormal accumulation of fluid in the serous cavities or in the tissues. In a large majority, such spontaneous increases in urinary output were associated with rapid improvement in all symptoms and at times the change was extremely striking once diuresis was established. Occasionally diuresis occurred as long as a week before any favorable change was noted but more frequently it immediately preceded the patient's improvement. There seemed to be no particular difference in the degree of diuresis obtained in those cases treated by rest and diet alone and in those which received additional therapy by intravenous glucose. It is of interest to note that in association with the diuresis following salyrgan, clinical improvement may not be an associated finding.

In only three out of thirty-seven cases showing diuresis during the course of the disease was there a failure to improve. In all the other cases improvement was continuous following the establishment of a real diuresis and the patient either recovered completely or at least entirely recovered from the acute liver injury even

though there remained some permanent damage to the liver. The nature of the acute or subacute liver injury seemed to have no relation to the patient's ability to establish a diuresis and it seems highly probable that the occurrence of this phenomenon was associated directly with an improvement in the function of a previously abnormal liver.

It is not within the scope of this paper to discuss possible physiological changes taking place in association with this diuresis. As previously indicated, many factors undoubtedly play a rôle in the abnormal accumulation of fluid as well as its removal during the different phases of liver disease. There can be no doubt, however, that following the removal of specific toxins, if they existed, plus rest and appropriate glucose therapy, hepatic efficiency was increased and concomitantly there was a shift in fluids from the tissues or serous cavities to the blood stream with the ultimate establishment of diuresis. Because of the fact that diuresis may occur even in the absence of obvious fluid accumulation it is highly probable that in most cases of seriously acute liver injury edema of the tissues is nearly always present although it may not be clinically demonstrable. We believe that the finding of such a shift in body fluids offers an excellent means of demonstrating changes in liver function and may be used clinically as a valuable prognostic aid in patients suffering from liver disease. We wish to stress the probable difference between the diuresis frequently noted after the use of salyrgan and that occurring without the administration of diuretic drugs. In the cases showing a spontaneous diuresis, prolonged clinical improvement apparently is a much more consistent result. This is well shown in the case illustrated by chart 11.

Of the various liver function tests that are at present in general use, few if any are of prognostic value unless repeated frequently throughout the course of the disease in order to obtain comparative determinations. The progress of a given case may be adequately followed by observations on the course of the jaundice, variations in the retention of the dye, variations in galactose tolerance, and the like, but frequently these tests fail to give an adequate basis for prognostication. Recent studies by Jones and Fish¹² indicate that single determinations of a plasma fatty acid carboxyl following the administration of adrenalin at times have real value for determining the future progress of a given case. All of the tests that have been devised to date require adequate and sometimes complicated laboratory facilities, such as are usually available only in hospitals and large medical centers. It is particularly for this reason that we have felt the importance of noting the appearance of a spontaneous diuresis in patients suffering from various acute or subacute

disorders of the liver Inasmuch as the only requirements for such a determination are approximately accurate estimations of fluid intake and urine output it is obvious that such observations can be made at the home as well as by the hospital bedside We believe that the observations recorded above warrant the significance that we have attached to such a procedure as being one of real clinical and prognostic interest When it occurs, we believe the appearance of a spontaneous diuresis in cases of serious liver injury nearly always means a fairly rapid and continuous change for the better in the patient's condition provided adequate treatment is maintained As a clinical sign it should be looked for and used as a prognostic guide

SUMMARY

- (1) We have discussed the common occurrence of abnormal accumulations of fluid in patients suffering from acute and subacute diseases of the liver
- (2) In a relatively unselected group of patients suffering from acute and subacute hepatic disorders we have noted the appearance of what may be called a spontaneous diuresis in a large proportion of cases
- (3) Following the appearance of such a phenomenon we have found almost invariable and continuous clinical improvement
- (4) We suggest the simple determination of fluid intake and urine output by ordinary measurements as a means of noting the appearance of such a diuresis and believe that such a test constitutes a simple and adequate means of determining prognosis in such cases

MYXEDEMA HEART

Report of a Case

BY JULIAN C GANT, M.D.*

LITERATURE

THE literature on the subject of the so-called "Myxedema Heart" has been accumulating since Zondek's¹ original paper published in 1918 The American literature begins with the report of a striking case by Fahr² in 1925 The findings of these original observers have been confirmed by a number of writers No attempt will be made to review the literature in this brief report as several excellent reviews have been given recently³⁻⁵ In the earlier papers there was considerable difference of opinion with reference to the "Myxedema

Heart" At present, however, there seems to be a uniformity of opinion on the existence of a cardiac syndrome characteristic of myxedema The generally enlarged heart, with characteristic electrocardiographic changes which return to normal after thyroid therapy, has been described by a number of writers While the mechanism by which these changes are produced is not clearly understood, the existence of this syndrome is no longer questioned

There is some difference of opinion on the point of the frequency of congestive failure in uncomplicated myxedema The observers at the Thyroid Clinic of the Massachusetts General Hospital³ feel that failure is relatively rare and

*Gant, Julian C—Assistant in Medicine Massachusetts General Hospital For record and address of author see "This Week's Issue" page 935

when present may be due to some complicating factor. Fahr⁹ and others believe that congestive failure is frequent in the absence of complications. The frequency with which the electrocardiographic changes occur is another controversial point. Ohler and Abramson⁴ found the changes in 62 per cent of these cases while Lerman, Clark and Means⁸ find these changes to be an essential part of the picture in 100 per cent of the cases. The presence or absence of pericardial effusion in this condition is as yet an unsettled point. Means⁷ points out the possible explanations of the cardiac enlargement as being hypertrophy, pericardial effusion, edema and dilatation. He states that pericardial effusion is possible but the x-ray appearance is against it. On the other hand Gordon⁶ reported a case where a large amount of fluid was withdrawn from the pericardium with a consequent reduction in the size of the heart shadow. This suggests that a pericardial effusion may account for the major part of the apparent enlargement of the heart. This would also account for the extreme sluggishness of heart action as seen under the fluoroscope. Thus sluggishness seems out of proportion to the size of the pulse and the degree of pulse pressure. It would seem reasonable to suppose that a pericardial effusion as well as an interstitial edema might be present in all cases in varying degrees. The question can only be settled by more pericardial taps and when more autopsy material is available.

So far as I know only two cases of auricular fibrillation occurring in myxedema heart have been previously reported. The first was reported by Walker⁵. In his case thyroid therapy had no effect on the fibrillation but no cause other than the myxedema could be found for the fibrillation. Quinidine was not tried. The other case of auricular fibrillation was given in the series reported by Ohler and Abramson⁴. In this patient sinus rhythm was restored by the giving of thyroid alone.

The case reported here is a striking example of reduction in size of the heart. So far as I am able to determine, there are but three previously recorded cases where the shrinkage in size was equal to or exceeded the one given here. The first was the original case of Fahr's³ and from the same clinic Davis¹⁰ published another one in 1931. The third is in the series of Lerman, Clark and Means⁸ appearing in 1933.

CASE REPORT

The patient was a white female aged sixty-six, complaining chiefly of general weakness, sleepiness and sluggishness. She had been a delicate child but had worked very hard as a young woman. Measles and whooping cough were the only childhood diseases. At the age of twelve she had had night-sweats. There were three normal pregnancies at the ages of eighteen, twenty-two and thirty-four. She enjoyed her best health during the five years following the birth of the third child.

Twenty-five years ago (1910) the uterus was removed because of a fibroid tumor and at the same time one ovary and half the other were taken out. The definite decline in health dates from the time the teeth were removed eight years ago. There was considerable hemorrhage following the extractions resulting in a weakness from which she did not recover. The general weakness and lethargy were progressive but became much more noticeable to the patient and her family two years ago. At that time she had a lump in the neck which caused a sore throat and difficulty in swallowing. The lump disappeared after about ten months. There has been no recurrence. The typical complaints of a myxedema patient were present. She did not enjoy anything, was unable to read and had no interest in her friends or her church. Concentration and memory were almost nil. While the skin had always been dry it had been much worse during the past two years. The hair had become brittle and there had been marked thinning. She was always cold, requiring an excessively warm living room and added clothing. The family had noticed the change in facial expression and marked slowness of speech and motion. As she put it, she just "wanted to be completely lazy." There was much indigestion and the appetite was rather poor. Her bowels were sluggish and the use of cathartics necessary. She was not overweight and there had been no significant change in weight. Dyspnea while not distressing was very definite. There was no orthopnea, no cough or precordial pain. There was a moderate amount of swelling of the ankles.

Physical examination revealed many of the typical signs of myxedema. Motion and speech were slow in the extreme. The face was pale, waxy and masklike. There was the usual puffiness around the eyes with the narrowing of the palpebral angles. The hair was dry and brittle and there was a near baldness on the top of the head. The skin was dry and scaly; this was very conspicuous on the arms where scales several mm. in diameter could be peeled off. No abnormality of the thyroid was found. Persistent crepitant rales were heard at both lung bases. The heart was markedly enlarged to percussion both to the left and right. Heart sounds were very distant and no murmurs were heard. The systolic blood pressure was 150 mm. and the diastolic 80 mm. The abdomen was rather prominent but no definite evidence of fluid could be made out. There was a moderate amount of pitting edema of the ankles. The cardiac enlargement was confirmed by fluoroscopic examination and the heart action was noted to be very sluggish.

There was a moderate degree of secondary anemia, the hemoglobin being 60 per cent, red blood cell count 3,480,000 and the white cell count 3,850. A teleroentgenogram of the heart showed general enlargement, the transverse diameter being 18.2 cm. and that of the chest 23 cm. The electrocardiogram showed auricular fibrillation with a ventricular rate of 60. The T waves were iso-electric and the QRS complexes were low. There was no abnormal axis deviation. The basal metabolism was minus 46 per cent.

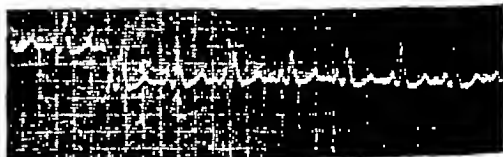

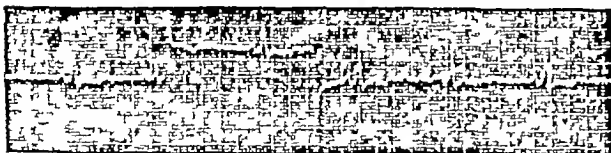

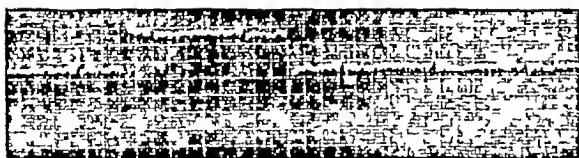

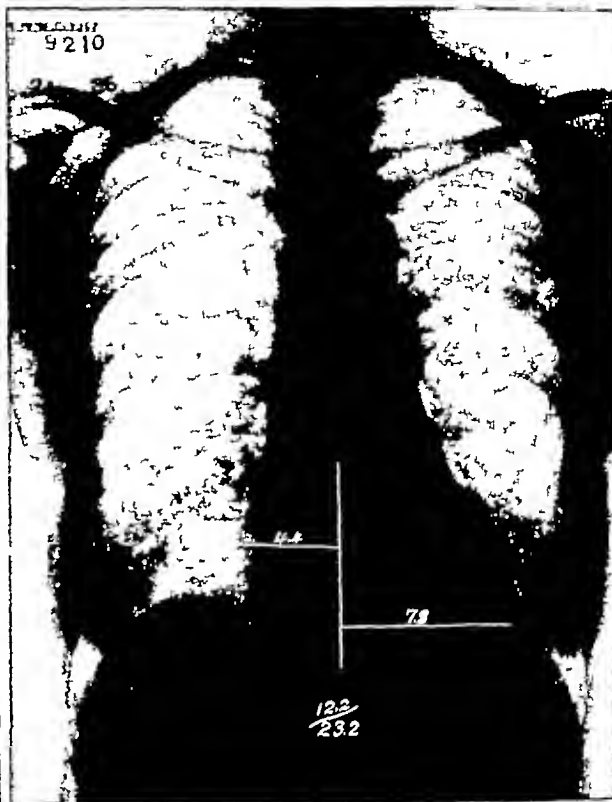

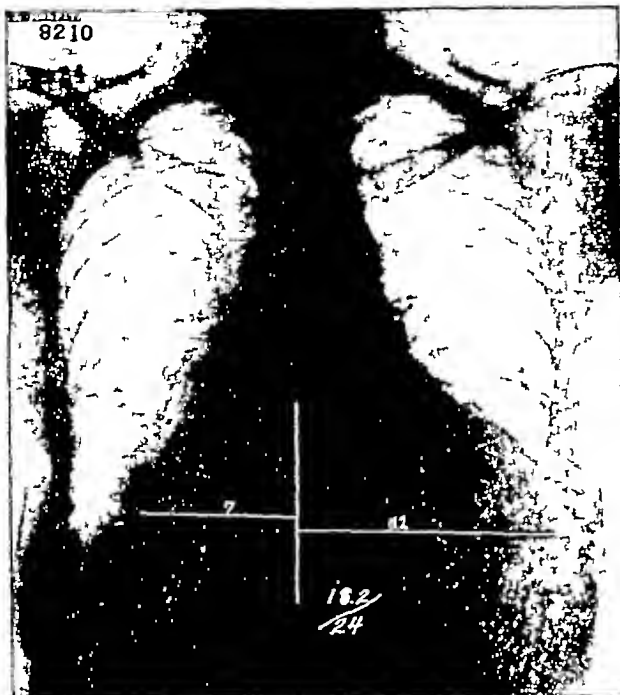

The patient was put on bed rest and started on $\frac{1}{4}$ gr. thyroid substance (Armon's) daily. The dose of thyroid was increased by $\frac{1}{4}$ gr. every three days. When the thyroid dosage reached 3 grs. daily the patient became increasingly nervous, making necessary a reduction in the daily dose. Eight weeks after starting treatment the patient took cold and also developed marked anorexia and some nausea. At this time the dose of thyroid was still further reduced to $1\frac{1}{2}$ grs. daily. After this opi-

sode her appetite improved and she gained strength more rapidly. During this period the systolic blood pressure varied from 120 to 150, the diastolic ranging from 50 to 80.

Five and one-half months after the first observations were made she entered the hospital for the second series of observations. The accompanying photographs show the marked change that had taken place. The thin brittle hair had been replaced by thick, brown hair with normal texture. The eyes were bright and the mask-like, waxy ap-

plaints had disappeared. The appetite was good and the bowels functioned normally. She was active and quick motioned. Her family and friends recognized her as an entirely changed individual.

The second teleroentgenogram showed that the transverse diameter of the heart had decreased by 6 cm and there was no evidence of congestive failure,

Date December 5 1934 Serial No 232

pearance had entirely disappeared. The skin was smooth and of fine texture as contrasted with the coarse scaly skin previously seen. She was alert, responding readily to questions and conversing interestedly. A moderate amount of general weakness still persisted but other than this the old com-

Date May 21 1935 Serial No 273

the lungs being entirely clear. The cardio thoracic ratio was normal. The electrocardiogram showed that normal rhythm had been restored. The rate was 90. The voltage was normal and the T waves were upright in all leads. There was a slight degree of intraventricular block and the QRS complex was widened to 12 sec. The basal metabolism was

minus 13½ per cent. Her weight was 103 lbs., this was 15 lbs less than her weight 5½ months previously. During the entire time the patient had been taking liver and iron (Lextron, Lilly) for the anemia. The hemoglobin was 65 per cent and the red cell count was 3 780 000

DISCUSSION

This report adds to the literature one more case of congestive heart failure associated with myxedema. That congestive failure was present is shown by the dyspnea and peripheral edema with the pulmonary congestion shown both by auscultation and x ray. Part of the gross enlargement here shown is no doubt due to the dilatation usually accompanying congestive failure. In this case the picture may not be due to uncomplicated myxedema, in view of the persistent intraventricular block and rather rapid heart on only 1½ grs of thyroid substance. However, the fact that the patient is now active without any signs of failure suggests that myxedema is the added factor responsible for the heart failure.

Myxedema as one of the causes for auricular fibrillation is suggested by this case. This seems strange in view of the frequency of this arrhythmia in hyperthyroidism. That normal rhythm was established coincidentally with the giving of thyroid in this case is a fact worth noting. The possibility of it being a coincidental finding is recognized.

This report again emphasizes two other points brought out several times in the literature. First, myxedema must be thought of in the normal and even underweight individual, as well as the obese. Secondly, thyroid must be given cautiously in these individuals. While it may be necessary gradually to increase the dose up to 8 or even 4 grs daily to rid the patient of all the signs of myxedema, the maintenance dose will usually be small. If an error is made it should be made on the side of caution. In cases with cardiac complications it is safer to maintain a basal metabolic rate of 15 to 20 per cent rather than bring them up to the theoretical normal.

MASSACHUSETTS STATE HEALTH COMMISSION

BY FRANK KIERNAN, A.B.*

ACTING under authority of Chapter XI of the Resolves of 1935, Governor James M. Curley on August twenty first appointed the Massachusetts State Health Commission to make a study and proposed revision of the public health laws and practices of the Commonwealth. The last study of this kind was made by Mr. Lemuel Shattuck in 1850. Mr. Shattuck's report, which is now a rare and historic document, described the public health practices and regulations of his day and made recommendations for improving them. Among the major recommendations of his report were the following: the appointment of a state health officer, the appointment of a State Board of Health, a revision of the laws relating to health, a record of vital statistics in the Health Department, and the establishment of a school of nurses at the Massachusetts General Hospital. He also advocated reforms in industrial hygiene and pointed out the growing menace of pools of stagnant water adjacent to mill ponds.

In the eighty five years which have passed

Kiernan, Frank—Executive Secretary Massachusetts Tuberculosis League, Inc. For record and address of author see "This Week's Issue," page 325.

since the Shattuck report much legislation affecting health, especially in recent years, has been enacted into law. Practices and procedure of public health useful ten, twenty, or fifty years ago have in the course of time become inadequate to meet the complexities of modern life. New laws have often been added to the statute books without sufficient thought as to their integration as part of the rational legal system for public health. Practices have grown up to meet current needs without sufficient planning as to the rôle they will ultimately play in the whole scheme of public health. For these reasons a revision of the laws and practices has been in the minds of public health officials for several years. As far back as the administration of Dr. Eugene Kelley as State Commissioner of Public Health and later in the administration of Dr. George H. Bigelow, the subject was discussed.

In October, 1934, the Massachusetts Central Health Council, an organization composed of fifteen public and private, state-wide health agencies, crystallized opinion on this subject and appointed a committee to initiate the movement to

secure affirmative action Professor Curtis M Hilliard, President of the Council, appointed for this purpose the following committee

Dr Wilson G Smillie, Chairman
 Dr Henry D Chadwick
 Dr Francis P Denny
 Mrs Leslie B Cutler
 Prof Curtis M Hilliard
 Dr William H Robey
 Dr Charles F Wilmsky
 Dr Gaylord W Anderson
 Mr Frank Kiernan

Dr Charles F Wilmsky, Deputy Commissioner of Health of the City of Boston, and Director of the Beth Israel Hospital, was Chairman of a Sub-Committee which guided the proposal through the various stages of its development, including the enactment of the necessary legislation for the appointment of the Commission. Part of the work of the committee named above was to secure a grant of funds for defraying the cost of the study. A grant of \$10,000 was secured from the Commonwealth Fund, which has also underwritten the cost of a number of public health projects in the Commonwealth.

The members of the Commission appointed by Gov Curley are as follows

Dr Henry D Chadwick,
 State Commissioner of Public Health
 Dr Winfred Overholser,
 State Commissioner of Mental Diseases
 Dr Charles E Mongan,
 President, Massachusetts Medical Society
 Professor Curtis M Hilliard,
 President, Massachusetts Health Council and Professor of Biology and Public Health, Simmons College
 Dr Wilson G Smillie,
 Professor of Public Health Administration, Harvard School of Public Health
 Dr Alexander S Begg,
 Dean, Boston University School of Medicine and Secretary, Massachusetts Medical Society
 Prof Samuel C Prescott,
 Dean of Science and Professor of Industrial Biology, Massachusetts Institute of Technology
 Dr Dwight O'Hara,
 Chairman, Public Health Committee, Massachusetts Medical Society and Professor of Preventive Medicine, Tufts College Medical School

Dr David D Seannell,
 Chief of Surgical Staff and President of Senior Staff, Boston City Hospital
 Dr Francis X Mahoney,
 Health Commissioner, City of Boston
 Dr Charles F Wilmsky,
 Deputy Health Commissioner, City of Boston and Executive Director, Beth Israel Hospital
 Dr Gerardo Balboni, Physician, Home for Italian Children and Member of the Staff of the Massachusetts General Hospital

The Commission, organized on September ninth, chose as its officers the following

Dr Henry D Chadwick, Chairman
 Dr Wilson G Smillie, Vice-Chairman
 Dr Charles F Wilmsky, Secretary-Treasurer

An executive committee was also appointed, which is composed of the officers and the following additional members of the Commission.

Dr Alexander S Begg
 Prof Curtis M Hilliard
 Dr Charles E Mongan

The Commission, at its organization meeting voted to adopt the policy followed by the New York State Commission which carried on a similar study of public health in 1932, viz, to appoint a number of special committees selected from leaders in the field of medicine and public health, the membership of the committees not to be confined to the Commission. The Commission decided upon thirteen such committees. The Commission leaders in the several fields which are to be studied by the special committees were asked to serve as chairmen. The list of the Committees, their chairmen and membership, is as follows

(1) *Codification of Public Health Laws*

Dr Henry D Chadwick, Chairman
 Dr Gaylord W Anderson
 Dr Alexander S Begg
 Dr Francis P Denny
 Prof Curtis M Hilliard
 Dr Francis X Mahoney
 Dr Charles E Mongan
 Dr Winfred Overholser

(2) *Public Health Practices and Procedure*

Dr Wilson G Smillie, Chairman
 Dr Gaylord W Anderson
 Prof Curtis M Hilliard
 Prof Murray P Horwood
 Dr Francis X Mahoney
 Dr Charles E Mongan
 Dr Ernest M Morris
 Dr Dwight O'Hara

Dr Stephen Rushmore
Dr L. Jackson Smith
Dr Charles F. Wilinsky

(3) *Communicable Disease Control*

Dr Paul R. Withington, Chairman
Dr Gaylord W. Anderson
Dr Frederick J. Bailey
Dr Henry D. Chadwick
Mrs Leslie B. Cntler
Miss A. Hamblin
Dr William O. Hewitt
Dr Edwin R. Leib
Dr Joseph W. Monahan
Dr Harrie W. Peirce
Dr Edwin H. Place
Dr John Pontas
Dr Elliott Robinson
Dr Conrad Wesselhoeft

(4) *Public Sanitation*

Prof Samuel C. Prescott, Chairman
Dr David L. Belding
Mr Joseph C. Cort
Mr Philip Drinker
Dr R. E. Dyer
Prof Gordon M. Fair
Prof. Murray P. Horwood
Dr James A. Keenan
Mr Hermann C. Lythgoe
Mr Frank E. Mott
Dr M. Victor Safford
Mr Arthur D. Weston
Mr Robert Spurr Weston

(5) *Maternal and Infant Hygiene*

Dr Frederick C. Irving, Chairman
Dr Stewart H. Clifford
Dr Robert L. DeNormandie
Dr M. Laue Diez
Dr Martin J. English
Dr Charles E. Mongan
Dr Charles W. O'Connor
Dr Lendon Snedeker
Miss Frances Stern
Dr Harold O. Stuart
Dr Charles F. Wilinsky

(6) *Child Hygiene*

Dr Richard M. Smith, Chairman
Dr Kirke Alexander
Rev Robert P. Barry
Dr Alice Blood
Dr Susan M. Coffin
Mrs Myron F. Converse
Dr Joseph Garland
Dr Percy R. Howe
Dr James A. Keenan
Miss Winifred Kenneren
Dr Fredrika Moore
Rev Richard J. Quinlan

Dr David D. Scannell
Mr Carl L. Schrader
Dr Warren R. Sisson
Dr Whitman G. Stickney
Dr Harold C. Stuart
Dr Douglas A. Thom
Mr Alfred Whitman
Dr Charles F. Wilinsky

(7) *Social Hygiene and Venereal Disease Control*

Dr E. Granville Crabtree, Chairman
Dr William P. Boardman
Miss Ida M. Cannon
Dr Oscar F. Cox, Jr
Dr Hilbert F. Day
Dr Harold L. Higgins
Dr Harold L. Leland
Dr Nels A. Nelson
Dr A. K. Paine
Miss Florence M. Patterson
Dr Dwight L. Suscoe
Dr Wilson G. Smilie
Mrs. Maida H. Solomon

(8) *Hospitals, Dispensaries, Clinics, and Health Centers*

Dr Frederio A. Washburn, Chairman
Rev Thomas J. Brennan
Richard K. Conant, Commissioner, Dept.
of Public Welfare
Dr Hilbert F. Day
Dr Nathaniel W. Faxon
Dr Channing Frothingham
Dr Joseph B. Howland
Dr George A. MacIver
Dr Henry M. Pollock
Mr Arthur G. Rotch
Dr David D. Scannell
Dr George C. Shattuck
Dr Eugene Walker
Dr Charles F. Wilinsky
Mr Frank E. Wing

(9) *Mental Hygiene*

Dr Winfred Overholser, Chairman
Dr Clarence A. Bonner
Dr L. Vernon Briggs
Dr Henry B. Elland
Dr Donald Gregg
Dr William Healy
Dr James V. May
Dr Douglas A. Thom
Dr Kenneth J. Tillotson

(10) *Tuberculosis Control*

Dr Frederick T. Lord, Chairman
Dr Gerardo M. Balboni
Miss Ethel Cohen
Dr Cleaveland Floyd
Dr John B. Hawes 2nd
Miss Eleanor Kelley
Mr Horace Morrison

Dr George O'Donnell
Dr Alton S Pope
Dr Sumner H Remick

(11) *Occupational Hygiene*

Mr Manfred Bowditch, Chairman
Dr W Irving Clark
Mr Philip Drinker
Dr Francis D Donoghue
Dr Dwight O'Hara
Dr Robert S Qunby
Mr Samuel Squibb
Mr Stephen E Whiting

(12) *Adult Hygiene and Special Medical Problems*

Dr Robert B Osgood, Chairman
Dr Walter Bauer
Dr Robert B Greenough
Dr Elliott P Joslin
Dr Herbert L Lombard
Dr George R Minot
Dr Charles E Mongan
Dr Frank R Ober
Dr William H Robey

(13) *Public Health Nursing*

Miss Florence M Patterson, Chairman
Miss Mabel M Brown
Prof Curtis M Hilliard
Miss Helen F McCaffrey
Mrs Harold A Marvin
Miss Sophie C Nelson
Miss Helen C Peck
Miss Marjorie Stimson

Miss Hazel Wedgwood
Miss Marion C Woodbury

On October twenty-first a general meeting of the chairmen of the committees was held at the office of Dr Henry D Chadwick in the State House. The general work of the Commission was discussed. The report of the New York State Commission, which will serve as a guide to the present group, was reviewed. Plans were made for calling the several committees into action within the near future.

The Commission has been fortunate in securing to carry on the field work, Dr Carl E Buck, Director of Field Service of the American Public Health Association. It has also been successful in securing Judge A K Cohen, the only living member of the State Commission which codified all the laws of the Commonwealth in 1921. Judge Cohen will assist the Commission in collating the present laws and preparing whatever new legislation the Commission may in its final report recommend.

The special committees as they meet will begin their work with a conference with Dr Henry D Chadwick, Chairman of the Commission.

An office for the Commission has been opened in Room 1150 in the Little Building adjacent to the offices of the Massachusetts Tuberculosis League. Mr Frank Kiernan, has been appointed Executive Secretary of the Commission. He is also Executive Secretary of the League. Miss Dorothy D Adams has been retained as Assistant Secretary.

PRACTICE OF ANESTHETIZATION*

The practice of anesthetization, at least so far as it relates to general anesthesia and spinal anesthesia, presents a problem different from that presented by the practice of roentgenology and of pathology. It comes more nearly, it seems to me, to making the anesthetist always a practitioner of medicine, who cannot lawfully perform his duties without having been licensed so to practice. In the course of anesthetization, reliance must be placed on the anesthetist's judgment to a very large extent, for the operating surgeon ordinarily finds his time and attention fully taken up with the operation itself. The relative independence of the anesthetist and the operating surgeon has been recognized in the decisions of courts that have held the operating surgeon not liable for the malpractice of the anesthetist although he is liable for the failure of those who may be properly termed his assistants to discharge the duties imposed on them. The custom of using anesthetists who are not licensed to practice medicine has, however, reached such proportions that it would be difficult to effect a change. Moreover, in effecting a change, it will be found necessary to take into consideration the difficulty of

finding in sparsely settled parts of the country physicians who can and will devote themselves to the practice of anesthetization to an extent sufficient to qualify them for such work in sufficient numbers to make them always available when needed.

Several states have enacted laws specifically authorizing the administration of anesthetics by unlicensed persons.

DRUG FIRMS FINED

Among the items which led to the successful conviction of several drug firms by the Federal Government are the following: internal medicine, cosmetics, liniments, pain killers, tonics for women's disorders, stomach, blood, liver, and functional ailments, gland treatments, laxatives, antiseptic soap, antirheumatic and tuberculosis medicines and a large number of preparations, alleged cures of other diseases.

The action of the government is based on fraudulent representation of efficacy of the various drugs, and tests in a government laboratory.

The concerns prosecuted in September were located in Tennessee, New York, Pennsylvania, Kansas and Massachusetts.

While much good is being accomplished, one may wonder why some of the best sellers among proprietary medicines are permitted to continue to do business.

*Extract from the address of Dr William C Woodward before the Joint Session of the Council on Medical Education and Hospitals and the Federation of State Medical Boards of the United States at the Annual Congress on Medical Education, Hospitals and Licensure, Chicago February 19 1935

CASE RECORDS

MASSACHUSETTS GENERAL
HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

FOUNDED BY RICHARD C CABOT M.D.

TRACY B MALLORY, M.D., Editor

CASE 21451

PRESENTATION OF CASE

A sixteen year old colored girl entered complaining of headache, stiff neck and generalized aches and pains.

She had been rather weak and readily fatigued during the four years prior to her admission but had been able to carry on ordinary light housework. She complained frequently during this time of headaches, dizziness and anorexia. Six weeks before entry she developed a bad cold which was associated with very severe epistaxis. She became quite weak and prostrated and lost five pounds within a week. Her neck became somewhat stiff and she complained of aching ears and dizziness. After two weeks in bed she arose for two days but became dyspneic, very weak, vomited several times and was compelled to return to bed. One week later she was admitted to a hospital. There was no cough, hemoptysis or night sweats. She complained of fleeting pain in the precordium and stabbing pain in the cervical spine and left knee. She ran a septic febrile course for seventeen days after her admission. Headache appeared, increased in severity, and since there was no improvement she was transferred to this hospital.

She had had a tonsillectomy, adenoidectomy and appendectomy seven years previously. She had had pneumonia at the age of eleven. For several years she had had repeated examinations at a tuberculosis clinic but no positive diagnosis had ever been made. She had had rheumatic fever at some time during her childhood.

Her mother died of heart disease. One sister was living and well.

Physical examination showed a well developed but thin young colored female who looked quite ill. The skin was warm and moist and the mucous membranes were slightly pallid. The pupils were artificially dilated. Fundus examination revealed bilateral papilledema of three to four diopters with some exudate. There was vague tenderness on pressure over the mastoids and frontal sinuses. Examination of the eardrums was not recorded. The neck and

vertebral column were remarkably rigid. The lungs were normal. The heart appeared to be markedly enlarged with the apex impulse in the sixth interspace near the midaxillary line. There was a questionable apical thrill. Loud systolic and diastolic murmurs were audible at the mitral area and transmitted to the base. P_2 was accentuated and greater than A_2 . The blood pressure was 180/50. The abdomen was soft but tenderness was elicited in both upper quadrants. There were no palpable masses. Neither the spleen nor the liver was felt. The knee jerks and ankle jerks were hyperactive. There were bilateral Kernig signs. The remainder of the examination was negative.

The temperature was 103° , the pulse 120. The respirations were 30.

Examination of the urine was negative except for a green reaction to Benedict's solution. The blood showed a red cell count of 3,300,000, with a hemoglobin of 56 per cent. The white cell count was 15,900, 90 per cent polymorphonuclears, 5 per cent lymphocytes, 2 per cent monocytes, 2 per cent eosinophils and one per cent basophils. A blood Wassermann was negative. A blood culture taken on the day following admission was positive for streptococcus hemolyticus.

A portable x-ray film demonstrated dullness in the left lower lung field which was obscured for the most part by an enlarged heart shadow.

The patient continued to complain of severe headache and pain in the right wrist and neck. A lumbar puncture was done and exhibited clear colorless fluid which was expelled with slightly increased pressure. There were 2 polymorphonuclears, 6 lymphocytes and 2 red blood cells per cubic millimeter. An alcohol test was very slightly positive and the ammonium sulphate test was negative. Sugar was 60 milligrams per cent. The Wassermann was negative and a culture of the fluid produced no growth. Four days after admission another lumbar tap revealed 640 cells per cubic millimeter, which were for the most part lymphocytes. Pressure was not increased and the fluid was clear. Ross-Jones and Pandey tests were negative. The protein was 71 milligrams per cent, the sugar 68 milligrams per cent. The chlorides were equivalent to 670 milligrams sodium chloride per 100 cubic centimeters of blood. Two days later petechiae were observed in the conjunctiva and subsequently several crops appeared elsewhere. Throughout her entire hospital stay the patient's temperature curve remained between 103° and 104° . She did not respond to palliative therapy and died on the eleventh day.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD C CABOT. Anyone would make a snap diagnosis of tuberculous meningitis after reading the first two lines of this history but

not her heart disease, would make her feel poorly

DR. CABOT They do not tell much about the joints at that time, that might have helped us to decide on that point.

As to the second point of Dr White's, cerebral abscess It is well taken and one that I should have said more about I have been fooled a number of times in saying meningitis when I should have said abscess Here it is not an important distinction In an ear case it would be an important distinction I do not know any way in which a differential diagnosis can be made with no localizing symptoms Abscess more often has none In the absence of any localizing brain symptoms I cannot say any more than Dr White has said, and I agree to it

DR ROBERT S PALMER What do you think of the bilateral papilledema without increased pressure by lumbar puncture?

DR CABOT I do not know what to think of it What do you think?

DR PALMER I have no idea

DR CHARLES S KUBIK Here is a record of the lumbar punctures, seven in all The spinal pressure at admission was 285, on two occasions it was 350, but following that it dropped and at the last lumbar puncture it was only 70

DR. CABOT That gives a higher impression than I had had before

DR ALFRED KRANES I saw this patient on the neurologic service and reached about the same conclusion as Dr Cabot has I might say that in the physical examination the murmur described as mitral was mainly aortic and she did have signs of consolidation or compression at her left base

She arrived with a letter from the hospital where she had been previously stating that they had done several blood cultures and obtained pneumococcus type I That was the only disturbing feature of the case We thought she had subacute bacterial endocarditis with meningeal lesions and probably a diffuse embolic encephalitis similar to several other patients we have seen The question of tuberculous meningitis came up but we thought that the high sugar on several taps practically ruled that out, although it was theoretically possible We felt if we could confirm the presence of type I pneumococcus it might be reasonable to try anti-pneumococcus serum The blood cultures showed hemolytic streptococcus and that was abandoned.

DR WHITE May I add a word about transmission of murmurs? The record says that "loud systolic and diastolic murmurs were audible at the mitral area and transmitted to the base" The truth is the other way round Aortic valve murmurs are often transmitted to the apex but mitral murmurs are almost never transmitted to the aortic area

DR MEANS Dr Mallory, Dr Crooke asked me if the radiologist could find any evidence of

congenital heart and explain the rest of the picture on that basis The clinical description does not sound like it

DR AUBREY O HAMPTON No, I do not think we can make anything out of that except a diffusely dilated heart with dilatation downwards to the left As Dr Cabot said, this is a portable film I would like to help you on the lower lobe but I do not think I can It could just as well be pressure atelectasis from enlargement of the heart, and there may be a small quantity of fluid on that side

DR TRACY B MALLORY Dr Kubik, you saw this patient clinically

DR KUBIK I might say a little more about the cerebrospinal fluid The cell count fluctuated a good deal At the first lumbar puncture only two or three cells were found, at another 649 They dropped after that to 46 and then went up to 300 and later dropped again to 150 We have seen other cases of bacterial endocarditis with meningeal symptoms in which the same thing has occurred In this case, as in most of the other cases that I have seen, the spinal fluid was xanthochromic and contained red blood cells, on one occasion 2,900 We often have difficulty in recovering organisms from the fluid and in some cases fail to find them This patient had seven lumbar punctures There is a record here of four cultures, all of them presumably negative Sugar content was normal and one wonders whether this was a real meningitis, or simply a cellular reaction due to embolism of small meningeal vessels without actual infection of the meninges by organisms Of course in addition to lesions in the meninges one would expect in a case of this kind to find numerous lesions in the brain, possibly many small lesions I do not believe that I have ever seen an abscess complicating bacterial endocarditis, but should suppose that it may occur

CLINICAL DIAGNOSES

Old rheumatic heart disease
Acute bacterial endocarditis (hemolytic streptococcus)
Multiple brain abscesses (embolic)

DR RICHARD C CABOT'S DIAGNOSES

Old rheumatic heart disease, aortic and possibly mitral
Bacterial endocarditis
Meningitis
Infarcts of the lung and spleen ?

ANATOMIC DIAGNOSES

Bacterial endocarditis, acute (hemolytic streptococcus), aortic, mitral and tricuspid
(Septicemia, hemolytic streptococcus)
Rheumatic heart disease, mitral, aortic

Cardiac hypertrophy
Multiple infarcts of the brain
Infarction of the spleen.
Nephritis, acute embolic, minimal
Pulmonary edema.
Pericardial effusion.
Operative scar Appendectomy
Petechial hemorrhages in conjunctivae, pericardium, and ureter
Pulmonary embolus.

PATHOLOGIC DISCUSSION

Dr. MALLORY The autopsy showed most of the findings that were expected. The heart was very much enlarged. It showed signs of old rheumatic heart disease on the mitral and aortic valves in the form of thickening and scarring of the leaflets and of the chordae tendineae not severe enough however, to suggest that either mitral stenosis or aortic insufficiency was present in significant degree until the terminal bacterial endocarditis developed. Bacterial vegetations were present on the aortic valve, where there was a very large mass, also on the mitral and they had spread onto the ventricular endocardium beneath the aortic valve and up on the auricular endocardium above the mitral valve. The tricuspid showed one small mass of vegetations and did not show any evidence of previous rheumatic involvement that we could make out. However, arising from the vegetation on the tricuspid there was a pulmonary embolus which had nearly completely plugged the artery leading to the right lower lobe. There was, however, no infarction. The left lower lobe was entirely negative. There was no evidence of old tuberculosis. As is almost invariably the case in bacterial endocarditis, we did find infarcts in other organs a couple of gross ones in the spleen, although the spleen as a whole was only very slightly enlarged. The kidneys showed no gross infarcts but on microscopic examination they showed the typical focal glomerular lesions that one regularly finds in cases of bacterial endocarditis.

The brain showed no grossly visible meningitis but on section small infarcts were found. There were no definite abscesses. I would agree with what Dr. Knibik said, that with bacterial endocarditis of the viridans type one probably never sees abscesses. I have frequently seen abscesses, however, when the endocarditis was due to the hemolytic streptococcus and I am a little surprised that the infarcts did not break down in this case.

Dr. WHITE Was this hemolytic?

Dr. MALLORY Yes.

Dr. CABOT Where did all these cells in the spinal fluid come from?

Dr. KUBIK That is rather hard to tell. We

have no microscopic sections of the brain as yet. I should expect to find some exudate in the subarachnoid space even though it is not visible to the naked eye. Here apparently there were showers of cells due possibly to successive emboli or crops of emboli with subsidence of the meningeal reaction in between.

CASE 21452

PRESENTATION OF CASE

A forty-eight year old married brass finisher was admitted complaining of loss of appetite, weakness and loss of weight.

About eight months prior to his admission the patient suffered a minor injury to his ankle. At this time he began to lose his appetite and soon developed weakness of the lower extremities and shortness of breath upon exertion. Shortly thereafter he had vague pain in one or the other shoulder and on the inner surface of the arms. This recurred several times a week. Occasionally he would be awakened at night with a sensation of suffocation and was compelled to sit up in bed. He continued to work although this became increasingly difficult for him. His appetite was so poor that he eliminated his breakfast and noon meal. Two months before admission he became very markedly dyspneic, even with minor exertion. At the same time weakness of the upper extremities became quite pronounced. He felt distended after meals, was frequently nauseated, and occasionally vomited. He now discontinued all regular meals and lived on a diet of raw eggs, beer, and milk. Six weeks before admission he found that three pillows beneath his head enabled him to sleep more comfortably. He suffered from a dull aching localized pain in the right costal margin which recurred every afternoon. Up to this time he had lost fifty-seven pounds. Three weeks prior to admission he was compelled to stop work. He began to vomit everything, except for the diet noted above, directly after ingestion. The vomitus was never blood stained. Ordinary walking became difficult because of asthenia and dyspnea. Two days before admission he developed an annoying cough associated with nasal discharge and hoarseness.

At the age of eighteen years he had been refused admission to the Army because of "rheumatic heart disease" although this had never caused him any symptoms. The patient had had influenza with pneumonia at the age of twenty-two years.

His father had died of "tuberculous abscess of the bronchus." He had one son then in the hospital with an appendiceal abscess. The remainder of the family history was negative.

His occupation had exposed him to aspiration of some brass dust

Physical examination revealed a well-developed, emaciated, slightly cyanotic and orthopedic man weighing 142 pounds. His teeth were in very poor condition and his breath was quite foul. The skin and mucous membranes were of normal color. His chest was normal in shape but there was absent tactile fremitus anteriorly from the third rib to the bottom on both sides. Posteriorly it was absent from the midportion of the scapula to the bases. These areas were percussed flat and breath sounds and vocal resonance were absent. The heart was normal in size and there were no murmurs audible. The blood pressure was 105/80. The abdomen was distended. There was shifting dullness in the flanks and a fluid wave was elicited. A tender liver edge was felt four centimeters below the costal margin. The spleen was not felt. The remainder of the physical examination was negative.

The temperature was 102.5°, the pulse 120. The respirations were 25.

Examination of the urine was negative except for a trace of bile. The blood showed a red cell count varying from 3,200,000 to 4,800,000 within two weeks, with a hemoglobin of 65 to 75 per cent (Tallqvist). The white cell count was 6,600 on admission and rose slowly to 11,950 during the period of hospitalization. There were 85 per cent polymorphonuclears, 10 lymphocytes and 5 monocytes. Platelets were reported as being normal. The sputum contained some blood but was otherwise negative. The vomitus was guaiac negative. The stools were negative. The serum protein was 6.9 per cent, the nonprotein nitrogen 28 milligrams per 100 cubic centimeters and the chlorides were equivalent to 94 cubic centimeters 0.1 normal chloride per 100 cubic centimeters. The icteric index was 4. A liver function test revealed 0 to 5 per cent retention. The van den Bergh gave a normal indirect reaction. A blood culture contained only contaminating diphtheroids.

X-ray examination revealed marked dullness in both lung fields obliterating the diaphragms. There was thickening in both lateral borders. There was stripe formation in the upper portion of dullness on the left side. The heart was displaced to the left and was not evidently enlarged. The lung markings were slightly increased with some mottling of the fields. The stomach and esophagus appeared to be negative. The liver was enlarged and the appearance of the abdomen suggested the presence of fluid.

On the second day a bilateral thoracentesis was performed, the left chest yielding 1,270 cubic centimeters of fluid and the right 550. This fluid had a specific gravity of 1.014 and

a total protein of 3.8 per cent. No organisms were present and there was no growth on culture. The cells were predominantly red blood cells. Takata-Ara reaction of serum and chest fluid was strongly positive. On the ninth day the patient felt well save for a continued poor appetite. Two days later his abdomen was observed to be rapidly enlarging. A week later the abdominal circumference began to diminish. There was occasional emesis. A chest tap obtained 700 cubic centimeters of amber-colored fluid from the left chest. There was no essential change in its content. A gastrointestinal series at this time showed a small hernia of the stomach through the esophageal hiatus. The stomach was high in position and there was constant prepyloric spasm without any evidence of disease in the stomach. The cap was not deformed nor was there any evidence of defect in the second portion of the duodenum. The upper loops of the small intestine were constantly dilated. No obstruction was visible. At the end of the third week an abdominal paracentesis yielded 3,000 cubic centimeters of hazy, pseudochylous fluid. This fluid had a specific gravity of 1.014. There were 630 cells, all of which were young polymorphonuclears and lymphocytes. The total protein was 3.5 per cent. A smear and culture were negative. An examination for tumor cells was negative. The patient was very weak and apprehensive at this time and had lost eleven pounds since admission. An x-ray exhibited marked increase in the process in both lung fields. The areas of consolidation were large and becoming confluent. There was also an increase in the amount of fluid. The spleen appeared to be enlarged. One month after admission he began to vomit more frequently and developed diarrhea, four to six movements daily, which did not respond to therapy. Shortly thereafter he began to cough, became rapidly weaker and expired on the thirty-eighth day.

DIFFERENTIAL DIAGNOSIS

DR EDWARD D. CHURCHILL. I admit beforehand that I do not know what the diagnosis is. It seems to be a problem of diagnoses. In fact in going over the case I do not see quite why it was given to a surgeon. Perhaps that will give us a lead as to diagnosis.

All through the present illness the loss of appetite is emphasized and reemphasized.

There is nothing in the present illness that points toward disease of any particular organ, just a loss of weight with gastrointestinal symptoms and disturbances that might go with advancing cachexia.

The patient was refused admission to the Army because of "rheumatic heart disease." Later on in the physical examination we find he has a normal heart.

With regard to the possibility of brass poisoning we used to consider the ague and chills common to brass foundries attributable to that cause. Now, however, the syndrome is thought not to be due to brass but to the fumes of zinc coming from molten brass. As far as I know there is no industrial poisoning due to brass itself. He was a brass finisher and I think that we may dismiss industrial disease.

We can also dismiss rheumatic fever and cardiac decompensation. There was no edema of the ankles and no other signs of cardiac decompensation.

The respiration rate was 25 despite the description that he was dyspneic, orthopneic and cyanotic. The blood showed a slightly reduced red cell count. The hemoglobin was somewhat low. The icteric index was a little elevated, going with the trace of bile but certainly not more than a subicteric degree of jaundice.

They were bold in taking off 1270 cubic centimeters of fluid from the left chest and 500 from the right. The cells were predominantly red blood cells, but the fluid was not described as bloody in the gross.

I had not heard of the Takata Ara reaction until yesterday and I hesitated myself trying to find out what it is.

DR. TRACY B. MALLORY. Dr. Crone was responsible for that. Perhaps he will put in a word.

DR. NEIL L. CRONE. The Takata Ara reaction in brief is a precipitin or a flocculation reaction and is read as a flocculent precipitate formed when varying dilutions of serum are added to sodium carbonate and mercuric chloride. There have been a number of papers written about it the gist of which is as follows. In normal people the test is positive in two out of every hundred. In patients with cirrhosis of the liver the test is positive in from 65 to 80 per cent, depending on whose observations are accepted. There are two other conditions in which the test has been reported positive by a number of observers. One is in generalized metastatic carcinoma, carcinomatosis. In such cases the liver is usually involved with milary metastases, but not always. The other condition is milary tuberculosis in which case also the liver is usually involved widely with milary tuberculosis but again not always so.

This patient's Takata Ara reaction was not a questionable reaction at all. It was strongly positive and, as I remember, I repeated it on both the serum and chest fluid the second time.

DR. CHURCHILL. What is the significance of a strongly positive Takata Ara reaction in the presence of a normal functional test of the liver?

DR. CRONE. The reason I am doing them is

to try to find out whether the Takata Ara reaction offers anything that the usual liver function tests do not offer. I cannot answer that. We have had positive tests in patients who clinically have cirrhosis of the liver but whose liver function by other tests was normal. Until we have done more, I do not think one can say.

DR. CHURCHILL. The diagnosis is boiling down, at least in my mind, to milary tuberculosis or generalized carcinomatosis. We also have to consider cirrhosis of the liver.

He has a small hernia of the stomach through the esophageal hiatus, a finding that is not uncommon and might be expected in a case with that much fluid.

We must consider the causes for a total illness of eight or nine months terminating in death. This is quite rapid for any type of liver cirrhosis that is accompanied by normal liver function and no jaundice. Chest fluid may appear in certain types of liver cirrhosis. I have never known it to be quite so pronounced as this. I am going to dismiss primary liver cirrhosis as the cause of this man's death. That brings us to milary tuberculosis. The blood is quite consistent with milary tuberculosis. The duration of the disease is long but particularly in adults of this age milary tuberculosis may run a chronic and an atypical course. The chest symptoms are quite suggestive. I do not think we can dismiss milary tuberculosis from the differential diagnosis. Then we turn to the very common disease that kills a man of forty-eight in eight months—carcinomatosis. The general picture as far as I can see is consistent with such a diagnosis except that we have absolutely no inkling as to a primary focus of the disease. In carcinomatosis we look for metastases and for a primary growth. In milary tuberculosis we look for changes in the lung fields. I wish Dr. Hampton would review these first two chest films.

DR. AUBREY O. HAMPTON. In the first film we have of the chest there is a very indefinite milary process present which can be seen only on close inspection. In this second film the milary process is quite distinct. The fluid which is present at both bases in the first film has not increased, probably because of chest taps. In the third film, taken one month and twenty-two days after the first, there has been a marked change in the milary process. The pulmonary lesion is now characterized by a diffuse bronchopneumonia. The fluid has not increased. I remember interpreting these films and we searched for a primary tuberculous lesion hoping to obtain a lead toward the diagnosis of milary tuberculosis but not one was found. There was thus slight displacement of the trachea toward the left by what appears to be a mass in the region of the thyroid. We were quite impressed by the symmetrical pleural effusion. I do not remember seeing this picture before but it must be

cur in late stages of miliary tuberculosis. The only significant finding was the rapid change in the character of the lesion. I think that this change was the reason we hazarded the diagnosis of miliary tuberculosis. We were content to explain the displacement of the trachea on the basis of exaggeration due to scoliosis.

DR. CHURCHILL: Then your diagnosis was miliary tuberculosis of the lung with the atypical finding of bilateral pleural effusion. The x-rays of the skeleton were negative. You saw nothing in the bones?

DR. HAMPTON: No.

DR. CHURCHILL: So the disease is striking chiefly in the chest and in the abdomen.

DR. HAMPTON: I think perhaps a film of the barium-filled bowel should be shown. I do not know that it offers much in the way of differential diagnosis, however.

This small bowel is apparently in a state of contraction and the margins of the gut show a fine irregularity. There are other evidences of irritability of the bowel. For example, the terminal ileum is empty, the cecum is filled and the right half of the colon is empty while the descending colon is well filled. The loops of the small bowel are rather widely separated and the cecum appears small. There is very little gas in the small bowel such as one would expect were ileus present as is usually seen in carcinomatosis. The Sterling sign which indicates ileocecal tuberculosis was not present, as you see the cecum is filled. From the gastrointestinal examination therefore we were unable to say that a primary tuberculous focus was present and we were unable to differentiate definitely tuberculous peritonitis and carcinomatosis.

DR. CHURCHILL: We are left with the differential diagnosis of miliary tuberculosis and carcinoma apparently labored over on the wards. The only possible clue to a primary lesion Dr. Hampton pointed out in the low thyroid, nothing very striking. I am not familiar enough clinically with the course of miliary tuberculosis in a man of this age to get a positive lead toward that diagnosis. Miliary tuberculosis, particularly in older people is apt to be atypical and the diagnosis frequently not made until autopsy. It certainly cannot be excluded. However, the gastrointestinal symptoms and the amount of fluid in both chests lead me to put carcinomatosis as my first choice. The origin is most probably in the gastrointestinal tract. Carcinoma of the appendix is known to give a diffuse involvement of the lymphatic channels throughout the diaphragm, pleural cavity and the lungs. The stomach we must assume to be normal by the x-ray, but the other parts of the bowel are not ruled out. It would be unusual for the prostate to produce this picture. It would be unusual for thyroid

carcinoma. To come back to the puzzling Takata-Ara reaction. It does not help us because Dr. Crone says it may be positive in either of these conditions. I would be glad for anyone else to offer opinions in this case. I should say (1) carcinomatosis, primary focus unknown, possibly appendix, (2) miliary tuberculosis, pulmonary and abdominal type, without meningeal manifestations.

DR. CHESTER M. JONES: Are you at all impressed by the fact that the spleen was felt the second time? Apparently it was missed at first on account of ascites. The abdomen was tapped and then the spleen was felt. Does that make you lean more toward miliary tuberculosis?

A PHYSICIAN: What was the temperature chart?

DR. CHURCHILL: We have only one notation, 102°.

DR. MALLORY: It was pretty constantly elevated, the rectal temperature running from 102° to 103°.

DR. CHURCHILL: The pulse was not elevated?

DR. MALLORY: No.

DR. CHURCHILL: The temperature is more suggestive of miliary tuberculosis than carcinoma. We have been working without the aid of the temperature chart.

I wish some of the internists would give their opinions on this case.

DR. FREDERICK T. LORD: It seems to me this pleural fluid has rather a lower specific gravity than one would probably find in an inflammatory fluid, which would make me also lean more toward a carcinomatosis.

DR. JONES: It seems to me there is nothing much on which to make a diagnosis of intra-hepatic disease unless there is secondary involvement. I am interested in Dr. Lord's remark about the fluid. It seems to me the protein in that fluid is high for a transudate and I think it is not consistent with cirrhosis any more than the rest of the picture is. As to its being non-inflammatory I do not know. I should think it was a higher protein content than you usually see in a transudate and I think it would be more in favor of an inflammatory type of reaction.

I am wondering about the story at the end of the first paragraph. Just before he came in he had a cold and was hoarse. That might have been an upper respiratory infection and nothing else, but the combination of hoarseness and the x-ray picture with displacement of the trachea makes one wonder if there was not a localized process as a result of the hoarseness.

I think the way Dr. Churchill summed the case up was the logical way to diagnosis.

DR. WYMAN RICHARDSON: The patient was on my service. I thought he had malignant dis-

case and I refused to accept Dr Hampton's diagnosis on the basis of the length of the story, which I thought was unusual for miliary tuberculosis.

One other thing, the examination of the smear showed degenerate reaction of polymorphonuclear cells which should have suggested infection.

CLINICAL DIAGNOSIS

Metastatic malignancy, generalized in the chest and abdomen, primary source

DR. EDWARD D. CHURCHILL'S DIAGNOSES

- (1) Carcinomatosis Primary focus unknown. /
- (2) Miliary tuberculosis

ANATOMIC DIAGNOSES

Tuberculosis, miliary, of the lungs, liver and spleen.

Tuberculous pleuritis, bilateral, with effusion

Tuberculous peritonitis

PATHOLOGIC DISCUSSION

DR. MALLORY The autopsy showed that the x-ray department had won out. Immediately

on opening the abdominal cavity we found innumerable minute tubercles studded over the peritoneal surfaces. Both pleural cavities showed an identical reaction. The lungs likewise were rather uniformly peppered on both sides with miliary tubercles. We did not find any old tuberculous focus as a source for the picture. I do not know whether it is fair to assume from the autopsy findings what the content of the pleura and peritoneum may have been like during life. At any rate certainly at autopsy a large proportion of the exudate was clotted so that it would be possible that the serum which was drawn off was simply supernatant fluid and for that reason had a lower gravity than it otherwise would have.

DR. JONES What did the spleen show?

DR. MALLORY It was normal in size.

The liver was slightly, not markedly enlarged. Both diaphragms were very low, probably explaining why the liver was readily palpable. There were miliary tubercles in the liver and there was also a definite bile stasis in the liver for which no obvious reason in the form of obstruction in the bile ducts or degeneration of liver cells was found.

We found no thyroid tumor.

A BILL TO RAISE THE QUALIFICATIONS FOR PRACTICE

RECENTLY there was filed with the Secretary of State the draft of a bill in which the Board of Registration in Medicine recommends to the General Court that certain changes in the medical practice act of Massachusetts be made. The proposals cover three points.

The first proposal adds two years of collegiate work to the high school education already required as a preliminary premedical education.

The second proposal explicitly authorizes the board to accept an equivalent of the medical course now formally stated to consist of four years of instruction of not less than thirty-two school weeks in each year. Many foreign universities have a different arrangement of the medical course and require five or six years of twenty-eight or twenty-six weeks in each year. Such courses if given in recognized schools of medicine may fairly be considered equivalent to the regular course adopted in the United States and should be recognized as such.

The third proposal introduces the characterization of a medical school of which the gradu-

ates are eligible for examination by the board, that it be approved by the board. This rather simple phrase "approved by the board" has great significance, and its introduction into the law or its continued omission therefrom carries with it the possibility of great good or of great harm to the health of the people of this Commonwealth.

Thus there is opened another stage in the campaign which has as its goal the giving to the people of Massachusetts of adequate protection against unqualified practitioners of medicine.

The long process of preparing the candidate for the practice of medicine is complicated in the extreme. The determining of just what qualifications a physician should possess is perhaps simple, if one does not make too long a list, if one is not too specific, and if one insists that they should be possessed by every physician. But how to determine which individuals have the capacity for developing into good physicians, how to determine into just what specific environment or educational procedure they should be introduced, how to determine at intervals in this time-consuming education if the reactions of the student are such as to justify his going on along this line of endeavor, how to determine finally whether he has developed to such a stage of knowledge and skill and character that he may reasonably be entrusted with the responsibilities of the physician, are problems which the most intelligent and honest of medical educators regard as having reached now only tentative solutions.

The issues are so critical, the danger of taking medical education lightly are so great, the harm that may result from any perversion of the power of conferring medical degrees, authorized by the state as a solemn responsibility, are so great, that the state should place upon some one of its administrative bodies, the duty of scrutinizing and evaluating and approving, or condemning if need be, all medical schools whose graduates may ask to be admitted to its examination.

The Board of Registration in Medicine of Massachusetts is to be commended for its continued interest in this aspect of protection and for its persistence in again recommending to the General Court a course of action which is in itself so reasonable and in practice has been found to work so well wherever it has been tried. The medical profession should make clear to the Legislature that it believes that the public should have the more adequate protection which the bill will provide.

THE HANDBOOK FOR PHYSICIANS

VOLUME 22, No. 3 for July, August and September, 1935 of *The Commonwealth*, issued by the Massachusetts Department of Public Health, appears as a *Handbook for Physicians*.

This publication will reach physicians of Massachusetts as soon as possible after release by the printers

In the foreword by Dr Chadwick, Commissioner of Public Health, the purpose of the issue is clearly stated to be for the "more effective utilization of certain of the community resources" at the disposal of the physicians of the Commonwealth

Although the classification of these aids is defined as restricted to those which "have a particular bearing upon the public health" the reader will find that guidance and information which will enable the practitioner to cooperate with the authorities in the public health activities of the State

The language of the document is clear and concise, so that there can be no excuse for failure to comply with all of the rules and regulations required of physicians in dealing with communicable diseases. In addition the resources of preventive and therapeutic medicine as applied to diseases under the supervision of public health bodies, are set forth

This should be the doctors' *vade mecum* for all physicians who may come in contact with diseases which are included in the reportable list

Dr Chadwick invites constructive criticism and comments for use in revisions of this publication

NEW YORK'S INFANT MORTALITY

A recent study of infant mortality in New York City since 1810, made by Dr Charles F. Bolduan, director of the Bureau of Public Health Education, and Louis Weiner, vital statistician of the department, shows that, contrary to general belief, child deaths have not declined steadily during the past century according to an article in the *New York Times*

The rate at the beginning of the nineteenth century—130 deaths per 1,000 births—was actually about the same as at the beginning of the twentieth century—just under 140 deaths per 1,000 births. Much of the drop in the infant mortality rate since 1870 has been shown merely to offset a marked increase in the preceding sixty years, the rate having risen rapidly from somewhere between 120 and 145 in 1810 to 180 in 1850, 220 in 1860 and almost 240 in 1870

There are reasons for this rise during the first three quarters of the last century. In the second quarter of the century far reaching social and economic changes took place. Population growth accelerated, factories multiplied and immigration increased with consequent crowding and lowering of standards of living. Wages especially after the panic of 1837, were repeated

ly reduced. The character of the city's milk supply deteriorated with a diminution in pasturage for the cows in the city dairies

During the Fifties and Sixties legislative action was finally obtained which resulted in the organization of the present Department of Health, with wide powers and after 1870 a decline in infant mortality was noted. By 1880 the rate had dropped to 200 and by 1900, as previously noted, it was again below 140. By 1910 it was 113, by 1920 85 and by 1930 it had dropped to 57. The rate in 1934 was 52, and so far this year it has been 51.7

The marked drop in the past fifty years has been due to many factors—improvements in the milk supply, including compulsory pasteurization, the establishment of baby health stations, organized educational efforts, and, undoubtedly, the great decrease in flies resulting from the introduction of motor cars

sent themselves have had such inadequate preparation in these fundamental sciences that they have not been able to profit as they should by their attempts to secure medical education. If the foundation is weak, the superstructure, no matter how carefully built, cannot be sound.

That collegiate instruction in physics, chemistry and biology is generally regarded as necessary is shown by the statutory requirements of all but eight States. In six of the eight, the requirement is by Board ruling, authorized by statute. Massachusetts is one of the two remaining States.

II *Authorizing the Accepting of a Medical Course Equivalent to Four Years of Thirty Two Weeks in Each Year*

The Board has found that rarely do graduates of foreign medical schools, even the best, fulfill exactly the present requirement of four years of thirty two weeks in each year. The reason for this is the different system of education and arrangement of the medical curriculum. Foreign universities require no shorter period of instruction, but the instruction is extended over five, six, or seven years, with less than thirty-two weeks in each year. The total number of weeks of instruction in the course is greater than that required by the present statute. Accepting the equivalent of the present requirement would not lower the standards, but make them more flexible.

III *Requiring That Medical Schools from Which There Graduate Certain Candidates for Examination for Registration Be Approved by the Board*

Since there still exist in the United States so-called medical schools which continue to admit students and give them the medical degree without providing for them a reasonably good medical education as judged by generally accepted standards, the Board recommends that the General Court of Massachusetts adopt protective measures against these unqualified graduates similar to the measures by which the legislatures of other States protect their citizens. This additional protection will be made possible if only graduates of schools approved by the Board are admitted to examination.

The Commonwealth of Massachusetts

In the Year One Thousand Nine Hundred and Thirty-Five

AN ACT relative to the Qualifications of Applicants for Registration as Qualified Physicians

Be it enacted by the Senate and House of Representatives in General Court assembled, and by the authority of the same, as follows:

SECTION 1. Section two of chapter one hundred and twelve of the General Laws, as appearing in the Tercentenary edition thereof, as amended by chapter one hundred and seventy one of the acts of nineteen hundred and thirty-three, is hereby further amended by striking out the second sentence of said

section and inserting in place thereof the following —

Each applicant who shall furnish the Board with satisfactory proof that he is twenty one or over and of good moral character, that he possesses the educational qualifications required for graduation from a public high school, that he has completed two years of pre medical collegiate work, including Physics, Chemistry and Biology, in a college or university approved by the board, that he has attended courses of instruction for four years of not less than thirty two school weeks in each year, or courses which in the opinion of the board are equivalent thereto, in one or more legally chartered medical schools, and that he has received the degree of doctor of medicine, or its equivalent, from a legally chartered medical school having the power to confer degrees in medicine and approved by the board, shall upon payment of twenty five dollars be examined, and if found qualified by the board, be registered as a qualified physician and entitled to a certificate in testimony thereof, signed by the chairman and secretary.

SECTION 2. The provisions of said section two as existing immediately prior to the effective date of this act shall continue to govern as to the eligibility of any applicant for registration as a physician who had matriculated prior to the effective date of this act in any legally chartered medical school having power to confer degrees in medicine.

THE APPOINTMENT OF DR ALICE HAMILTON

Dr Alice Hamilton of Boston has been appointed as technical adviser to Secretary Perkins in connection with a vigorous campaign against the menace of industrial accidents and diseases.

THE AWARD OF THE NOBEL PRIZE

On October 24, 1935, the Nobel Prize for Medicine was awarded to Dr Hans Spemann, Professor of Zoölogy at the University of Freiburg im Breisgau, Baden.

This prize includes an award of 160,000 kroner, or about \$42,000.

Dr Spemann's work for which he is especially recognized has been in connection with experimental biology.

He was born in Stuttgart, Germany, June 27, 1869, the son of Wilhelm Spemann, a publisher. He was educated at Eberhard Ludwigs Gymnasium from 1878 to 1888. He had military training and studied medicine from 1891 to 1894 at the University of Heidelberg, Munich and Würzburg and was given work as an assistant in the University of Würzburg in 1895.

In 1914 he became director in the Kaiser Wilhelm Institute for Biology in Berlin and later was appointed professor of zoölogy at the University of Freiburg im Breisgau. — *Abstracted from the report in the New York Times, October 25, 1935.*

RED CROSS DISASTER, HEALTH AND SAFETY SERVICES

Death and destruction rode in the wake of the rising waters when cloudbursts in southern New York State early in July caused the greatest floods that area has known in fifty years. Forty-three lives were lost, 255 persons were injured, 9000 homes were damaged or washed away and even greater suffering would have resulted had not Red Cross Chapter workers arrived on the scene before the crest of the flood was reached to assist panic-stricken victims to reach places of safety and provide emergency care for those made homeless.

Chairman Grayson of the American Red Cross mobilized his workers with amazing swiftness and before the rain had ceased to fall the Director of Disaster Relief and his aids were en route from Washington, by plane to this beautiful finger-lake country visited by hundreds of vacationists each year but then embroiled by the raging waters of streams and rivers filled to overflowing by the forty-eight hour deluge.

More than 9000 families were affected by this single disaster and at the height of the emergency the Red Cross was feeding more than 7000 persons and providing shelter for half that number. But

this was only a beginning of the work of the Red Cross for among those made homeless more than 4000 families were without the financial means to rehabilitate themselves and must have the assistance of the Red Cross in rebuilding and repairing their homes and providing a thousand and one essentials before they could resume normal living.

The Red Cross sets no arbitrary limit on kinds of relief. If a family with no resources of its own has lost its home or if the home is in need of repairs, if the furnace is damaged or if the furniture is swept away or ruined if fencing is down on a farm if vital farm machinery is ruined the Red Cross meets the needs. The Red Cross makes no loans whatever assistance it gives. It gives outright, with no strings attached.

You yourself may never need the services of Red Cross disaster workers. You may never need the ministrations of a Red Cross public health nurse but someone else surely does. You may never be saved from drowning by the timely arrival of a Red Cross life saver and the application of the prone pressure method of artificial respiration—but many are the men and women, the boys and girls who walk the land today because someone trained by the Red Cross was at hand in an emergency.

Year after year through more than half a century citizens before us have maintained by membership the American Red Cross as the great humanitarian agency—and there is nothing in all its many valuable services which is more helpful more neighborly than these services which pertain to the conservation of human life. Nothing could be more unselfish or appeal more strongly to the generous instincts of a people.

Some months ago an epidemic of malignant malaria broke out in a southern State. Now malaria is something usually thought of as slow working a drain upon physical energy but hardly in a group with some of the other contagious diseases like typhoid fever or smallpox. Actually here in this progressive public-spirited community this form of malaria struck swiftly and terribly. First diagnosed as malarial fever later dengue, there were developed seventy-four cases five deaths before a hurry call was sent to the Red Cross. A representative of the Red Cross nursing service after a rapid survey telegraphed the needs to headquarters. The director of the service scanned her lists for the most conveniently located available nurses quickly dispatched eight to the scene. They at once made their presence felt in a nursing campaign lasting several weeks helping physicians to check the progress of the disease effectively and nursing their patients back to health.

A number of times each year there are emergency demands for nurses similar to the example just cited. Disaster so often strikes rural communities, leaving behind a trail of injured to be cared for in improvised hospitals. Sometimes unsanitary conditions are potential breeders of disease. Typhoid lifts its head here and there in rural districts and

small towns—just as it did last year in one of the Northwestern States. The need for help is great—and the Red Cross responds, for there are more than 36,000 nurses on the active list of the Nurses' Reserve ready for instant service in the Army, the Navy or for the Red Cross emergency service. These nurses meet the highest professional standards and are available in every part of the Nation. They constitute a powerful line of health defence.

Half the child population of a county high up toward the Canadian line was found to be suffering from goitre when an itinerant Public Health nurse of the Red Cross made her first school inspection after arriving for her tour of duty. Symptoms ranged from slight to toxic. Cases were at once referred to physicians for treatment and upon their advice iodine tablets were distributed, which checked the progress of the malady and had the effect of awakening the community to the importance of preventive measures.

Continuing her school inspections, she brought about the immunization of 428 children from diphtheria and obtained dental inspection and services for children whose teeth had been noticeably neglected.

This sort of thing is all in the day's work of the Red Cross nurse. The press occasionally carries stories of more spectacular nursing achievements, reflecting the heroism of Red Cross nurses in time of epidemic and disaster, of their bravery of the elements and disregard of self, but perhaps the largest contribution of all is their daily bedside nursing, their detection of unsanitary conditions, their coöperation with local health authorities in the improvement of health situations, their health inspections of children and adults, their zeal in promoting immunization against contagious diseases, their teaching of simple home nursing.

This last year Red Cross Chapters employed more than 800 public health nurses that means year round programs of bedside nursing. They made more than a full million nursing visits and went into the schools and inspected 600,000 children—detected defects before they developed serious complications sent many a child to doctor or dentist or oculist for corrections that made school work easier and safeguarded future development.

Of course, it is humanly impossible for even a large group of professional nurses to respond to all the demands for service. To meet this pressing need, the Red Cross trains many of its nurses to teach mothers, fathers and even younger members of the family to take care of chronic invalids, the aged, sick brothers and sisters and others in the home who need special care but do not require the services of a trained nurse. Last year more than 2000 nurses were authorized to conduct courses in Red Cross Home Hygiene and Care of the Sick. More than 50,000 students were awarded certificates for satisfactory completion of the course. Since the Red Cross first undertook the teaching of home hy-

giene classes, approximately three-quarters of a million certificates have been issued.

In safety, as in health, the Red Cross is the great evangelist. In Washington, D. C., a slow gas leak fills a house with deadly fumes, a whole family is slowly succumbing. A young woman in the household is a holder of several Red Cross first aid certificates, has even been authorized to instruct in the subject. She rushes to fling open the windows, turn off the gas, summons a physician and places the victims where they will be in uncontaminated air, at once busies herself applying the prone pressure respiration to the one most desperately affected. She saves those lives.

In the old days of the muddy, treacherous swimming hole and unsupervised bathing beaches water tragedies took terrific toll. They still do. But they are at last being definitely checked and the trend of drownings is downward. There are 8000 drownings a year, but there are thousands, perhaps millions, more swimmers. The Red Cross is making progress—it is looked to for safety leadership, furnishes hundreds of camp counselors, teaches swimming, trains for safety, equips teachers to carry on the work. It holds a series of National aquatic schools each spring for men and women who make swimming and outdoor activities their vocation or summer avocation.

Summarizing briefly a twelve months' record of accomplishments by the companion Red Cross Services, First Aid and Life Saving: 183,000 first aid certificates awarded, 74,000 life-saving certificates.

In twenty-one years 633,000 life saving certificates have been issued, and in the last quarter of a century first aid certificates have been granted to more than 946,000.

Think of all the bruises and wounds that have been dressed by these hundreds of thousands, the infections that have been prevented, the fractures that have been cared for until the arrival of medical help, the blood flows that have been stopped, the shocks that have been mitigated, the innumerable and varied emergencies that have been successfully met because of Red Cross training!

Red Cross health and safety services are supported—just as are other Red Cross services—by the annual Roll Call. Everyone ought to have a part in the Red Cross, by joining through the local Chapter. This year, as always, the period between Armistice Day and Thanksgiving Day—November 11-28—has been set aside for Nation-wide enrollment of members. Won't you join the Red Cross?

NEWS ITEMS

The annual conference of the National Society for the Prevention of Blindness will be held at the headquarters of the Society in Rockefeller Center, New York, December 5 to 7, it has been announced by Lewis H. Carris, managing director. Among the topics to be discussed will be Medical Social Eye Work, The Prevention of Eye Accidents Caused by Fireworks, and The Division of Responsibility be-

between Official and Unofficial Agencies in the Movement for Prevention of Blindness

The election of the following as honorary vice-presidents of the Society is announced Dr George E. DeSchweinitz of Philadelphia emeritus professor of ophthalmology in the Medical School University of Pennsylvania Dr John H. Finley associate editor of the *New York Times* and Miss Lillian D. Wald president of the Henry Street Settlement of New York City Other honorary vice-presidents of the Society are the following United States Senator Thomas P. Gore of Oklahoma Helen Keller and Mrs. Winifred Holt Mather

Dr. Walter B. Lancaster of Boston associate in ophthalmology Harvard University Medical School and Dr. Bernard Samuels of New York City professor of clinical surgery Cornell University Medical School, have been elected to the Society's board of directors

NEWS ITEMS FROM MAINE

The Franklin County Memorial Hospital Medical Institute of Farmington, Maine, held a Cancer Clinic on October 11, 1935

2-5 P.M. World Rounds and Case Clinic.

6 P.M. Dinner

7 P.M. Paper "The Successful Diagnosis and Treatment of Cancer," by Dr. Barbara Hunt, of Bangor, Maine

Paper "Some Recent Advances in Cancer Research," by Dr. C. C. Little, Director of the American Society for Control of Cancer

THE MAINE MEDICAL ASSOCIATION CLINIC

The Annual Maine Medical Association Clinic was held this year at Lewiston, Maine, October 24-25, 1935. Sessions on the twenty-fourth were at St. Mary's Hospital in the morning and afternoon and on the twenty-fifth at The Maine General Hospital.

PROGRAM

From 9 A.M. to 12 noon each day surgical clinics with operations and demonstration of cases

12 M. Buffet luncheon.

2 to 5 P.M. Fifteen-minute papers by members of the hospital staffs

5 P.M. Thursday Neurological conference by Dr. Elliott C. Cutler

5 P.M. Friday Round Table conference on Cancer in Maine conducted by Dr. Clarence O. Little

7 P.M. Each night. Banquet at DeWitt Hotel.

8 P.M. Thursday "The Surgeon and His Art," Dr. E. C. Cutler

8 P.M. Friday "Problems Pertaining to Cancer," Dr. C. C. Little

CORRESPONDENCE

TROUBLE AHEAD

The Commonwealth of Massachusetts
Department of Public Health
State House, Boston

October 21, 1935

Editor *Acta Eng and Journal of Medicine*

The diagnosis and management of syphilis and especially of early syphilis, have been written and talked about so much in recent years that there is bound to be trouble ahead for the physician who makes mistakes in diagnosis or who fails to treat the patient properly. Appearance before the Board of Registration in Medicine is the least that can happen. Suits for malpractice will follow as rapidly as the public becomes acquainted with what it has a right to expect from the physician. The following cases are presented:

Early in February an indigent male called upon a city physician presenting a penile lesion of a few days duration. The patient testified before the Board of Registration in Medicine that the lesion was painted with mercurochrome boric acid ointment or wash was prescribed and the patient advised that the lesion was of no consequence and would disappear.

The following April the patient's wife who was then two months pregnant called upon the same physician. She presented a rash, sore throat and gonitral lesions. The clinical picture was so characteristic that the physician (who had no recollection of having taken a blood test on any patient for several years) suspected syphilis. He had no serological outfits handy and requested that the patient return the next day. He failed to impress her with the possible seriousness of her condition and she did not return. The physician made no attempt to determine that she ever received any further medical attention nor did he report her to this Department for investigation.

A month or so later the same physician was called to this family's home because the younger (two years old) of two small daughters had a rash. The physician is reported to have stated that her condition "might be German measles" but that "he didn't think so." No further study of her condition was made.

Eventually these three members of this family were found, by another physician, to have syphilis. The mother was then more than six months pregnant.

The outrageous mismanagement of these infectious was so obvious that investigation by the Board of Registration in Medicine was requested.

There are a number of points about this case which deserve the attention of the medical profession.

1. Syphilis and especially a recent infection or syphilis in a pregnant woman is a dangerous communicable disease.

- 2 The husband's infection could have been diagnosed immediately by darkfield examination of serum from the lesion. Any syphilologist and most of the syphilis clinics in the State are equipped to make darkfield examinations. The very least that could have been done would have been the making of repeated blood tests, although once the blood has become positive the chance of clinical and serological cure has dropped at least 10 to 15 per cent.
- 3 Diagnosis of the husband's infection and its immediate and proper treatment might have prevented the infection of the wife. If she were already infected, she could have been kept under constant observation and treatment could have been begun immediately upon the appearance of evidence of infection. Or, if the sexual history indicated exposure, and the patient acquainted with the advantages of immediate treatment, infection could have been assumed and treatment begun at once.
- 4 The contact infection of the two year old daughter would have been prevented.
- 5 Treatment of the wife's infection could have been begun early in pregnancy. Treatment begun before the fifth month and continued to term is almost certain to prevent a congenital infection.
- 6 The adequate treatment of primary syphilis results in clinical and serological cure in 85 to 90 per cent of cases. In the secondary stage the chance of clinical and serological cure is from 15 to 20 per cent less. Thereafter "cure" in the double sense is problematical.

The records of the Board of Registration in Medicine show the following case as an example of the serious damage which may be done by erroneous diagnosis, particularly when the accepted diagnostic procedures are neglected.

A woman went to a physician because of some symptoms referred to her back. A diagnosis of syphilis was made by the Abrams' electrotonic method. Later the husband was examined by the same method and a diagnosis of syphilis was again made. These diagnoses led to recriminations and almost broke up the family, but as both histories were negative for syphilis another physician was consulted.

After the generally accepted laboratory tests had been applied and the patients had been properly examined, both were declared to be free of any evidence of infection with syphilis. The complaint of deceit was laid before the Board of Registration in Medicine.

The Department of Public Health has sent each of the 6,000 physicians in Massachusetts at least twenty-one reprints on the modern management of syphilis and gonorrhea during the last six years. It has enjoyed the advice of a large group of consultant specialists in the preparation and selection of this material. The Department offers free serological diagnostic laboratory service to every phy-

sician in the State. It offers arsenicals without charge to every physician who wishes to treat syphilis. It offers speakers on these diseases to any medical society or club that wishes a speaker. There is not a clinic chief in the state who would not welcome the opportunity to teach the management of syphilis or gonorrhea to any physician who will take the time to attend clinic sessions. Every possible effort is being made to enable the physician to add to and retain in his private practice those patients who come to him with either of these diseases.

Syphilis and gonorrhea are among the most prevalent of the reportable communicable diseases. Numerically, economically, socially and pathologically, they constitute the major, modern public health problem. Congenital and accidentally acquired syphilis account for from 15 to 20 per cent of the problem. Innocent infections in wives account for well over half the infections with either syphilis or gonorrhea in women. At least 10 per cent of all gonorrhea in the female is in girls under fourteen years of age, most of which is innocently acquired.

Gonorrhea and syphilis are no respecters of persons or morals. They are to be found in every physician's practice if they are looked for. The control of both diseases depends largely upon prompt and correct diagnosis, adequate treatment, constant control of the patient and a thorough search for related cases. When the medical profession adequately appreciates these facts, such situations as those described in this lengthy communication will be considerably less prevalent than they are, most unfortunately, today.

Yours truly,

N. A. NELSON, M.D., Assistant Director,
Division of Communicable Diseases

IODINE AS AN ANTISEPTIC

Harvard University Medical School
Department of Surgery

October 17, 1935

Editor, *New England Journal of Medicine*,

A recent editorial in your *Journal* boldly described iodine as the antiseptic "par excellence." Since there is abundant evidence to the contrary I have felt that perhaps you would accept this small note with its references and opposing attitude for publication so that those of your readers who doubt the editorial writer's opinion may feel a little relieved.

The true appraisal of an antiseptic is a difficult measure. Unfortunately, all too often the measuring rod used is the efficiency of a drug to kill bacteria in vitro. This test is really of no value if we mean by a useful antiseptic one that is useful in wounds or for the preparation of the skin. It has been repeatedly shown that though iodine may have a high bactericidal action on organisms in vitro, if blood is added the killing power of the

drug is greatly diminished or even lost. It has also been shown that a drug which has a high killing power in vitro is of little value in destroying organisms on the skin. It would appear that your editorial writer was interested in the use of iodine by surgeons, which would mean in wounds and on skin. Yet your writer quotes as evidence of the value of iodine tests which involve only the exposure of bacteria in vitro to iodine a matter of little concern to the surgeon.

The following table of references and results em

phasizes without need of further discussion the fallacy of the in vitro method as a means for testing the value of antiseptics for surgical use, and that iodine though it has a high killing power in vitro is useless as an antiseptic in the presence of blood or as a skin preparation. Of course I may have misused the meaning of the word antiseptic by your writer for iodine in a bacteriological sense is a good bactericide.

Very truly yours,

ELLIOTT C. CUTLER, M.D.

RECENT DEATHS

BROWN—EDWARD WELLS BROWN, M D, of 337 Elm Street, Northampton, died at his residence suddenly, October 25, 1935

His office was at 16 Center Street. Dr Brown was born in 1871 in Milwaukee and previous to the study of medicine was educated at Yale and the University of Wisconsin. He received his M D degree from Columbia University College of Physicians and Surgeons in 1894

Dr Brown joined the Massachusetts Medical Society in 1898 and was also a Fellow of the American Medical Association. He was a member of the staff of the Cooley Dickinson Hospital and for several years held the position of chief. He had served Hampshire County as Medical Examiner for the last twenty years

Surviving him are his widow, a daughter, Miss Janet Brown, two sons, Dr Stephen Brown and Mr Richard B Brown and a brother, Mr Howard Brown of Springfield

RICH—FRANK A RICH, M D, of 8 Union Street, Burlington, Vermont, died recently in that city. He was born in 1861 and graduated from the University of Vermont Medical School in 1893. He also practiced Veterinary Medicine

Dr Rich served as a member of the faculty of the University of Vermont for forty years

MORAN—HORACE S MORAN, M D, of 12 Richardson Avenue, Wakefield, Massachusetts, died suddenly October 18, 1935

He was born in Wakefield, graduated from the Harvard Medical School in 1893 and was formerly a member of the Massachusetts Medical Society

Dr Moran is survived by a brother, George W Moran, and a sister, Miss Caroline H Moran

OBITUARIES

JOHN W KEEFE, M D, F A C S, L L D

1863-1935

Dr John W Keefe of Providence died at his summer home, Narragansett Pier, August 3. The cause of death was cerebral hemorrhage. John William Keefe was born at Worcester, Massachusetts, April 25, 1863, the son of Denis and Alice (McGrath) Keefe. His early life was spent in Worcester and after graduating from the public schools, he entered upon the study of medicine at the University of Michigan, 1882 and 1883. He then went to New York and received his medical degree at the University Medical College, New York University, in 1884. He interned at Bellevue Hospital, receiving an appointment on the first surgical division. Following his graduation from Bellevue Hospital he came to Providence and established himself in general practice. He early became connected with the Rhode Island Hospital and served that institution thirty-three years, first in the capacity of Surgical Externe in 1886, Out Patient Surgeon from 1887 to 1895, Assistant Visiting Surgeon from 1895 to 1897

when he was appointed Visiting Surgeon which position he filled for twenty-two years. He resigned in 1919 as Active Visiting Surgeon and was appointed Consulting Surgeon

Dr Keefe took a very prominent part in the founding of St Joseph's Hospital serving as Visiting Surgeon four years and later as Visiting Gynecologist for ten years retiring in 1905, and was appointed Consulting Surgeon. He built the John W Keefe Surgery in Providence in 1913 and conducted that institution until a few years ago doing most of his private surgical work there

He was one of the founders of the American College of Surgeons and of the New England Surgical Society. He was Past President of the Rhode Island Medical Society, of the New England Surgical Society, of the New England Branch of the American Urological Association, and President (1916) and Vice-President of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons. During the administration of President Taft he received a commission in the Medical Reserve Corps and during the World War served as Major in the Medical Department of the United States Army

Dr Keefe, realizing that a surgeon should be an anatomist, was a constant student of anatomy and devoted much time to the study of this subject. He did frequent dissections on the cadaver as well as operative surgery on animals and animal experimentation. Early in his career he saw the advantages of study in Foreign Clinics and made several trips to Europe to observe and familiarize himself with the surgery of the masters of his day. He was a frequent visitor to the large and famous clinics of this country and a faithful attendant at meetings of many surgical societies to which he belonged

He was the first practitioner in Rhode Island to give up the general practice of medicine and confine himself to the practice of surgery as a specialty. Endowed with natural talents and those qualities which make for the successful surgeon, with an engaging personality and a constant aim to advance and achieve, Dr Keefe's record and attainments stand preëminently in the history of surgery in Rhode Island and New England as well as achieving a national reputation in his chosen specialty. I think it can be safely said that the surgeons of every state in the Union knew of "Keefe of Rhode Island", of his reputation and ability and of his contributions to surgical literature. If the oft heard saying be true that "surgeons are born and not made," it most certainly applies to Dr Keefe for he had in addition to an excellent training, those qualities of a deft hand with a technique of manipulation and a finesse in operating that marks the true artist in surgery, a sound judgment and the quality of decision, with the courage, ability and faith to act upon that decision

He was the author of many essays on surgical subjects. In 1931 he presented to the Rhode Island Medical Library a collection of his essays, forty-three in number. These papers were read before the Providence Medical Association, the Rhode Island Medical Society, the American Urological As

sociation and the New England Branch of the American Urological Association the New England Surgical Society and the American Association of Obstetricians Gynecologists and Abdominal Surgeons. A perusal of these papers is valuable and very interesting for they begin with the early history of operation for appendicitis. The paper on this subject in 1891 was the first paper on appendicitis read before the Rhode Island Medical Society and was followed by a second paper in 1894 the title of which was "Twelve Consecutive and Successful Operations for Appendicitis." This seems a small number of appendix cases to report when we compare it with the immense number of appendix cases which Dr. Keefe did in the years that followed. At the time of writing this paper however many of the doctors in Rhode Island were advocating the cure of appendicitis with large doses of castor oil and there was considerable controversy between the medical men and the surgeons as to the proper treatment of appendicitis. There are several of Dr. Keefe's essays which stand out as reports of pioneer work such as a paper in 1913 on "Stenosis of the Pylorus in Infancy" with report of two cases followed by a second paper in the same year with report of six additional cases. The technique of the operation done by Dr. Keefe preceded the published technique of the Ramstedt operation for this particular condition. In the literature of more recent years Dr. Keefe has been given credit for his priority in this operation. In 1916 he wrote a paper entitled "Sheet Rubber Superior to Gauze in Abdominal Operations." This was an original contribution to surgical technique and many surgeons throughout this country adopted this method of walling off viscera and were enthusiastic over its advantages. In 1925 he presented a paper before the Rhode Island Medical Society entitled "Traditions of Medicine in Rhode Island" which is a particularly valuable and interesting writing. In fact this compilation includes so many valuable and interesting papers that one could well afford to devote many hours pleasantly and profitably in reviewing these writings.

Dr. Keefe received an LL.D. from Manhattan College, New York in 1909 and one from Providence College in 1932. The latter college said of him in its citation:

In Dr. Keefe Providence College beholds a success attained through persistence in striving for professional perfection. The College would therefore honor such achievement for its own sake for the sake of its inestimable benefit to the common good, and for the sake of these pre-professional students within the college who look forward to a successful career. By honoring Dr. Keefe it would hold up an example how alone genuine professional success is secured and sustained, namely by the ceaseless and untiring expenditure of personal effort evoked not merely during the years of preparation but ever afterwards, even when reputation has been made and recognition granted.

In addition to Dr. Keefe's love for his profession and his deep interest in surgery he was a

student of history and a lover of biographies. He was devoted to hunting and fishing having done considerable large game hunting in Maine and Canada, as well as fishing in those regions. Sword fishing was one of his favorite sports and in which he indulged as late as only last year.

At the time of his death he was Consulting Surgeon to St. Joseph's Hospital, the Rhode Island Hospital, the Charles V. Chapin Hospital, the Providence Lying-In Hospital, the South County and Westerly the Woonsocket and the Pawtucket Memorial Hospitals.

In 1895 Dr. Keefe married Statia Sherman Maher of Brookline Mass. who died three years ago. He leaves four daughters, Mrs. John A. Bolster and the Misses Alice Sherman, Mary Ruth and Gertrude Sharman Keefe.

His reputation will endure, his memory will be cherished by his many intimate and loyal friends and by numberless patients who have received the benefits of his expert skill and his kindly ministrations.

ARTHUR T. JONES
WALTER L. MUNRO

DR. NATHAN FRIEDMAN

RESOLUTIONS

WHEREAS our friend and fellow worker Dr. Nathan Friedman has been called to his everlasting rest

We, the staff of the Jewish Hospital for Chronical Patients in meeting assembled hereby resolve that in his demise the institution has lost a devoted friend, a loyal physician and a kindly minister to the sick.

It is further resolved that we extend our sincere sympathy to his beloved family in their hour of trial and to express the hope that the fragrance of his memory will ever be their everlasting solace.

In accordance with our sense of loss we deem it fitting that its expression be spread upon our records in order that his services as secretary, associate and counselor be forever recorded in affection and appreciation.

MAURICE GERSTEIN, M.D., *Chairman of Staff*
Greater Boston Bikur Cholim Hospital.

NOTICES

MEDICAL CLINIC AND STAFF ROUNDS AT THE PETER BENT BRIGHAM HOSPITAL

At 3:30 P.M. on Thursday November 14 in the amphitheater of the Peter Bent Brigham Hospital, Dr. Henry A. Christian, Physician-in-Chief, Hersey Professor of the Theory and Practice of Physics in the Harvard Medical School, will give a medical clinic. To it are cordially invited practitioners and medical students.

On Saturdays in the wards of the Peter Bent Brigham Hospital from 10 to 12 staff rounds will be conducted by Dr. Christian.

LAWRENCE CANCER CLINIC

Established 1928

Lawrence, Mass, October 22, 1935

To the Physicians of the North Half of Essex County

Dear Doctor

The regular Lawrence Cancer Clinic, to be held at Lawrence General Hospital, One Garden Street, Lawrence, upon Tuesday, November 19, at 10 00 A M, will be a Demonstration Clinic with Channing C Simmons, M D, of Boston, Surgeon-in Chief to Collis P Huntington Memorial Hospital, and member of the Cancer Commission of Harvard University, Boston, present as consultant. You are invited to accompany any of your patients whom you desire shall have this service, or to send them with a note, and a report will be returned to you. This service is gratis. Your attendance at the Clinic is always welcome.

This Clinic is endorsed by the Committee on Post-graduate Instruction of the Massachusetts Medical Society.

A DEBATE RELATING TO MEDICAL SERVICE

The University of Kansas
University Extension Division
Lawrence

To the Secretaries, State and National Medical Associations

I think you are aware of the fact that some thirty or more high school debating leagues are debating this year the following question

"Resolved That the several states should enact legislation providing for a system of complete medical service available to all citizens at public expense"

The medical profession throughout the entire country has been most helpful in assisting these schools and debaters in securing authoritative information

The National Broadcasting Company is providing the facilities of its Red Network for a chain broadcast on this question on Tuesday afternoon, November 12. The following statement gives the essential facts concerning this broadcast.

Speakers

Affirmative William Trufont Foster, Director, Poliak Foundation. Professor Bower Aly, University of Missouri, Editor of the Debate Handbook. Negative Dr Morris Fishbein, Editor, *Journal of the American Medical Association*. Dr R G Leland, Director, Bureau of Medical Economics, American Medical Association.

Time—November 12, 2 00 to 3 00 P M, Eastern Standard Time (1 00 to 2 00 P M, C S T, 12 00 to 1 00, M S T, 11 00 to 12 00, P S T)
Stations Broadcasting — NBC Red Network and affiliated stations

HAROLD G INGHAM,
Chairman, N U E A Committee on Debate
Materials and Interstate Cooperation

ANNOUNCEMENT

W H WATTERS, M D, of 270 Commonwealth Avenue, Boston, announces that he will open the Boston Miami Clinic, Coconut Grove, Fla, for its eleventh winter season on November 11.

REMOVAL

M M ANSHIN, M D, announces the removal of his offices to 99 Franklin Street, Lynn, Mass.

REPORTS AND NOTICES
OF MEETINGS

HAMPDEN DISTRICT MEDICAL SOCIETY

The regular seasonal meeting of the Hampden District Medical Society began with a luncheon at the Monson State Hospital on September 25 at 1 30 P M. This was followed by a medical program arranged by the Hospital Staff. Dr Theodore S Bacon of Springfield, President of the Society, presided. There was an attendance of sixty members. The first paper was read by Dr Stein on "The Role of Mental Hygiene in General Practice." He dwelt on the sociological and psychological qualifications desirable in a great physician, the lack of which may cause a thousand quacks to rush in. He instanced the different problems presented at different periods of life and set forth a classification of mental disorders in which etiological factors were considered. The problem of the neuroses was touched on and a case report of a fifteen year old girl with enuresis was discussed.

Dr Roderick Heffron of the State Department of Public Health outlined the State Pneumonia Program, based on studies carried out in a large number of hospitals during 1931, to which the State Department supplied type sera and facilities for typing and who reported back their results. He stated that the laboratories of some fifty hospitals were qualified to carry on the work of typing, etc. The serum used is a concentrated one, Felton's Antibody Solution, effective for Types 1 and 2. The State is planning to take over the work of its production and distribution in the near future and the leading hospitals will also keep it on hand. Indications, contraindications, precautions and technique, and the possible types of reactions, were discussed. Charts were shown illustrating the marked reduction of the mortality where serum was properly used.

Dr Yakovlev of the Monson State Hospital Staff presented cases of Wilson's Disease, progressive lenticular degeneration of the corpus striatum.

brain, and cirrhosis of the liver a rare disease yet one which is increasingly met with

The meeting adjourned with a vote of thanks to the Hospital Staff

CARNEY HOSPITAL CLINICAL MEETING

On October 21 1935 at 8 30 P.M. the third clinical meeting of the Carney Hospital was held.

Dr A. McKay Fraser spoke on "The Early Diagnosis and Treatment of Appendicitis". He prefaced the main part of his address with a brief historical sketch of the disease and the probable influence of familial tendencies and body types. He brought out the various symptoms and physical signs which should be watched for and stressed the importance of the education of the lay person against the use of cathartics in abdominal pain. He gave careful consideration to the differential diagnosis. As to the treatment he was not didactic but gave the pros and cons of early operation late operation and the Ochsner expectant treatment. His talk was followed by a general discussion in which several of the visitors consulted him on cases of theirs which were somewhat obscure.

Dr R. H. Aldrich followed Dr Fraser with a discourse on "The Treatment of Burns". Dr Aldrich stressed his theory on the rôle of infection in burns and stated that he did not believe that the etiology of the toxemia in a burned patient was due either to an absorption of a split protein from the burned area or to a shifting of the water balance of the body with the resulting blood concentration. He stated that in practically one hundred per cent of large burns the betahemolytic and the gamma streptococcus existed in pure culture on the burned areas. From this he deduced that a burned patient should be considered to have an infected open surgical lesion. He considered asepsis and antiseptics to be the logical treatment. He has recently abandoned gentian violet for a combination of three of the anilin dyes namely crystal violet, brilliant green and neutral acriflavine. He described the technique of the treatment and concluded with an emphasis on two points: first that the treatment of burns requires a great deal of work and is not to be lightly considered, and the second, that if and when some other substance is found that is superior to the combination of the three dyes that substance also will be an antiseptic possessing the properties of analgesia and escherosis.

The address was followed by lantern slides, charts showing the history of the treatment of burns, and a demonstration of a severely burned patient.

THE MASSACHUSETTS MEDICAL BENEVOLENT SOCIETY

The Annual Meeting of the Massachusetts Medical Benevolent Society was held at the Boston Medical Library on October 24 1935

The Treasurer Dr Roger I. Lee reported that

during the last year the Society has been of financial assistance to twenty-two doctors' families. In the cases of more than half of this number the help has gone to the widows and children of deceased physicians. The necessity for increased funds so as to be even more helpful was evident as was the need for a larger sustaining membership among the practicing physicians of Massachusetts.

Dr George Gray Sears resigned his Presidency of the organization and the following officers were elected:

President Dr Robert M. Green.

Vice President Dr Lincoln Davis.

Secretary Dr Hilbert F. Day

Treasurer Dr Roger I. Lee.

Trustees Dr Lloyd T. Brown Dr Charles G. Mixer Dr Charles C. Lund.

HILBERT F. DAY M.D. *Secretary*

THE SOUTHEASTERN MASSACHUSETTS ASSOCIATED BOARDS OF HEALTH

More than seventy health workers representing seventeen towns and cities in Barnstable and Bristol Counties met on Wednesday October 23 at Handy's Inn in Falmouth for the regular fall meeting of the Southeastern Massachusetts Associated Boards of Health. The President, Dr T. L. Swift of Falmouth called the meeting to order and two of the selectmen of the town welcomed the visitors and the speaker for the afternoon Mr F. W. Goodhue of the Massachusetts Department of Welfare, was introduced.

The subject for consideration was "Reportable and Supportable Diseases" and the treatment was from the administrative rather than the medical point of view. Boards of health are interested in reportable diseases while welfare officials are involved in financial matters related to them and there is almost absolute confusion as to the relative positions of the two departments in such matters. If the disease is reportable it must come to the attention of the board of health and have proper supervision but when, as in a majority of the cases, there are questions of finance apparently the welfare officials should be responsible. In cases in this category there seems to be no well advised mode of procedure. Even in health matters there are widely varied customs. Quarantine for example, should be a very definite procedure but some boards isolate the worker the support of the family while other boards permit him to go regularly to work. Thus there seems to be no real definition of quarantine but, as a fundamental matter this is one feature that ought to be standardized.

In cases of pregnancy complicated with venereal disease, it has been asserted that the board of health should care for the disease while the welfare pays the pregnancy costs. For another example how about the multitude of indirect charges, such as the care of the family when the wage-earner is stricken with a notifiable disease? It seems pretty well established as a principle that medicine is under obligation to cooperate with the board of health but

where is the limit? When does special care cease, and what items should be within the province of the welfare board? These matters are very complicated today

The presentation of many instances of a nature akin to those noted above constituted the major portion of Mr Goodhue's address, leading to the emphatic expression of the necessity of some real agreement between health officials and welfare boards as to the practical limits of their respective spheres. He called attention to the fact that the recently created State Health Committee, the purpose of which is to review the health laws, looking toward revision, desires the fullest information on matters like those now under consideration here

Dr M E Champion of North Harwich, formerly with the State Health Department in Boston, and now a member of the Public Health Council of Barnstable County, dwelt quite at length on the unfortunate condition, based as it is on customs that are really archaic, and urged steps toward the betterment of the situation. In the general discussion which followed, Mr W G Kirschbaum of New Bedford, Mr Charles R. Bassett of Yarmouth, Dr A P Goff of Hyannis, Dr R P MacKnight, local District Health Officer, and Dr W O Hewitt, of Attleboro, offered affirmative arguments

There was the usual exchange of experiences before the meeting, the social features of which included a dinner enlivened by music by a high school string ensemble

CARNEY HOSPITAL

OUT-PATIENT STAFF

The monthly meeting of the Out-Patient Staff will be held Tuesday, November 12, at 11 30 A M

Speaker Dr Curran

Subject Pneumonia.

W J MACDONALD, M D., *Secretary*

MASSACHUSETTS SOCIETY FOR MENTAL HYGIENE

The Annual Meeting of the Society will be held on Wednesday, November 20, at the Twentieth Century Club, Boston, beginning with a luncheon at one o'clock.

Speakers are Rev Phillips E Osgood, Rector of Emmanuel Church, who will speak on "Personal Religion as a Force for or against Normal Life," and Dr Winfred Overholser, Commissioner of the Massachusetts Department of Mental Diseases, who will talk on "The Mental Health Program of the State Department of Mental Diseases"

THE SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the office of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, November 19, 1935, at 12 noon. The speaker will be Francis Lowell Burnett, M D, Di-

rector of Health Class for Psoriasis, Massachusetts General Hospital, Director of Health Class for Arthritis, Peter Bent Brigham Hospital. The title of his talk will be "New Principles for Normal Nutrition and Health to Cure Disease." Lantern slides will be used. All physicians are cordially invited to attend this meeting. Luncheon will be served at 1 o'clock

NORFOLK DISTRICT MEDICAL SOCIETY

PROGRAM FOR 1935 1936

November 26, 1935

Norwood Hospital at 8 P M

Papers by the staff

January 28, 1936

Hotel Kenmore at 8 P M

Dr Benedict F Boland—"Cauterization of the Cervix Uteri Using Various Electrical Methods" Illustrated with lantern slides

February 25, 1936

Massachusetts Memorial Hospitals at 8 P M

Papers by the staff

March 31, 1936

Hotel Kenmore, at 8 P M.

(Subject to be announced)

May, 1936

Annual Meeting

(Place, date and subject to be announced)

The censors meet for the examination of candidates November 7, 1935, May 7, 1936, November 5 1936

FRANK S CRICKSHANK, M D

1236 Beacon Street,

Brookline, Massachusetts

NEW ENGLAND ROENTGEN RAY SOCIETY

The November meeting of the New England Roentgen Ray Society will be held at the Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, Mass., on Friday, November 15, at 8 15 P M

DR A S MAOMILLAN, *President*,

483 Beacon Street,

Boston, Massachusetts

DR RICHARD DRESSER, *Secretary*,

695 Huntington Avenue,

Boston, Massachusetts

BOSTON FLOATING HOSPITAL

There will be a Staff meeting of the Boston Floating Hospital from 12 noon to 1 P M, on Friday, November 15. Discussion of Poliomyelitis with special reference to the use of vaccines, by Dr James M Baty

MASSACHUSETTS MEMORIAL HOSPITALS

There will be a meeting of the Surgical Section in the Ladies' Aid Room, Talbot Memorial, 82 East Con-

cord Street, Boston on Friday November 8 1935
at 1st noon.

Dr Milo C Green will present 'A Case of Peritoneal Tumor' and there will be a case presentation by Dr Phillips L. Boyd

Milo C GREEN *Secretary*

NEW ENGLAND OPHTHALMOLOGICAL SOCIETY

The next meeting of the New England Ophthalmological Society will be held on Tuesday November 12, 1935 at 8 P.M. at the Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston.

PROGRAM

Tuberculous Sclerosis with Tumor of Optic Nerve.
Dr Harry C Messinger

Paper Etiology of Trachoma. Analysis of Recent Studies Dr Phillips Thygeson Iowa City Iowa.
Discussion

BENJAMIN SACHS M.D. *Secretary-Treasurer*

MASSACHUSETTS EYE AND EAR INFIRMARY

The annual meeting of the Alumni of the Infirmary will be held on Wednesday November 13. It will begin at 9 A.M. and continue all day

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held in the Peter Bent Brigham Hospital Amphitheatre (Shattuck Street Entrance) Tuesday evening November 12, at 8 15 P.M.

PROGRAM

Presentation of Cases

Recent Studies in Yellow Fever—A Virus Disease
By Dr Frederick F. Russell, Lecturer in Preventive Medicine and Hygiene, Harvard Medical School.

MARSHALL N. FULTON M.D. *Secretary*

WORCESTER DISTRICT MEDICAL SOCIETY

GRAFTON STATE HOSPITAL,
WEDNESDAY NOVEMBER 13 1935

6 30 P.M. Buffet Supper (Main Auditorium)

7 30 P.M. Scientific Program

a. Repression and Communicability in Catatonic Stupor Dr Benjamin Cohen Research Member of Grafton State Hospital Staff.

b. Parenteral Paraldehyde Dr Bardwell Flower Assistant Superintendent, Grafton State Hospital

Dr Charles Mongan our present State President, will also address this meeting concerning many problems confronting the Massachusetts Medical Society

SPECIAL MEETING

Town House—34 Elm Street, Worcester Mass
8 15 P.M., Wednesday November 14 1935

The Holy Cross College Debating Team will debate on the following subject

Resolved, that a system of Compulsory Sickness

Insurance should be enacted by the Massachusetts Legislature

This meeting and debate is on a subject of intense interest to the Medical Society at the present time. The meeting is open to members of the Society and their wives and other members of their families.

Dr. ERWIN C. MILLER, *Secretary*

Dr. WILLIAM LYNCH, *President*

SOCIETY MEETINGS CONGRESSES AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING MONDAY NOVEMBER 11 1935

Tuesday November 12—

9 10 A.M. Boston Dispensary 25 Bennett Street, Boston. Report on the Results of Short Wave Therapy in the Past Year Dr P. Hoefer

2 3 P.M. Radio Broadcast. NBC A Debate Relating to Medical Service.

2 39 P.M. Pediatric Ward Visit. Massachusetts Eye and Ear Infirmary

7 45 P.M. Gardner Auditorium, State House, Boston. The Management of Disease in Childhood in Relation to Mental Health Bronson Crothers M.D.

8 P.M. New England Ophthalmological Society Massachusetts Eye and Ear Infirmary 43 Charles Street, Boston.

8 15 P.M. Harvard Medical Society Peter Bent Brigham Hospital Amphitheatre (Shattuck Street entrance)

Wednesday November 13—

9 A.M. Massachusetts Eye and Ear Infirmary. Annual Meeting of the Alumni.

9 10 A.M. Boston Dispensary 25 Bennett Street, Boston. Ward Cases Dr S. J. Thannhauser

11 A.M. Clinico-Pathological Conference. Children's Hospital.

Thursday November 14—

8 30 9 30 A.M. Clinic Surgical and Orthopedic Staffs of Children's Hospital at the Children's Hospital.

9 10 A.M. Boston Dispensary 25 Bennett Street, Boston. Recent Observations on the Functional Properties of the Vascular System and on the Hemodynamics in Arterial Hypertension Dr Soma Weiss

2 30 P.M. Medical Clinic at the Peter Bent Brigham Hospital.

5 P.M. Lecture on 'The Care of the Patient,' Dr Arthur R. Crandell. Harvard Medical School, Amphitheatre C.

Friday November 15—

9 10 A.M. Boston Dispensary 25 Bennett Street, Boston. Ward Cases. Dr S. J. Thannhauser

11 A.M. Boston Floating Hospital Staff Meeting

8 15 P.M. New England Roentgen Ray Society Massachusetts Eye and Ear Infirmary 43 Charles Street, Boston.

Saturday November 16—

9 10 A.M. Boston Dispensary, 25 Bennett Street Boston. Liver Disease. Dr S. J. Thannhauser

10-12. Staff rounds at the Peter Bent Brigham Hospital.

Open to the medical profession.

Open to Fellows of the Massachusetts Medical Society

BOOK REVIEWS

Food and Beverage Analyses Milton A Bridges 246 pp Philadelphia Lea & Febiger \$3 50

This small and handy volume of analytical data is a real contribution to the practice of nutrition. Most of the book consists of a table of the nutritive and caloric values of all kinds of food, for here the raw product, as well as its combination in commonly used commercial preparations, is listed. The figures given represent the caloric value and the protein, fat, and carbohydrate content of average portions in grams, and also household portions, of each food. In other chapters, tables of the acid and alkali ash, mineral, inorganic salt, vitamin, and iodine values of foods, are given. And at the end of the book, the composition, alcoholic content, and fuel values of malt liquors, wines, and distilled spirits are listed. There is also a complete bibliography, a good index, and the print is clear. The book should be found very useful to practitioners, dietitians, and medical students.

A Bibliography of Two Oxford Physiologists, Richard Lower 1631-1691, John Mayow 1643-1679 John F Fulton 62 pp New Haven Yale University Press

A complete bibliography of these two important seventeenth century physiologists has long been anticipated. The importance of the work of Richard Lower and John Mayow was emphasized in a paper published in 1908 by Professor Francis Gotch. Before his paper very little was known of John Mayow and hardly more about the more important of the two men, Richard Lower. Professor Fulton has now given us a carefully edited bibliography, similar in appearance to his well known bibliography of Robert Boyle, published in 1932-3. This new bibliography sets a high standard and is of inestimable value to the historian of medicine and science. There is a brief introduction by Dr K J Franklin, who has done so much to add to our knowledge of the Oxford physiological group. The separate editions of the works of both Lower and Mayow are carefully collated, their contributions to other works noted, biographies and commentaries are listed, many of the important title pages are reproduced, and there is an excellent index.

VOLUME 213

NOVEMBER 14, 1935

NUMBER 20

MALIGNANT HYPERTENSION*

BY HARRY A. DEROW, M.D. † AND MARK D. ALTSCHULE, M.D. ‡

INTRODUCTION

MUCH has been written in the recent years concerning a rapidly fatal form of hypertension termed by various authors "malignant hypertension", "malignant nephrosclerosis", "arterioneerosis", "arterioloneerosis", and "malignant phase of essential hypertension". A survey of this literature reveals important differences in the descriptions of the clinical picture and more particularly of the underlying pathology in this type of hypertension. It was therefore considered desirable to study the postmortem material obtained from patients in whom the diagnosis of malignant hypertension had been made during life. This paper represents the result of such a study.

Clinically, malignant hypertension manifests itself by a history of severe headache, weight loss, weakness, and visual disturbances. Examination of patients with these symptoms reveals severe persistent hypertension and a typical retinal picture. The retina in malignant hypertension has been described by Wagener¹ and others.^{2, 10, 11, 12} It has been termed "renal retinitis", "retinitis of malignant hypertension", "albuminuric retinitis", "malignant hypertensive neuroretinitis",¹³ and "hypertensive neuroretinopathy".¹⁴ Edema and hyperemia of the optic discs are the outstanding features. In addition, sclerosis of the arterioles, retinal hemorrhages, and "cotton wool" spots are present.

The earlier^{1, 2, 4, 5} authors stressed the invariable terminal occurrence of acute uremia in patients with malignant hypertension. On the other hand, Keith, Wagener, and Kernohan⁴ and Murphy and Grill⁵ emphasized the failure of other organs particularly the heart and brain, in such patients, and described cases in which there was absolutely no evidence of renal insufficiency. Volhard and Fahr,¹ Stern,² Herrheuser,⁴ and Fishberg⁵ regard the fundamental pathology of malignant hypertension to consist in renal necrotizing arteriolitis, while Keith, Wagener, and Kernohan,⁴ described only a very widely distributed arteriolar medial hypertrophy. Murphy and Grill⁵ observed little medial hyper-

trophy, but they did find renal arteriolitis in some instances but could demonstrate no correlation between its presence and the occurrence of renal insufficiency.

There has however, always been universal agreement that the elevation of blood pressure in malignant hypertension is of the *primary essential type*.

Analysis of the cases seen at the Beth Israel Hospital, Boston, with the clinical picture of malignant hypertension as described by Keith, Wagener, and Kernohan⁴ revealed the fact that the hypertension in some of them was unquestionably of secondary origin. This was discovered only at postmortem examination and was entirely unsuspected during life. Moreover, even in those instances in which the hypertension was undoubtedly primary, autopsy revealed a variety of underlying pathological processes. Five cases typical of the series under the direct observation of the authors, are reported.

REPORT OF CASES

CASE 1 History I B (B I H No 4740) a forty-three year old Russian Jewish iron worker with a family history of heart trouble in one sister and with a past history of measles in childhood occasional slight epistaxis from the left nostril since childhood several sore throats each winter and nocturia of four or five times a night for about four years entered the hospital on December 13, 1929 complaining of weakness of two weeks duration. About four weeks before admission the patient noted loss of appetite dyspnea while at work, spells of dizziness, and a slight cough, the last most marked at night. These symptoms progressed and the patient took to bed two weeks before admission. At that time he also became orthopneic and his cough began to be associated with pain in his right chest. Twelve days before admission the patient was told that he had high blood pressure. He lost twelve pounds in weight in the four months preceding admission.

Physical Examination The patient was a dyspneic orthopneic man with slight cyanosis of the ears and lips and Cheyne-Stokes respiration. The anterior-posterior diameter of the chest was increased. The percussion note was somewhat hyperresonant. A few moist rales were heard of the lung bases. The heart was moderately enlarged and presented an accentuated aortic second sound. The liver was palpable three centimeters below the costal border. The peripheral arteries showed marked thickening and tortuosity. The blood pressure was 22½ systolic and 140 diastolic. Ophthalmoscopic examination revealed hyperemia of both discs with slight papilledema. The vessels were narrowed and tortuous and showed marked arteriovenous nicking. Both fundi contained numerous

*From the Nephritic Clinic of the Beth Israel Hospital, Boston, Massachusetts, and the Department of Medicine, Harvard Medical School.

†Derow, Harry A.—Assistant Physician, Beth Israel Hospital, Altschule, Mark D.—Resident in Medical Research, Beth Israel Hospital. For records and addresses of authors see "This Week Issue" page 331.

irregular areas of degeneration temporally and scattered punctate, linear and irregular fresh and old hemorrhages as well as areas of exudate, the last especially prominent about the maculae

Laboratory Data Seven urine examinations showed a specific gravity ranging from 1.002 to 1.012, with a trace to a large trace of albumin in all specimens the sediment was negative except for the finding of a few leucocytes on one occasion and several granular casts on another. The white blood cell count ranged between 10,900 to 14,200 per cu mm with an increase in the polymorphonuclear cells to 82 per cent. The red blood cell count was 4,200,000 per cu mm. with a hemoglobin of 70 per cent (Tallqvist). Blood Wassermann reaction was negative. Phenolsulphonphthalein excretion after intramuscular injection of the dye was 5 per cent after two hours and ten minutes on two occasions. The blood sugar was 95 mg per cent. The blood nonprotein nitrogen on admission was 54 mg and the blood creatinine was 3.6 mg. These values rose to 141 mg and 71 mg per cent respectively during the following two weeks. The icteric index was 11.3. The serum phosphate was 7.1 and 8.9 mg per cent on two occasions toward the end of his course, and the serum calcium was 10.2 and 9.3 mg per cent. The blood CO₂ combining power ranged between 30 and 38 volumes per cent. The blood cholesterol on two occasions was 208 and 195 mg per cent respectively.

Electrocardiogram showed normal rhythm rate 90, with inverted T" and T'" and slurred QRS'

Clinical Course The patient was given a salt poor 30 gram protein diet, fluids to 1500 cc and was digitalized. His blood pressure fluctuated about 210 systolic and 120 diastolic during the first two weeks of his stay and then slowly fell to 170 systolic and 95 diastolic as the patient lapsed into coma. During the three weeks of his hospital stay he had several attacks of angina pectoris and severe epistaxes. His weakness and cyanosis increased and the patient failed rapidly, expiring on the twenty-first day of his stay.

Autopsy (No A301) Autopsy was performed by Drs Stern and Schlesinger two hours postmortem. Both legs showed considerable edema. The eyelids were puffy. The peritoneal cavity contained 250 cc of serous fluid. The left pleural cavity contained 750 cc and the right 700 cc of fluid. The surfaces of both lungs bore a few small fibrous adhesions. The pericardial cavity contained 100 cc of clear, straw colored fluid.

The right kidney weighed 190 and the left 200 grams. The capsules stripped with difficulty, leaving a slightly granular, pitted, pale brownish-yellow surface. The kidneys were firm in consistency. The cortex was well demarcated from the medulla and measured 5 mm in thickness. The kidneys appeared congested. Microscopic examination revealed a moderate increase in the interstitial connective tissue. The connective tissue was edematous and contained a small number of chronic inflammatory cells, the latter occurring in foci in some areas. The glomeruli presented varying degrees of fibrosis. A moderate number showed marked fibrosis of the tufts and some were represented only by a mass of fibrous tissue. Most of them were normal except for occasional tiny foci of polymorphonuclear cell infiltration. The glomerular capsules showed slight thickening in a few areas but no definite crescent formation. In a few instances adhesions had formed between capsule and tuft. The larger arteries showed slight to moderate intimal thickening. Many of the arterioles were entirely normal. A very few showed medial hyaline thickening and thickening. In rare instances, there were small foci of arteriolar necro-

sis at the point at which the afferent arterioles entered their respective glomeruli. The tubules showed marked atrophy of the lining epithelium. Many of the lumina contained granular debris, masses of fibrin, and casts of various sorts. In short, the kidneys showed chronic glomerular nephritis, and rare foci of arteriolonecrosis.

The heart weighed 650 grams. The valves were all normal. The left ventricle was markedly hypertrophied measuring 3.7 cm in thickness except at the apex where it was thinned, measuring 0.3 cm. The right ventricle measured 0.8 cm in thickness. The circumflex branch of the left coronary artery was completely occluded and the descending branch markedly narrowed. The other arteries showed moderate atheromatous change.

The lungs were somewhat congested and presented small scattered, pneumonic areas.

The aorta was normal in size but showed diminished elasticity. There were a few scattered atheromatous plaques, one of which in the thoracic region had ulcerated leaving a denuded area measuring 10 x 6 mm.

All of the other organs showed varying degrees of congestion. The liver showed, in addition, moderate central necrosis. The arteries presented moderate sclerosis. The arterioles of the pancreas and adrenals showed slight to moderate medial thickening and hyalinization. Those of the spleen showed similar, though more marked changes, with foci of medial necrosis and thrombosis.

Comment This middle-aged patient with a negative past history entered the hospital with a present illness characterized by loss of weight of four months' duration, dyspnea, dizziness and cough of four weeks' duration and orthopnea and pleuritic pain of twelve days' duration. Examination revealed dyspnea, orthopnea, cyanosis, slight emphysema, a few râles at the bases of the lungs, moderate cardiac enlargement, a palpable liver, marked arteriosclerosis and a blood pressure of 225 systolic and 140 diastolic. Ophthalmoscopic examination showed typical malignant neuroretinitis. There was a slight anemia. The other laboratory findings indicated marked renal impairment. His course was steadily downhill and he died in uremia three weeks after admission. Postmortem examination revealed chronic glomerular nephritis with a small amount of superimposed vascular nephritis. Rare foci of arteriolonecrosis were also observed in the kidneys. This patient with autopsy findings of chronic glomerular nephritis presented a typical picture of malignant hypertension terminating in uremia.

CASE 2 History E. R. (B. I. H. No 14671), a twenty-two year old American Jewish housewife with a negative family history and with a past history of measles and uncomplicated scarlet fever in childhood, entered the hospital on May 26, 1932, complaining of blindness of two days' duration. The patient was accepted for life insurance one year before admission. She was entirely well until four months before admission at which time she began to experience slight fatigue, occasional frequency and enuresis, and slight blurring of vision, the last relieved by glasses. She visited a physician who told her that her blood pressure was slightly elevated. Two days before admission she suddenly began to experience marked blurring of vision,

severe frontal headache and severe vomiting. She soon became quite blind. She also became confused and at times comatose. She lost nineteen pounds in weight in the two months preceding admission.

Physical Examination. The patient was a well developed poorly nourished young woman lying in bed in no distress. The heart was normal in size, with a reduplicated first sound and an accentuated second aortic sound. There was slight thickening of the walls of the peripheral arteries. The lungs, abdomen and extremities were entirely negative. The blood pressure was 200 systolic and 140 diastolic. Ophthalmoscopic examination revealed moderate elevation of the right disc with absent cupping. The left disc outline was blurred. The retinal vessels were entirely negative. There was a single hemorrhage above the right disc.

Laboratory Data. Eight urine examinations revealed a specific gravity ranging as high as 1.034. All the specimens showed slight or very slight traces of albumin. Several contained occasional leucocytes and rare erythrocytes and granular casts. The red blood cell count on admission was 4,650,000 per cu. mm. and the hemoglobin was 75 per cent (Tallqvist). These values slowly fell to 4,200,000 per cu. mm. and 70 per cent, respectively. The white blood cell count ranged between 11,000 and 20,300 per cu. mm. with a polymorphonuclear cell count of 81 to 85 per cent. The blood sugar was 105 mg. blood nonprotein nitrogen 29 to 33 mg., blood creatinine 1.6 mg. per cent and the blood CO₂ combining power 57 to 61 volumes per cent. The blood Wassermann, Kahn and Hinton reactions were negative. Phenolsulphonphthalein excretion after two hours and ten minutes following intramuscular injection of the dye was 60 to 55 per cent. Basal metabolism was plus 12 per cent. Lumbar puncture revealed an initial pressure of 210 mm. of water with normal dynamics. Examination of the spinal fluid revealed one cell, no globulin, a negative Wassermann reaction and a total protein of 50 mg. per cent.

X-rays of the skull and kidneys were negative.

Clinical Course. The patient was given a salt poor 40 grams protein diet with fluids to 3000 cc. During her first day she received magnesium sulphate by mouth and intramuscularly every four hours, and was also subjected to a venesection of 275 cc. After several hours her vision became normal. The next day her optic discs both showed cupping and definite margins. At this time a tiny hemorrhage and several patches of exudate were also noted. Arteriovenous nicking developed during the following week. In the course of her ten-day stay her blood pressure fell to 170 systolic and 120 diastolic. She continued to receive 50 per cent solution of magnesium sulphate by mouth in smaller doses. She was discharged on her tenth day with orders to continue the above régime at home. She was quite well for one week, and then weakness, anorexia, frequent vomiting and attacks of pain with paresthesias in the arms supervened. At this time her blood pressure was 180 systolic and 140 diastolic. During the second week following discharge she suddenly lost the sight of her right eye. The blindness slowly improved. Thereafter for the next two months she was fairly comfortable except for irregular fever, occasional headaches and pains in various parts of her body. Two and one-half months after discharge she suddenly became completely blind and had seven bouts of left-sided convulsions over a period of several hours. Examination at this time revealed the absence of all deep reflexes. After two days she reverted to her previously fairly comfortable state. Her weakness and anorexia became worse and in the four and one-half months after

discharge she lost twenty-four pounds in weight. She therefore reentered the hospital on October 23, 1932.

Second Admission Physical Examination. At this time the examination revealed the same findings as on the first admission except that there was marked wasting. The blood pressure was 215 systolic and 150 diastolic. Ophthalmoscopic examination revealed blurring of the disc margins and absence of cupping. The arterioles were narrowed and slight arteriovenous nicking was present. There were many patches of exudate and one hemorrhage.

Laboratory Data. Fourteen urine examinations showed a maximum specific gravity of 1.016. More albumin and a greater number of leukocytes were present in all specimens than during the first admission. The blood nonprotein nitrogen was 31 mg. and the blood creatinine was 1.3 mg. per cent. The red blood cell count on four occasions varied between 4,000,000 and 4,350,000, the hemoglobin was 70 per cent (Tallqvist). The white blood cell count ranged between 6,100 and 9,100 with a normal differential count and smear. Phenolsulphonphthalein excretion following intramuscular injection of the dye after two hours and ten minutes varied from fifty per cent on admission to twenty-five per cent shortly before death. Lumbar puncture showed an initial pressure of 250 mm. of water with a positive globulin test and a total protein of 75 mg. per cent.

X-rays of the skull and kidneys were negative.

Clinical Course. Her course during the remaining forty-nine days of her life was characterized by apathy and listlessness with frequent headaches and occasional sensations of numbness and tingling in various parts of the body. The blood pressure fluctuated about 200 systolic and 150 diastolic. The eye ground changes were progressively increased in severity. On the forty-ninth day of her stay she suddenly became comatose and shortly thereafter expired.

Autopsy (No A32-36). Autopsy was performed by Drs. Krakower and Schlesinger through a limited abdominal incision. There was a large subconjunctival hemorrhage over the left eye. The glands of the axillae and inguinal regions appeared somewhat enlarged as were those of the peritoneal cavity. There was a moderate amount of yellowish fluid in both pleural cavities, particularly the right.

The right kidney weighed 40 grams and the left 140 grams. The right kidney was small. The ureters and vessels were normal in position and origin. The right renal artery was small. The capsule of the right kidney stripped easily revealing moderate focal lobulations. The surface was otherwise not remarkable. On section through the long axis of the right kidney a sharp line of demarcation between the upper and lower portions was noted 5.5 cm. from the upper pole. The entire kidney measured 10.5 cm. in length. In the upper portion the cortex was well defined and measured 0.2 cm. as compared with 1.3 cm. below that point. The pelvis of the upper portion was somewhat dilated and the medulla thinner than normal indicating the presence of a slight partial hydronephrosis. The cortex in the lower portion of the right kidney appeared swollen and poorly outlined. The pelvis in this portion of the kidney was quite normal. The capsule of the left kidney stripped easily revealing scattered pit-like depressions. The cortex appeared swollen and measured about 1.0 cm. in thickness. The pelvis was not remarkable. Microscopic examination of the atrophic upper portion of the right kidney showed slight collagen proliferation of the glomerular tufts with congestion in some areas but no infiltration. None of the glomeruli appeared hyalinized. The glomerular cap-

sules were thickened, but presented no cellular proliferation. The afferent arterioles showed moderate hyalinization of the media and narrowing of the lumen. The tubules all appeared very small and presented thickening of the basement membrane. The lumina of the tubules were almost entirely obliterated. A slight increase in interstitial fibrous tissue with a few scattered foci of lymphocytic infiltration was noted in the medulla. The larger arteries revealed fibrous thickening of the adventitia and the intima. The microscopic picture in the lower portion of the right kidney and in the entire left kidney was quite different. Here the glomeruli were entirely normal and the afferent arterioles showed no evidence of hyalinization. The convoluted tubules were markedly dilated and in some areas vacuolization of the cells was present. The basement membrane was nowhere thickened. There were a few scarred areas near the cortex, containing a small number of chronic inflammatory cells. There was slight intimal proliferation in the larger arteries.

The heart weighed 240 grams. There was some atheromatous deposit in the aortic valve and in the aortic leaflet of the mitral valve. The coronary vessels were normal except for occasional small atheromatous plaques especially at their origin. The aorta presented a few scattered atheromatous plaques particularly about the orifices of the intercostal and iliac vessels. The elasticity of the aorta was good. The circumference of the aorta in the thoracic region was 4.0 cm and in the lumbar region 3.0 cm. The gastrointestinal tract was not remarkable except for scattered patches of congestion and pinpoint areas of hemorrhage. The adventitia of the colon was thickened. Several of the arteries in it were thrombosed.

The muscularis of the gall bladder was edematous. The adventitia was markedly thickened and fibrosed. The arterioles showed slight hyalinization and marked thickening and fibrosis of the media. Marked thickening of the intima of the arterioles was also noted. Necrosis and thrombosis of the arterioles with hemorrhage and inflammatory cell reaction were present in several areas. A large artery in one section showed marked intimal thickening with thrombosis.

The other organs showed varying degrees of congestion. The arterioles of the intestines, pancreas and adrenals showed slight medial thickening and hyalinization, and those of the spleen presented similar though more marked changes.

Comment. This young woman with a negative past history entered the hospital with a present illness characterized by slight fatigue, occasional frequency and enuresis, slight blurring of vision and hypertension of four months' duration, palpitation of two weeks' duration and severe headache, vomiting and blindness of two days' duration. Physical examination was entirely negative except for hypertension of 200 systolic and 140 diastolic. Ophthalmoscopic examination revealed malignant neuroretinitis. Her course was steadily downhill for the next seven months and was terminated by the sudden onset of coma due apparently to a cerebral accident. Postmortem examination revealed necrosis of the arterioles of the gall bladder. The kidneys were entirely normal except for an early partial hydronephrosis, with resulting atrophy of the upper portion of the right kid-

ney. This patient whose only renal lesion was a partial hydronephrosis of one kidney presented the typical picture of malignant hypertension terminating abruptly with coma.

CASE 3. History P. S. (B. I. H. No. 20013), a fifty-six year old Russian Jewish cattle dealer, with a family history of the death of his father of heart disease and with a past history of typhoid fever in 1919 and a fracture of the right leg in 1913, entered the hospital on October 7, 1933, complaining of vomiting of one day's duration. He was accepted for life insurance in 1928. He was quite well until about a year before admission, when he began to experience severe morning headache and frequent attacks of dizziness and tinnitus. He also became aware of dyspnea and palpitation on exertion, loss of appetite and nocturia of once a night. From time to time, he also had attacks of substernal pain which radiated to the neck and back and occasionally down the left arm. He lost twenty-five pounds in weight in the year preceding admission. Six months before admission all his symptoms became worse and he also developed marked blurring of vision. Several weeks before admission he began to have crampy pains in the hands and feet and the day before admission commenced to vomit.

Physical Examination. The patient was a fairly well-nourished, middle-aged man lying in bed in no distress. The heart was not enlarged. The heart sounds were of good quality. The second aortic sound was accentuated and ringing. The lungs and abdomen were normal. The peripheral vessels were thickened and tortuous. The deep reflexes were somewhat hyperactive and there was a positive Hoffmann's sign on the right. The fingers were slightly clubbed. Blood pressure was 230 systolic and 155 diastolic. Ophthalmoscopic examination revealed pallor of the discs with obliteration of the outlines and peridisc edema. The arterioles were markedly narrowed. There were many areas of hemorrhage and a few patches of exudate.

Laboratory Data. Four urine examinations revealed a specific gravity ranging from 1.004 to 1.015. All the specimens contained very small amounts of albumin and rare erythrocytes and leukocytes as well as hyaline casts on rare occasions. The red blood cell count on admission was 5,390,000 per cu. mm. with a hemoglobin of 90 per cent (Tallqvist). This gradually fell to 3,890,000 per cu. mm. with a hemoglobin of 70 per cent. The white blood cell count fluctuated between 10,200 and 18,800 per cu. mm. with a polymorphonuclear cell count of 85 per cent. The blood smear was normal. The blood Wassermann, Kahn and Hinton reactions were negative. The blood sugar fluctuated between 85 and 101 mg. per cent and the blood nonprotein nitrogen between 27 and 36 mg. per cent. The icteric index was 7.5. Lumbar puncture revealed normal pressure and dynamics, a positive globulin test and a total protein of 110 mg. per cent, sugar of 74 mg. per cent, and chlorides of 618 mg. per cent. The spinal fluid Wassermann was negative. Phenolsulphonphthalein excretion after two hours and ten minutes following intramuscular injection of the dye on two occasions was 15 and 25 per cent respectively.

X-rays of the kidneys showed no abnormalities. A seven foot film of the heart revealed no cardiac enlargement.

Clinical Course. The patient was given a house diet with fluids to 5000 cc. His blood pressure fluctuated about 230 systolic and 160 diastolic, tending to fall slightly below this level shortly before

death. He became confused soon after admission. Slight improvement followed a venesection of 500 cc. on his fifth day and lumbar puncture on his third and eleventh days. Nevertheless his mental state became worse and several days before death he became comatose. At this time signs of pneumonia at the right base were noted. He died on his twenty first day.

Autopsy (No A33-58) Autopsy was performed by Drs Greenblatt and Schlesinger through a limited abdominal incision two hours postmortem. The right kidney weighed 90 and the left 130 grams. The peritoneal fat was adherent to the thickened capsules, but the capsules stripped with ease presenting only a few points of adhesion. The kidneys, especially the right, were contracted. They presented a finely granular mottled yellowish and brownish surface. The cortex of the right kidney was irregular and atrophied, measuring 2 to 5 mm in thickness. It appeared pale and yellowish-gray in color. The cortex of the left kidney was similar in appearance but was wider and better defined. The left renal pelvis showed numerous hemorrhagic points. The ureters were normal. Microscopic examination revealed a small amount of patchy scarring. Such areas contained fibrosed glomeruli and small foci of chronic inflammatory cell infiltration. The rest of the glomeruli were swollen and congested. Scattered about were a small number of foci of necrosis. These occurred mainly in the glomeruli but also in afferent arterioles and small arteries. These areas contained masses of fibrin. A few of the afferent arterioles showed hyalinization and thickening of the media. Most of the arterioles were normal. The larger arteries presented marked intimal proliferation throughout. In some areas the intubules showed colloid degeneration. In one section there was a large, old infarct consisting of a mass of edematous scar tissue containing dilated capillaries, a few chronic inflammatory cells, scattered atrophic tubules, and several completely fibrosed glomeruli and tubules. In short these kidneys showed arteriosclerosis and a small amount of acute necrotizing glomerulitis and arteriolitis.

The heart weighed 435 grams. The left ventricle appeared hypertrophied. The valve and endocardium were normal. The aorta was 65 cm. in circumference in the thoracic region, and 70 cm. in circumference in the lumbar region. There was atheromatous deposit with ulceration from the arch to the bifurcation most marked in the lumbar region. The elasticity of the aorta was absent.

The liver presented as incidental findings two small hemangiomas. There was also congestion and slight central necrosis.

The other organs showed varying degrees of congestion. The arterioles of the intestine and the pancreas presented slight medial thickening and hyalinization while those of the spleen showed more marked changes of the same nature.

Comment This elderly man with a negative past history entered the hospital with a present illness characterized by morning headaches, dizziness, dyspnea and palpitation on exertion, loss of appetite, nocturia and loss of weight of one year's duration. Physical examination was entirely negative except for a blood pressure of 230 systolic and 155 diastolic, generalized arteriosclerosis and hyperactive tendon reflexes on the right. Ophthalmoscopic examination revealed typical malignant neuroretinitis. An anemia

gradually developed while the patient was in the hospital. His renal function showed slight impairment. His course was rapidly downhill and on his twenty first day he died of bronchopneumonia. Postmortem examination revealed arteriosclerosis and a small amount of necrotizing glomerulitis and arteriolitis of the kidneys. This patient with postmortem findings of a small amount of renal arteriosclerosis and occasional foci of necrosis in the glomeruli and afferent arterioles presented the typical clinical picture of malignant hypertension terminating with bronchopneumonia.

CASE 4 History S. L. (B. I. H. No 20001) a forty-one year old Russian Jewish clothing worker with a negative family history and with a past history of influenza in 1918 entered the hospital on October 6, 1938 complaining of severe headaches of two years duration. The patient was quite well until two years before admission, when he began to experience severe headaches chiefly frontal, lasting eight to twelve hours daily. He also commenced to suffer with nocturia of twice a night and slight palpitation on exertion. He entered a hospital where he was told that his blood pressure was elevated. He was ordered to restrict his meat intake. He was free from headaches until thirteen months before admission when they recurred lasting each time from one-half to twenty-four hours. They were accompanied by nausea, and rarely by vomiting. He was admitted to another hospital where he was found to have hypertensive changes in the eyegrounds, a diffusely enlarged thyroid gland, sclerosis of the peripheral vessels, an enlarged heart and a blood pressure of 228 systolic and 150 diastolic. All specimens of his urine showed small amounts of albumin and casts. His basal metabolism was plus 25 to 30 per cent. A subtotal thyroidectomy was performed and his blood pressure fell to 170 systolic and 100 diastolic. His basal metabolism at this time was plus four per cent. Microscopic examination of his thyroid gland revealed no evidence of hyperplasia. He was discharged with a diagnosis of essential hypertension and arteriosclerosis. Following discharge he was well until eight months before admission to the hospital. From this time on he experienced constant recurrences of his headaches, dimness of vision and increased irritability. Six months before admission to this hospital the patient became depressed and suspicious, and developed delusions. At this time the blood pressure was 208 systolic and 142 diastolic. The patient's headaches and vomiting became worse and were sometimes accompanied by loss of memory and changes in personality. He also had transitory diplopia. His dyspnea, palpitation and weakness increased. In addition the patient had two attacks of hematuria each lasting several days, four months and three days respectively before admission to this hospital. He lost 50 pounds in weight in the two years preceding admission.

Physical Examination The patient was a well developed, poorly nourished middle-aged man lying in bed in no distress. The heart was not enlarged. The second aortic sound was accentuated. The lungs, abdomen and extremities were normal. The peripheral arteries showed advanced sclerosis. The blood pressure was 230 systolic and 150 diastolic. Ophthalmoscopic examination revealed swelling and hypereimia of both discs and obliteration of the disc margins. The arterioles were narrowed and beaded. There were scattered hemorrhages and patches of exudate.

Laboratory Data Ten urine examinations showed a specific gravity ranging from 1.008 to 1.020. All the specimens contained albumin in varying quantities. Rare granular casts and leukocytes were seen in the sediments and on one occasion there was a shower of erythrocytes. Four red blood cell counts ranged between 4,660,000 and 5,250,000 per cu mm with a hemoglobin of 75 per cent (Tallqvist). The white blood cell count fluctuated between 8,900 and 14,400 per cu mm with a normal differential cell count and smear. The blood Wassermann, Kahn and Hinton reactions were negative. The blood sugar was 82 mg per cent, the icteric index 10, the serum calcium 9.4 mg per cent and the serum phosphate 4.3 mg per cent. The blood CO₂ combining power varied between 49 and 54 volumes per cent and the blood nonprotein nitrogen fluctuated between 38 and 51 mg per cent. Phenolsulphonphthalein excretion two hours and ten minutes following intramuscular injection of the dye varied between five and fifteen per cent on three occasions. Lumbar puncture revealed an initial pressure of 200 mm of water with normal dynamics, no cells, and negative globulin and Wassermann reactions.

A seven foot heart x ray revealed no cardiac enlargement.

Electrocardiogram showed normal rhythm, rate 100 to 110, left axis deviation, deep S" and diphasic T' and T"

Clinical Course The patient was given a house diet and fluids to 3000 cc. His blood pressure fluctuated about 240 systolic and 160 diastolic. His chief symptom was mental dullness which responded temporarily to venesections and lumbar puncture. There was no great change in his condition and he was discharged on his twenty-seventh day to another hospital where his course continued slowly downhill. He died of bronchopneumonia in December, 1933.

Autopsy (No A33 102) Autopsy was performed by Drs Greenblatt and Schlesinger. Several cc of clear fluid were found in the peritoneal cavity.

Each kidney weighed 100 grams. The capsules stripped easily, revealing finely granular, mottled, red and gray surfaces. The cortex measured 5 to 7 mm. The right renal pelvis was the site of a large petechial hemorrhage. The left was normal. Microscopic examination revealed moderate congestion and edema and slight patchy fibrosis with chronic inflammatory cell infiltration. Most of the glomeruli were normal except for slight thickening of the tufts. In rare instances there was thickening of the capsule due to proliferation of the lining cells. The tubules were atrophic, and showed thinning of the lining cells. Many contained precipitated protein and casts of various sorts. The arteries showed moderate intimal thickening. The arterioles in many areas showed intimal proliferation and in rare instances, slight to moderate hyalinization of the media. However most of the arterioles were free of hyalinization. In short, the kidneys showed a small amount of arteriosclerotic and arteriolosclerotic change.

The heart weighed 400 grams. The coronary arteries were palpable and studded with small atheromatous plaques. The valves and endocardium were normal. The lungs were negative except for generalized congestion and some pneumonia in the left lower lobe.

The aorta showed good elasticity. A moderate amount of patchy atheromatous change was present. The brain weighed 1390 grams. There was marked arteriosclerosis of the superficial arteries. The rest of the organs showed varying degrees of congestion. The arteries of the prostate were slightly sclerosed. The arterioles in the pancreas

presented slight medial hyalinization and similar more marked changes were visible in the spleen.

Comment This middle-aged man with a negative past history entered the hospital with a present illness characterized by severe headaches, loss of weight, nocturia and palpitation of two years' duration, nausea of one year's duration, blurring of vision and mental changes of eight months' duration and two attacks of hematuria shortly before admission. Physical examination was entirely negative except for hypertension of 230 systolic and 150 diastolic, and generalized arteriosclerosis. Ophthalmoscopic examination showed typical malignant neuroretinitis. Laboratory data revealed evidence of slight renal impairment. There was no anemia. Postmortem examination revealed generalized arteriosclerosis. The kidneys showed slight arteriosclerotic and arteriolosclerotic changes. This patient with marked generalized arteriosclerosis and slight arteriosclerotic and arteriolosclerotic nephritis presented the typical picture of malignant hypertension with renal impairment terminating in bronchopneumonia.

CASE 5 History F C (B I H No 23296), a forty-three year old white American garage-man, with a family history of hypertension and vascular disease, and a past history of jaundice fourteen years previously, and of dyspnea on moderate exertion for two years, visited an ophthalmologist on March 30, 1934 complaining of blurring of vision in the right eye of one week's duration. That physician noted the presence of marked retinitis with elevation of the disc four diopters on the right, and marked caliber changes and nicking in the retinal vessels in the left eye. He found the patient's blood pressure to be elevated. The patient was then referred to the Out Patient Department of the Beth Israel Hospital. He was entirely well until January 1934, when he first noted increasing thirst, nocturia of three to five times a night, temporal headache and attacks of nausea. In March, the headaches became worse, and he suddenly developed the blurring of vision referred to above. He lost eighteen pounds in weight since the onset of the present illness.

Physical examination in the Out Patient Department was entirely negative except for moderate cardiac enlargement, moderate generalized arteriosclerosis and a blood pressure of 220 systolic and 140 diastolic. Ophthalmoscopic examination revealed hyperemia and edema of the discs, more marked on the right, and peridisc edema. The arterioles showed marked caliber changes and nicking at the arteriovenous crossings. Many fresh and old hemorrhages, as well as patches of exudate, were also noted.

Four urine examinations in the Out-Patient Department revealed a maximum specific gravity of 1.018. A small trace to a trace of albumin was noted in all specimens. The sediment was negative except for occasional leukocytes and rare granular casts. Phenolsulphonphthalein excretion fifteen and thirty minutes following intravenous injection of the dye was 28 and 12 per cent respectively. The red blood cell count was 5,490,000 per cu mm with the hemoglobin of 80 per cent (Tallqvist). The white blood cell count ranged between 9,350 and 12,200 per cu mm with a normal differential cell count and smear. The blood Kahn and Hinton reactions were nega-

tive. The blood nonprotein nitrogen was 33 mg and the blood creatinine 1.2 mg and the blood cholesterol 280 mg per cent.

The patient was observed repeatedly in the Nephritic Clinic of the Out Patient Department where gradual loss of weight, fatigability and increasing severity of the headaches were noted. The right optic disc underwent secondary optic atrophy while the left became swollen during this period. The blood pressure showed no significant change. He was admitted to the hospital on July 19, 1934.

Laboratory Data. The red blood cell count was now 4,300,000 per cu mm with a hemoglobin of 65 per cent (Tallqvist). The white blood cell count was 9,100 per cu mm. The blood nonprotein nitrogen was 53 mg. per cent, and the blood creatinine was 2.8 mg. per cent. These values fell to 39 and 1.5 mg. per cent respectively during the next few days. Phenolsulphophthalein excretion after two hours and ten minutes following intramuscular injection of the dye was 35 per cent. A urine concentration test revealed a maximum specific gravity of 1.010. Lumbar puncture findings were entirely normal except for an initial pressure of 350 mm. of water and a total protein of 40 mg. per cent.

Trays of the skull and kidneys were negative.

Clinical Course. The patient was given a house diet with fluids to 5000 cc. His blood pressure fluctuated about 200 systolic and 140 diastolic. His headache improved markedly with complete bed rest and lumbar puncture. His eyegrounds showed no change during the eleven days of his hospital stay. He was discharged to be followed in the Nephritic Clinic of the Out Patient Department.

His headaches soon recurred he continued to lose weight and his vision became progressively worse. Magnesium sulphate by mouth relieved the headaches somewhat. The blood pressure fluctuated about 180 systolic and 120 diastolic. Two months after discharge from the hospital he developed severe persistent projectile vomiting and was therefore readmitted. Physical examination was essentially unchanged. Ophthalmoscopic examination revealed secondary atrophy of the right disc, choking of the left disc and marked retinitis. The blood pressure was 230 systolic and 160 diastolic.

Laboratory Data. Fifteen urine examinations revealed a maximum specific gravity of 1.012. All the specimens contained a slight trace to a trace of albumin and occasional erythrocytes, leukocytes and granular casts. Five red blood cell counts ranged between 4,000,000 and 4,360,000 per cu mm with a hemoglobin of 53 to 60 per cent (Tallqvist). The blood nonprotein nitrogen was 56 mg. per cent on admission and slowly rose to 80 mg. per cent the blood creatinine rose from 2.8 mg. on admission to 4.9 mg. per cent several days later. Terminally the blood CO₂ combining power fell from 58.4 to 42.7 volumes per cent. Phenolsulphophthalein excretion after two hours and ten minutes following intramuscular injection of the dye ranged between five and ten per cent respectively. Lumbar puncture was negative.

Clinical Course. The patient was given a bland diet with fluids to 5000 cc. His blood pressure fell to 210 systolic and 140 diastolic about which level it fluctuated. The vomiting soon ceased but recurred as the blood nonprotein nitrogen rose. The patient became drowsy. During the second week of his stay the patient commenced to have attacks of paroxysmal dyspnea. He was digitalized and the fluid intake was reduced to 3000 cc. The drowsiness and vomiting became more severe and the patient finally died on the thirty-fourth day of his hospital stay.

Autopsy (No A34-109). Autopsy was performed by Drs. Frehling and Schlesinger. The right kidney weighed 100 and the left 90 grams. The capsules were thickened and were stripped from the perinephroma with difficulty. The surfaces thus exposed were uniformly brownish red in color and appeared coarsely pitted and markedly granular. The cut surfaces revealed the absence of the normal markings. The cortex was poorly defined and measured about 4 mm. in thickness. A moderate increase in the pelvis fat was noted. Microscopic examination revealed marked thickening and hyalinization of the media of the afferent arterioles. Similar changes were noted in the larger arterioles. There was moderate thickening of the intima of the arteries. Many of the glomeruli were fibrosed. All stages of this fibrotic process from slight thickening of the tuft to complete fibrosis and hyalinization were noted. There was a large amount of irregular interstitial fibrosis with chronic inflammatory cell infiltration. The tubules showed a varying amount of degenerative change with formation of casts in some areas. There were in addition, a small number of foci of acute arteriolitis with thrombosis of the involved vessel and infiltration with acute and chronic inflammatory cells. In some areas the thrombosed arterioles were completely organized. Similar changes were also observed in a few of the glomeruli and the larger arterioles.

The heart weighed 500 grams and presented marked hypertrophy and dilatation of the left ventricle. The valves were quite normal. Microscopic examination revealed moderate intimal thickening of the small arteries and a small amount of irregular patchy fibrosis with occasional foci of round cell infiltration. The arterioles were not remarkable. There was a moderate amount of thickening of the intima of the aorta.

The lungs were normal except for slight acute bronchitis and a small amount of patchy peribronchial pneumonia. The liver presented only a small amount of central necrosis due to congestion. The capsule of the spleen was thickened. The interstitial fibrous tissue was also increased. The arterioles of the spleen presented marked hyaline thickening of the media with numerous areas of acute arteriolitis. The pancreatic arterioles presented the same picture though to a lesser degree. There was marked intimal thickening in larger arteries of the pancreas with the formation of fresh thrombi in some areas. The prostate gland, gall bladder and retina presented moderate to marked hyaline thickening of the media of the arterioles and a small amount of acute arteriolitis with occasional thrombosis and hemorrhage. There was also a small amount of arteriosclerosis in the adrenal glands. In short there was widespread arteriosclerosis with marked chronic vascular nephritis and cardiac hypertrophy. There was in addition a small amount of acute arteriolitis in the kidneys, pancreas, prostate gland, gall bladder and retina with similar more marked changes in the spleen. A small amount of bronchopneumonia was present.

Comment. This middle aged man entered the hospital with a past history of dyspnea on moderate exertion for two years and with a present illness characterized by nocturia, headache, loss of weight and attacks of nausea all of three months' duration, and blurring of vision of one week's duration. Physical examination was negative except for cardiac hypertrophy, generalized arteriosclerosis, and a blood pressure of 220 systolic and 140 diastolic. Ophthalmoscopic examination revealed typical malignant

neuroretinitis. Laboratory studies showed progressively increasing renal impairment. At postmortem, advanced vascular nephritis and a small amount of acute arteriolitis of the kidneys were noted. There was also widespread arteriosclerosis, cardiac hypertrophy and arteriosclerosis of the parenchymatous organs most of which contained foci of acute arteriolitis. This patient with marked chronic vascular nephritis and a small amount of acute renal arteriolitis, presented the typical picture of malignant hypertension terminating in uremia.

DISCUSSION

Malignant hypertension has heretofore been considered a form of primary hypertension. According to Fishberg⁵, all patients with malignant hypertension have a past history of benign, essential hypertension or evidence of its previous existence in the form of cardiac hypertrophy.

We have observed that in addition to patients with malignant *primary* hypertension, there are many others in whom the malignant phase supervenes as the end stage of a previously unrecognized morbid process characterized by *secondary* hypertension.

Thus, the typical clinical picture of malignant hypertension was found in case 1 of our series, but the autopsy revealed chronic glomerular nephritis. Similarly, other authors have pointed out that the same clinical picture may occur with hypertension secondary to acute, subacute or chronic glomerular nephritis⁶.

It has been claimed by some authors⁷ that malignant hypertension with renal failure and chronic glomerular nephritis with renal failure may be differentiated by the fact that the latter frequently progresses more slowly and may show remissions in its course. However, cases of acute, subacute, or chronic glomerular nephritis may not infrequently have a very explosive termination in renal failure, at the end of a period of relative quiescence with severe hypertension. It is true that some of these cases of glomerular nephritis may be recognized as such because of the antecedent history of an acute attack with edema, hematuria or hypertension, but in many instances of chronic glomerular nephritis it is not possible to obtain such data. These latter cases of chronic glomerular nephritis with secondary hypertension are indistinguishable clinically from cases of primary malignant hypertension. Such patients are usually regarded as having primary malignant hypertension until the autopsy demonstrates otherwise. MacMahon¹³ and Klemperer and Otani¹⁴ have made similar observations.

Longcope¹⁵, in 1933 reported the case of a young woman of eighteen with a three months' history of vomiting, headache, clouding of vi-

sion, soreness of the back and marked weight loss, and who on physical examination showed severe hypertension, enlargement of the heart and malignant neuroretinitis. She died in uremia and her kidneys showed extreme contraction due to pyelonephritis. The microscopic examination of the kidneys was not described. Longcope states, "It is remarkable to what extent the insufficiency of renal function may advance in many of these patients (with pyelonephritis), without noticeable impairment of the health of the individual. When serious symptoms of renal failure appear, however, the course is often very rapid, and within a period of a few weeks, the patient may die in uremia." Similar cases have been reported by Cain¹⁶, and Mallory¹⁷. The latter author noted the presence of acute arteriolitis in the kidneys of his patient.

Certain cases of chronic lead poisoning with severe hypertension may exhibit convulsive seizures or other acute cerebral manifestations. Such patients may present the typical neuroretinopathy of malignant hypertension¹⁸.

Oppenheimer and Fishberg¹⁹ in 1924, described a patient who presented a short history of severe hypertension with physical findings of severe diastolic hypertension, malignant neuroretinitis and cardiac hypertrophy, with death from cardiac insufficiency, autopsy revealed hypernephroma of the right suprarenal gland, multiple adenomata of the left suprarenal gland, and anatomically intact kidneys. Winkel's²⁰ case also falls into this category.

Friedberg and Gross²¹ series of cases of rheumatic heart disease with periarteritis nodosa contain one (case 4) with a history and physical findings typical of malignant hypertension. The kidneys in this case showed necrotizing arteritis. Reports of other similar cases of periarteritis nodosa with or without rheumatic heart disease are to be found in the literature²²⁻²⁴.

MacMahon, Close and Haas²⁵ state that pituitary basophilism may have some features in common with malignant nephrosclerosis.

Klemperer and Otani¹⁴ have commented on the striking similarity between many of the manifestations of hyperemesis gravidarum and malignant hypertension.

It is apparent, therefore, that the clinical picture of malignant hypertension may occur in a wide variety of diseases in which secondary hypertension occurs, and that the presence of these underlying morbid processes may frequently be unsuspected.

In addition to those patients who develop the syndrome of malignant hypertension late in the course of either primary or secondary hypertension, there is another group of patients presenting the same clinical picture in whom

there is absolutely no evidence at necropsy of any long standing previously existing hypertension. Thus, in case 2 of our series postmortem examination showed no evidence of cardiac hypertrophy and no widespread arteriosclerosis. It is reasonable to believe that in this case the syndrome arose "de novo."

It may well be that the reason certain pathologists believe malignant hypertension is a specific disease is the fact that they have grouped together series of pathologically identical cases and have found that they presented similar clinical features. If, however, an attempt is made to group together cases which resemble each other clinically, as has been done in this paper, it will be found that such a group of cases presenting the clinical picture of malignant hypertension will show a wide variety of pathological processes associated with primary or secondary hypertension.

A consideration of all of the foregoing data makes it possible to classify all patients presenting the clinical picture of malignant hypertension into the following groups:

1 Primary Hypertension

- a Patients with a history or other evidence of long standing essential hypertension
- b Patients with no evidence of long standing hypertension ("de novo group")

2 Secondary Hypertension

- a. Acute, subacute, or chronic glomerular nephritis
- b. Pyelonephritis
- c. Adrenal tumor
- d. Pituitary basophilism
- e. Chronic lead poisoning
- f. Periarteritis nodosa
- g. Hyperemesis gravidarum

The concept that malignant hypertension is a syndrome which may occur in patients with either primary or secondary hypertension explains the wide variety of pathological pictures found in the kidneys of such patients postmortem. The histology of the kidney varies depending upon the duration of the elevation of the blood pressure if it is primary and with the nature of the underlying morbid process if the hypertension is secondary. In some instances, the kidneys are essentially sound (case 2).

Some authors^{1, 2, 3, 14} consider the essential pathology of malignant hypertension to consist in necrotizing renal arteriolitis. It has, however, been shown repeatedly^{4, 15} that the kidneys of patients with malignant hypertension may contain no such lesions (case 2) or an extremely small number (also cases 3 and 4 of our series). In such instances foci of acute necrotizing arteriolitis may be more numerous

in viscera other than the kidneys (cases 2, 3 and 4), this may also be observed in patients whose kidneys show many such lesions (case 5).

Renal insufficiency was formerly held to be an invariable concomitant of the presence of necrotizing arteriolitis in the kidneys, but this is no longer believed to be true. Murphy and Grill¹ and Klemperer and Otani¹⁴ described such lesions in the kidneys of patients in whom there was not the slightest sign of renal insufficiency. On the other hand, Murphy and Grill¹, Cam¹⁶, and Keith, Wagener, and Kernohan⁴, failed to observe renal arteriolar necrosis in a number of instances in which death was definitely due to uremia. Necrotizing arteriolitis has also been frequently found in the kidneys of patients with hypertension secondary to various forms of renal pathology. Such patients may or may not present the typical syndrome of malignant hypertension. Renal necrotizing arteriolitis therefore cannot be considered specific for any single morbid process. Its presence may, however, indicate an unusually severe degree or prolonged duration of hypertension.

The nature of the underlying pathological process responsible for the appearance of the clinical syndrome of malignant hypertension apparently does not influence the course of the syndrome. In all cases the prognosis appears to be uniformly poor.

CONCLUSIONS

1 Malignant hypertension is a syndrome which may occur,

a With no evidence of previously existing hypertension

b As the end stage of essential hypertension with or without uremia.

a As the end stage of a miscellaneous group of conditions, characterized by hypertension secondary to acute, subacute or chronic glomerular nephritis, pyelonephritis, adrenal tumor, pituitary basophilism, periarteritis nodosa, hyperemesis gravidarum, chronic lead poisoning or cetera.

2 It is impossible to decide during the life of a patient exhibiting the syndrome of malignant hypertension whether the hypertension is primary, or secondary to some unrecognized morbid process.

3 Since malignant hypertension is a syndrome and not a specific disease the renal pathological picture will show wide variation from patient to patient. The presence of acute necrotizing arteriolitis does not establish the diagnosis of primary malignant hypertension, nor does its absence rule it out.

4 Whatever the nature of the underlying pathological process responsible for the appearance of the syndrome of malignant hypertension the prognosis is uniformly poor.

TRAUMATIC RUPTURE OF THE LIVER

BY WILLIAM M. SHEDDEN, M.D.,* AND FULTON JOHNSTON, M.D.*

FROM the time of Hippocrates till the latter part of the nineteenth century wounds of the liver were considered as fatal, although isolated cases of spontaneous recovery from serious hepatic injuries were recorded from time to time. An interesting example of this was reported by Fabricius Hildanus³⁶ in the early part of the seventeenth century. A young man was stabbed during a quarrel and suffered a severe hemorrhage. A large piece of liver appeared in the wound and was removed by forceps. In spite of this fact the patient recovered.

Although many operations have been performed on the liver and with a steadily decreasing mortality it can still be said that surgery of this organ is an imperfectly developed field. From the beginning hepatic surgery has been feared and shunned because of hemorrhage.

Spontaneous hemostasis of a traumatized liver is rare and for the following reasons:

- (a) The thin-walled hepatic veins are without valves and tear easily, gaping without retracting or contracting.
- (b) Blood mixed with bile coagulates slowly.
- (c) The respiratory movements of the diaphragm and abdominal wall produce a continuous variation of blood pressure.

Tillmanns⁸⁵ in 1879, after removing wedge-shaped pieces from the livers of animals, closed

the abdominal wound without liver suture. All his animals recovered. He concluded that hepatic wounds are dangerous only when large vessels are involved, and that the low blood pressure and slow current in the liver vessels favor a more rapid hemostasis than in other organs.

Langenbuch⁴⁶ in 1888 controlled a severe secondary hemorrhage from the liver with mass ligatures. The patient recovered.

It was discovered during the next decade that animals could survive although large amounts of liver were removed. Ponfick⁶³ in 1890 found that his experimental animals could live though retaining only one-eighth of their original hepatic tissue. It seemed reasonable, then, that the operator need not fear any marked deleterious effect upon the system from considerable loss of liver substance, and with the control of sepsis, hemorrhage remained as the outstanding danger from hepatic trauma.

Clementi¹⁸ in 1890 first used temporary compression clamps to effect hemostasis. The following year Ullmann⁶⁶ employed cautery and the infolding of the wound over a tampon for the same reason.

Kousnetzoff and Penski⁴³ in 1894 laid great stress upon the use of a supple needle of the type of Hagedorn armed with a thick double thread which was passed back and forth through the liver wound. This needle was blunted so that it would be pushed aside by, rather than transfix, hepatic vessels. He circumstitched the larger vessels in the cut surface and ligated them. The same year while Snegirew⁷¹ was ad-

*Shedden William M.—Assistant Surgeon to Out Patients Massachusetts General Hospital Johnston Fulton—Member of the Emerson Hospital Staff For records and addresses of authors see 'This Week's Issue' page 931

vising the use of steam as a homostatic, Cecherelli¹⁶ and Bianchi were advocating whale bone and later decalcified bone plates on the upper and lower surfaces of the liver with sutures through them, leaving the ends of the sutures long and ligating them over the cut surface. The decalcified bone was usually completely absorbed. Other plates of various sorts have been used, ivory, magnesium and even slices of turnip and potato.

In 1902 Carl Beck⁴ slit a broad band from each border of the abdominal wall including peritoneum fascia and in some cases also muscle and leaving one end attached to the abdomen. These strips were used as supports for suture material. During the same year Koehel¹⁷ employed compression forceps to crush the liver substance. These forceps were removed after twenty-four hours.

In 1905 while Cullen¹⁸ was using overlapping mattress sutures to effect hemostasis, Gillette¹ was passing ligatures through the liver substance, thence through the abdominal wall. These made an exit between the ribs and were tied around the ribs on the cutaneous surface.

Pringle⁶⁴ in 1908 employed digital compression of the portal vein at the foramen of Winslow which completely arrested all bleeding from an extensive laceration of the liver.

In 1912 Boljarski¹ recommended an isolated omental plastic with suture, and Halsted drew omentum through a large perforating wound of the liver with an excellent result, as regards hemostasis.

McDill⁶⁶ in the same year clamped the vessels in the gastrophrenic omentum with an enterostomy clamp. He stated that procedures can thus "probably with safety be made entirely bloodless for at least 8 to 10 minutes."

From the fact that so many methods and modifications of methods of hemostasis have been advocated and also from the fact that combinations of three or four methods have been resorted to we must infer that there is no one method which can be relied upon for all occasions.

Though the liver is more frequently injured than any other solid organ, yet rupture of this viscous is one of the rarest reported surgical emergencies. However, it is probably more common than the reported cases would indicate as hepatic lacerations without distinctive symptoms undoubtedly pass undiagnosed and are included under the general caption of shock. It appears approximately once in every thirteen hundred cases brought to the accident room of any large general hospital, yet in a series of 365 cases of subcutaneous injury of solid viscera studied by Edler²² the liver was injured in over fifty per cent.

The liver's large size, its friability and above all its fixed position between the navel and the prominent vertebral column posteriorly and the

firm costal margin and the abdominal wall anteriorly, all combine to render it particularly vulnerable to external force. The fact that the site of injury is most commonly along the posterior surface where the liver lies in contact with the vertebral column indicates that anteroposterior compression is the commonest cause of laceration.

According to Moynihan²² the subcutaneous wounds are of three kinds: (1) rupture of liver tissue with laceration of Glisson's capsule, (2) separation of the capsule with subcapsular hemorrhage, (3) central rupture leading to hematoma and thence to abscess or cyst. He further states that the right lobe is injured six times as often as the left. Occasionally cases are first seen at quite an interval after injury. These would obviously be in the groups designated as No. 2 or No. 3.

Robertson and Graham²³ report the case of a boy of fourteen who, three weeks after an automobile accident was found to have a large tumor in the right upper abdomen. He had suffered no undue pain. On incising the liver capsule "two quarts of old blood and bile were evacuated." His convalescence was complicated by a sinus which drained old blood and bile for five months.

A similar case is that of a girl who suffered an abdominal injury while coasting. During the next four weeks she occasionally vomited bright blood and had persistent epistaxis. She developed a marked anemia and a high fever. Autopsy showed an immense cavity in the right lobe of the liver.

If the tumor occurs soon after the injury it can be assumed that the content is blood. If it is late in forming bile will constitute an important volume of the content of the cavity. Here marsupialization might be employed.

When traumatized the liver has a tendency to split or crack in a stellate manner with massive hemorrhage accompanied by varying amounts of bile. Frequently other abdominal viscera or thoracic organs or the diaphragm are also injured thus producing more or less serious complications which may mask symptoms referable to the injured liver.

Aside from acute anemia and shock, the high mortality in these cases may be in part caused by gastrointestinal stasis with its resulting toxemia as an effect of the trauma in the peritoneal cavity or leakage of bile. Another factor which keeps the mortality high is an imperfect estimate of the gravity of the situation when the case is first seen, for, occasionally a relatively trivial trauma may cause rupture or severe hepatic injury may be accompanied by comparatively insignificant primary symptoms. There may be little or no pain or shock at first and the individual may keep on for several hours with his usual activities without suffering much inconvenience. Robin²⁴ describes a case of a man who fell across a ditch striking his abdo-

men He suffered only slight discomfort, walked to a car and was driven home More than twelve hours later he was found to be bleeding severely from hepatic rupture

SYMPTOMATOLOGY

The chief clinical features are as follows (1) Pain in the right upper quadrant, though the pain may be generalized throughout the abdomen or not present at all McKnight⁵⁰ states that, if the convex portion of the right lobe is injured, pain is referred to the right scapular region while if the concave portion is involved the discomfort is referred to the waistline anteriorly Bloch⁷ reports a case of ruptured liver in which the maximum tenderness was in the left lower quadrant (2) Boardlike hardness and exquisite tenderness over the involved area as a rule (3) Increase in liver dullness, upward or downward (4) Shock, due to the single impact or to the flooding of the peritoneal cavity with blood or bile, though there have been many reports of cases of ruptured liver with little or no clinical signs of this phenomenon Noble reports the case of an individual struck by an automobile who showed at the time of the accident no evidence of shock or, in fact, of any injury at all Twenty-four hours later laparotomy revealed a rent in the region of the hilus Death ensued five hours after the operation The degree of immediate shock, therefore, does not represent the injury often enough to be a guide in cases where no shock is observed Free exposure and hemostasis at the earliest possible moment is advised (5) A sharp rise in the leucocyte count and a slower fall in the erythrocyte count and hemoglobin The leucocytic reaction presents a characteristic curve reaching a height of 150 per cent to 300 per cent within the first ten hours (6) Jaundice, though this phenomenon seldom appears before the third or fourth day, if at all McKnight⁵⁰ advances the theory that the jaundice may be due to the shattering of Glisson's capsule He reasons that as a result of this laceration the secretory pressure of the liver is decreased and the bile dammed back and forced into the lymphatic channels It may, of course, also be due to hepatic sepsis! Andersson¹ reports the case of a laborer who developed jaundice two weeks after an abdominal injury Exploratory laparotomy nine days later revealed a liver abscess The hepatic capsule was intact (7) It must be remembered that liver rupture is sometimes accompanied by a slow pulse McKnight⁵⁰ cites the case of an individual who had a pulse rate of seventy twelve hours after the injury though seven hours later a quart of blood was found in the peritoneal cavity Bradycardia has been produced in dogs by causing hepatic injury, but only when there was a profuse discharge of blood and bile into the free peritoneal cavity.

Thorotrast (25 per cent thorium dioxide) has been employed as a diagnostic aid but its use apparently is not without danger Burke and Madigan¹⁴ in 1933 report what is probably the first case of liver rupture in which thorotrast was thus used They state that the patient died of peritonitis on the sixth day after operation Stewart⁷⁶ et al, describe eight cases of trauma to the liver in which thorotrast was employed Seven of these died but Stewart declares that "none of these deaths is directly attributable to thorotrast"

The thorotrast was found to be deposited in the endothelial cells of the liver and spleen Stewart⁷⁶ believes that this medium probably remains permanently in the endothelial cells of the liver

Tripoli⁸⁶, on the other hand, injected 25 cc of this solution into each of fifteen individuals "with no immediate or late untoward results" These cases were not, however, complicated by liver trauma

DIFFERENTIAL DIAGNOSIS

(1) Simple shock Hourly blood counts will aid in deciding upon or rejecting this diagnosis

(2) Simple traumatism to abdominal wall Blood examination will help here also White⁸⁹ has also employed diagnostic aspiration of the peritoneal cavity with a large needle

(3) Splenic Rupture Though the pain and tenderness are usually in the left upper quadrant of the abdomen, the symptoms here may be identical with hepatic rupture and the lack of localizing signs, of course, does not rule out trauma to the liver

TREATMENT

When possible, immediate operation is essential The importance of early recognition and prompt institution of surgical measures can best be emphasized by Thole's⁸² statistics He demonstrated from a study of 260 cases of ruptured liver that if operation takes place within six hours the mortality is 40 per cent, between seven and twelve hours it is 50 per cent, while between thirteen and twenty-four hours it is 67 per cent After twenty-four hours the mortality rapidly mounts to 86 per cent, though cases have been operated on with recovery two to thirty days after liver rupture

If blood cannot be obtained from other sources, autotransfusion of blood may be employed However, the presence of extravasated bile and the possibility of the presence of the contents of hollow viscera should make this a procedure to be done only after careful abdominal exploration This technic was advocated by Thies⁸¹ in Germany in 1911 and used by Ogilvie⁸⁷ in England in 1922 White⁸⁹, in 1920, was probably the first to employ autotransfusion in a case of liver rupture in the

United States Bloch⁷ reports a similar case with recovery in 1930, and Robin⁸ one in 1934

It may be found, on opening the abdomen, that the hemorrhage has ceased and that a careful removal of the blood and an abdominal closure are all that is necessary

If the bleeding is not severe a gauze pack may be sufficient to check the hemorrhage. The hepatoduodenal ligament may be compressed while the packing is inserted. Graham⁹ states that this ligament may be safely compressed for a half hour. It is probably well to remove the pack after forty eight hours under general anesthesia. Drainage introduces infection and occasionally causes a secondary hemorrhage. Robin⁸ describes a case in which the pack was left in for two weeks. A liver abscess resulted. The third week the patient had a series of secondary hemorrhages.

If the bleeding is checked when the pack is removed, a piece of rubber may then be inserted to the level of peritoneum in order to take care of a possible later leakage of bile.

If the pack does not check the hemorrhage, suture of the liver should be attempted, employing if possible a large blunt needle.

If a large amount of liver tissue had been damaged it is probably well to administer glucose freely. It has been clearly demonstrated that hepatectomized animals die because of a glucose deficiency.

PROGNOSIS

This seems to depend on

- The amount and rate of hemorrhage
- The escape of bile into the peritoneal cavity which may be a contributory cause of paralytic ileus
- The amount of destruction of liver tissue.
- The presence or absence of injury to structures other than the liver

An extraordinary instance of multiple injury with recovery is reported by Gemmill and Martin¹⁰. The patient, a woman of twenty-six, was injured by an automobile. There was excision of intestine severe laceration of the liver and a torn right kidney. The intestine was returned to the abdomen and the liver and kidney sutured. The patient is said to have had an uneventful recovery in forty-six days.

(e) Careful attention to postoperative complications

The following are case reports of two instances of ruptured liver

J. T. CASE 1. Aged 20 years single. Entered October 29 1933

History While playing football the patient was hit across the abdomen by an opponent. This was the first play of the game. The patient played during the remainder of the half but

sat on the sidelines during the second half. He felt pain in the region of the umbilicus and a desire to urinate but was unable to do so. After the game was over he lay down on a bench and had difficulty in getting up again. He then rode home. The pain in the region of the umbilicus persisted. He entered the office of one of us (F. J.) at which time an internal injury was suspected and he was referred to the hospital walking in three and a half hours after the injury. His pulse was then 100 and his blood pressure 92/60. During the night his blood pressure and pulse readings were as follows:

10 00 P.M. Blood pressure—98/64 Pulse—88
1 20 A.M. Blood pressure—78/48 Pulse—104
5 30 A.M. Blood pressure—80/52 Pulse—100

One of us (W. M. S.) was called in consultation at six o'clock the morning following entrance.

Physical Examination At entrance to the hospital the patient's skin was very pale—grayish white. He was apparently in great pain. Head—skull and scalp negative. Eyes—pupils equal. Ears—no bleeding. Nose—no bleeding. Mouth—negative. Neck—negative. Chest—lungs clear. No rales. Heart—normal sounds. Good quality. No murmurs. Abdomen—extremely tender and spastic, particularly over the right upper quadrant. No tenderness in flanks. No distention. Extremities—normal. Rectal—negative. Urine—no blood. Fourteen hours after the accident the leucocyte count was 36 000.

A catheter specimen showed no blood.

The spasticity and the tenderness of the whole abdomen, particularly the right upper quadrant, and the high white count suggested that the boy had a ruptured viscus probably the liver. Despite the fact that his blood and pulse had remained essentially the same for four hours one of us (F. J.) noticed that his general appearance was distinctly worse. It was decided therefore to operate. Given 1000 cc. 10 per cent glucose intravenously before the operation.

Operation (15 hours after the accident) (W. M. S.)

About one and a half litres of blood in the peritoneal cavity. On the posterior surface of the right lobe of the liver there was a good sized adherent blood clot. This was not disturbed. Transfused with 500 cc. of whole blood. Six hours after the operation. Blood pressure—114/75. Pulse—118.

November 1st. Pain in the left arm and no to shoulder which persisted for three or four days. Examination of arm negative.

Blood pressure—120/62.

Pulse—96.

Urine—negative.

Blood count—3 000 000 Hgb—45

November 1st. 2 500 000 Hgb—50

2nd. 3 200 000 Hgb—55

3rd. 3 750 000 Hgb—65

Uneventful convalescence otherwise. Discharged on the fourteenth day.

When seen one and one-half years after the operation, the patient had no symptoms and had a well healed wound

R J CASE 2 Female Admitted April 15, 1934

History Patient was thrown out of an automobile when it turned sharply and tipped over. She arrived at the hospital within thirty minutes of the accident.

Physical Examination At entrance her skin was clammy and her pulse almost imperceptible, its rate being about 110. Her blood pressure registered zero. She was semiconscious and could just describe tender areas of abdomen. There were abrasions on forehead and right arm and a laceration at the lateral canthus of the right eye.

Skull—negative

Pupillary reactions—normal

Ears and nose—no bleeding

Mouth—no injuries

Chest—lungs clear No râles

Heart—very rapid Sounds normal

Abdomen—quite rigid, markedly so in the right upper quadrant, where there was much tenderness and spasm

There was no blood in urine

The examination of the abdomen suggested a ruptured viscus, probably liver. She was getting rapidly worse. It was felt that a white count this early after injury would not aid in a decision as to therapy, for if it were relatively normal we would disregard it. If it were high we would operate anyway as soon as intravenous fluid and, if necessary, transfusion put her in good condition. Exploratory laparotomy, we felt, was urgent.

She was given 1000 cc of 10 per cent glucose intravenously after which the blood pressure rose to 90/50. Her pulse was of fair quality during the operation, but rose from 116 to 134.

Operation (W. M. S.) A tear was found in the postero-inferior surface of the right lobe, and bleeding steadily. This was packed with the gauze ends of two cigarette wicks, which caused adequate hemostasis. She was then transfused with 500 cc of whole blood.

Forty-eight hours after the operation, the cigarette wicks were taken out and a rubber drain was placed through the peritoneal level.

She was in a precarious condition for the first three days and was given intravenous glucose, hypodermoclyses and rectal fluid.

April 17th W C—19,000 R C—22 Hgb—55

19th W C—7,600 R C—23 Hgb—55

21st R C—31 Hgb—55

27th Clay colored stool, but none thereafter

27th Vaginal bleeding

29th Still some vaginal bleeding

May 1st. Dilatation and curettage for incomplete miscarriage (F. J.)

16th W C—10,800 R C—32 Hgb—55

18th. Transfusion of 500 cc of whole blood.

23rd W C—7,800 R C—38 Hgb—75

Temperature From the first to the eleventh day—
from 100.2° down to 98.6°

From the eleventh day to the thirtieth day—
up to 102°

From the thirtieth day to the thirty-ninth day—
from 102° down to 98.6°

Bile Bile from the wound from the first to the twelfth day postoperative

Vomiting Vomiting small amount from the time of the operation for thirteen days

Discharged well on the forty-second day

When seen one year after the operation, the patient had no symptoms and had a well healed wound

BOSTON DISPENSARY VARICOSE VEIN CLINICS

THE ORGANIZATION OF A VARICOSE VEIN CLINIC

BY HILBERT F. DAY, M.D.*

THE Vein Clinic at the Boston Dispensary has been a success because of its organization and because it has continued uninterruptedly for so long. It was one of the first clinics in Boston to appreciate the advantages of the injection treatment of varicose veins and to start treating patients by this method.

At the Boston Dispensary, we consider that organization depends upon

- 1 Personnel
- 2 Quarters
- 3 Equipment
- 4 The methods of treatment.
- 5 Follow-up

The continuation of the Clinic has been made possible by the sustained interest of the personnel as well as that of the institution. The service rendered its patients has maintained the demand for this form of treatment.

As to *Personnel*, we have found that the best organization is to have one surgeon who is responsible for his associates' and assistants' attendance at the clinics and who himself is in charge of part of the work. His service runs throughout the year and this enables him to see that uniform care is given to the patients and a proper division of work carried out. All of our doctors in charge of the Clinic have been for several years in this work. Only doctors who have received special training are allowed to inject veins. Students, internes or graduate students are not allowed to do so until they have observed the methods for a number of times and then only under strict supervision. No doctor is allowed to be in charge of a clinic who has had less than six months' experience in this type of work. We have found that it requires an even longer time to train a man so that he has proper judgment in deciding the type of treatment to institute, and to make him capable of doing his best work.

Our Vein Clinic has been fortunate in having for a long time the same nurse in attendance, one who understands how to help each man and who knows the patients. We think that such a nurse is essential in the smooth running of the Clinic. A volunteer clerk, also, is quite necessary. The volunteer clerk should have some social training so as to be able to meet the patients pleasantly and to handle them properly. This worker, under direction, attends to the follow-up of patients through correspondence, particularly in relation to the completion of treatments. When a larger problem arises, it is

handled by a trained social worker. Problems which come under this heading are transportation, the obtaining of the dressings for home care, aid toward bed rest, and the general social problems of relief.

Equipment Ordinary tables on which the patient may sit or lie are necessary, also stools of various sizes. A dressing table with one or two shelves for bandages, sheet-wadding and ointment jars should be provided for each cubicle, or the table should be so arranged that it can be easily moved from one cubicle to another. On the top of this table, there should be a sterile sheet and on it a sufficient number of syringes and needles prepared for use. On one shelf of the table there should be a blood pressure apparatus, a stethoscope, tourniquets and sterile gauze. The various solutions used for injections, plus adrenalin (for use in case of an untoward reaction) should be conveniently at hand.

Method of Treatment All new cases are examined in one day by the head of the Clinic, who then maps out for each patient the necessary medical and laboratory work preliminary to their treatment. They are then referred to the Clinic which is in the charge of a doctor particularly interested in some special form of treatment, such as high ligation, multiple injections, the treatment of ulcers and the treatment of phlebitis.

We believe that regular conferences should be held at which the whole staff gives reports on progress in the various methods used and where new methods of treatment are discussed. As to solutions used, we believe that well tried out solutions should be employed until new ones have proved themselves better. For instance, we at first used salt solution for injections, but later the use of quinine urethane became the rule. Now various other solutions are being tried out. In the case of ulcers, at first a simple supporting bandage was used. Now we are sure that a sponge plus adhesive plaster speeds up the healing of an ulcer.

Follow-up We have found that it is necessary to keep in touch with our patients because they have a tendency to disappear from the Clinic after their primary symptoms have been relieved and before a complete obliteration of the veins, including the long saphenous in the thigh, has been accomplished.

Finally, I would say that the reasons for the success of this Clinic are the special training of the men who take care of it and the adequate follow-up.

*Day Hilbert F.—Surgeon-in-Chief, Boston Dispensary. For record and address of author see "This Week's Issue" page 991.

THE TREATMENT OF THE VARICOSE ULCER*

BY EDWARD T. WHITNEY, M.D.,† AND PETER A. CONSALES, M.D.†

FOR success in the treatment of varicose ulcers, the underlying pathology must be recognized. In the first place, the flow of blood in the saphenous veins is downward instead of upward¹ and this puts such an added burden on the deep veins that a second factor is produced, namely, a *generalized chronic passive congestion* of the lower leg and foot. Early in the disease, no definite signs of this chronic passive congestion are present although the symptoms of fatigue, aching and cramps of the lower legs are probably the result of this latter condition. Later on, however, edema, induration of the tissues and discoloration appear with an increase of the symptoms.

A third factor is a *local passive congestion* due to some trauma, skin infection, phlebitis, cellulitis or lymphangitis. The trauma does not need to be very severe because it requires only the smallest amount of added congestion so to diminish the nutrition of the skin that it breaks down. The two most common skin infections in this location which predispose to ulcer formation are the staphylococcus and the epidermophyton, either singly or in symbiosis.² A superficial phlebitis temporarily improves the circulation as it stops the reverse flow of the blood in the saphenous veins but after this infection thrombus is re-canalized, the resulting situation is even worse than it was before, in that, the vein walls are dilated even further, their tone is diminished even more and the chronic passive congestion becomes even more serious than it was previously.

A fourth underlying factor is the tendency of the skin edges to separate once the continuity of the skin has been broken. This is readily observed when the skin is incised. The skin edges of these ulcers tend to separate constantly and the wear and tear on the epithelial margins must, naturally, be very great.

Treatment should correct all of these conditions. To start with, there is always some skin infection in and around an untreated ulcer and more likely than not, a fungus is there as well, so that a fungicide, as well as a germicide, is called for and, as we are going to cover the whole ulcer leaving no drainage, a generous amount of this antiseptic is necessary. In the clinic, we use a ten per cent mercurochrome ointment or one per cent gentian violet ointment, while in private practice we employ one of the other mercurials such as merthiolate

ointment. The ointment is applied to the ulcer and to the skin surrounding the ulcer for a distance of one to two inches. Over all of this are laid strips of adhesive one inch wide, overlapping. This word "laid" is used advisedly because no tension must be put on the skin

FIG. 1. Mr. B—Before treatment

FIG. 2. The left leg is that of Mr. B after six treatments. The right leg is that of a man treated elsewhere by confinement in bed for eleven weeks. They both had the same sized ulcer in the same location and with the same number of varicosities. Mr. B. lost no time from work.

The adhesive serves four purposes. First, it keeps the skin edges from separating farther, secondly, it keeps the germicidal ointment in place and prevents it from drying, thirdly, it keeps the ulcer flooded with its own healing secretion, and fourthly it supplies a base for the application of the sponge which follows. This sponge should be approximately one inch larger

Read before the Twenty Fourth Clinical Congress of the American College of Surgeons at the Boston Dispensary October 17, 1924.

†Whitney, Edward T.—Assistant Surgeon, Boston Dispensary.
Consales, Peter A.—Junior Surgeon, Boston Dispensary. For records and addresses of authors see "This Week's Issue," page 931.

in diameter than that of the ulcer and should be approximately one inch in thickness. It is laid on the adhesive over the ulcer and then is strapped on with more adhesive, enough pressure being applied to reduce its width by about one-half. McPheeters³ is responsible for popularizing the sponge treatment in this country, but his directions call for placing fluffy gauze over the ulcer, and in our hands it has been found that such a course in many cases causes gangrene of the skin because too much pressure was produced by the gauze at one particular point. Our modification of strapping the sponge on over adhesive never produces any such gangrene. The object of the sponge is to control the local chronic passive congestion in the base of the ulcer and in the tissues immediately surrounding the ulcer. Furthermore, it presses the newly growing skin edges down into the granulation tissue, providing a thick, well-nourished layer of skin intimately fastened to the underlying tissues rather than a thin, one-celled layer which is easily raised by trauma or infection.

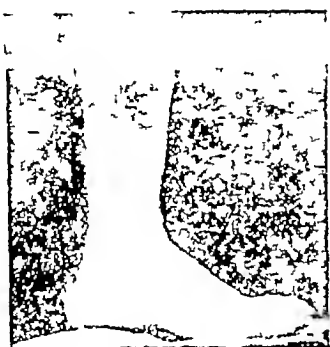

FIG 3 Ulcer covered with antiseptic ointment

Injection of the varicosities immediately proximal to the ulcer is made at the first visit and further injection is made at each dressing until all of the varicosities in both the leg and thigh have been obliterated. Personally, we believe in the multiple injections of all of the veins entering the ulcer area with a small amount of sclerosing fluid rather than the injection of a larger amount of fluid at some one point. If it is found that ligation is also indicated, such a procedure can be accomplished at the same time that the ulcer is being treated.

Having dressed the ulcer and having injected the veins, the leg must be bandaged in order to overcome the generalized chronic passive congestion. This can be accomplished in several ways. In the clinic we use sheet wadding and gauze bandage. Private patients, if they can afford it, may have some form of elastic adhesive bandage. The ordinary ace and Bender bandages do not serve the purpose well enough, in our experience, and elastic or canvas stockings are too expensive to soil. Whatever band-

age is chosen should be put on by the doctor treating the patient, as it is almost impossible for the patient to apply a bandage with just the right amount of compression, in fact, a great many doctors require considerable experience before they are able to bandage a leg correctly. Such a bandage is an art, and every one has his own method. Personally, we like to put on a figure of eight going up the leg, and to cover it with spiral coming down. This makes two definite layers of gauze running in opposite directions, and the friction has a tendency to keep the gauze in place. When such a bandage is applied correctly and firmly, the patient will return at the end of a week with the bandage in as good condition as it was when applied.

If the ulcer is large and with an offensive odor, this whole dressing should be changed twice a week and later on every five to seven days. We have found in private practice that at the end of the fifth day the dressing has a tendency to become uncomfortable, the antiseptic ointment has lost its power and without drainage the germs have begun to multiply again, so that the ideal time for changing is approximately just short of a week. In the clinic, it, of necessity, has to be a week. Either or carbon tetrachloride is used to clean the skin and ulcer at the time of dressing.

Modifications of this treatment must be used for varying conditions. Often the staphylococcus bores little holes in the skin beneath the adhesive beyond the area covered by the antiseptic ointment and when this becomes serious, a good scrub with carbon tetrachloride and an application of a drying powder is applied, covered with gauze only. At the end of a few days, it will be found that this condition has entirely disappeared. Occasionally, patients show idiosyncrasies to various procedures included in the treatment. One here and there cannot stand the sponge, another cannot stand mercurochrome ointment and others cannot stand adhesive plaster. Although many patients state that their skin cannot stand adhesive, it will be found that such statements frequently arise from the fact that staphylococci are growing beneath the skin. A plentiful application of the antiseptic ointment prevents this so that after the first dressing such patients stand the adhesive well enough. Cases which have eczema surrounding the ulcer clear up very nicely following the application of the antiseptic ointment and the adhesive, but in these cases drainage must be allowed at first by not overlapping the adhesive. Many a weeping eczema has been found to have disappeared by the time the ulcer is healed with no other treatment than that given the ulcer.

Occasionally, a large ulcer in the lower part of the leg occurs, with considerable fibrous tissue surrounding it, which does not respond to this type of treatment. Such an ulcer is usually preceded by a deep phlebitis, and the Ho-

man's operation, or a modification thereof, is about the only method of attack.

The after-care of these ulcer cases is very important. In the first place, after it has entirely healed, the tender skin needs the protection of adhesive for several weeks and this should be changed once a week, never less often than

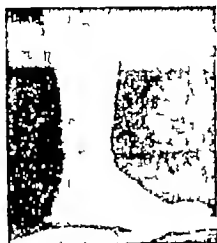

FIG. 4 Ointment covered with adhesive

once in ten days, because the skin has a tendency to macerate if the adhesive is left on for a longer period. A very small amount of antiseptic ointment and a layer of adhesive is all that is necessary. However, all the varicose veins should be obliterated, and even then the use of a canvas or elastic stocking or bandage should

FIG. 5 Sponge being strapped on.

be continued if there is lymphatic blockage. As we have said before, all legs following deep phlebitis are prone to ulcer formation probably as a result of the lymphatic system disturbance so that these swollen postphlebitic legs need careful support for years and maybe for life. This often becomes increasingly important if they show a tendency to ulcer formation. Further protection for the leg can be given, especially in the case of a male patient, by having him wear a leather puttee under his trousers. We have fifteen or twenty men in New England wearing leather puttees in this manner.

They are all men who perform some type of manual labor and who have had a recurrence of ulcers due to trauma.

Incidentally, other denudations of the lower leg, not of the varicose variety, such as burns or wide, incised wounds, can be treated to advantage by this method after the active process has quieted down and granulation is beginning to take place.

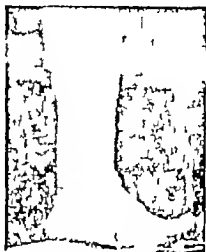

FIG. 6 The whole covered with a supporting bandage.

We see all healed ulcer cases on an average, every three months, whether they need treatment or not, as many tender pigmented areas have served as forewarnings of trouble, and preventive measures have been instituted early enough to produce successful results.

The length of time required to heal an ulcer definitely depends upon its size, location, chronicity, whether complicated by lymphatic blockage, whether surrounded by much inflammatory fibrosis and induration, and on the amount of local infection in and around it. Those over or distal to the malleoli are particularly stubborn probably because of the wear and tear on the skin edges from the frequent motion of the ankle.

The success of this treatment can be judged from the fact that for nearly three years it has been a standard method in this clinic and in our private work and from the fact that the clinic ulcer cases alone have increased from ten to fifteen a week to fifty to sixty. Such numbers speak for themselves.

THE TREATMENT OF PHLEBITIS*

BY EDWARD T. WHITNEY, M.D.†

IN order to treat phlebitis properly, it is necessary to recognize the distinction between the phlebitis of non-varicose veins and that of varicose veins.

Phlebitis of the *non-varicose* variety is usually the deep phlebitis of the iliac or femoral veins and sometimes the saphenous. Homans¹ and others² have repeatedly shown that not only is the vein damaged but that the lymphatic system surrounding the vein has also been injured. This latter damage, however, results in obstruction or blockade of the lymphatics.² The damage is often irreparable and produces a chronic passive congestion of this system. The sign of such a congestion is a brawny edema of the lower leg, either in whole or in certain spots, notably the calf (Diagram No 1).

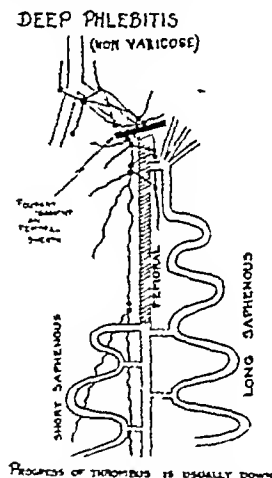

DIAGRAM NO 1 showing location of a deep phlebitis and the anatomy of related lymphatics. Note how the vessels including the lymphatic ducts pass through a bottleneck of fibrous tissue at the femoral sheath. Contracting scar tissue in this area may completely obstruct the lymphatics especially those in close relationship with the femoral vein from the knee up.

In the vein, a red thrombosis is formed.³ Such a thrombosis is usually made up of blood elements with very few fibrous elements. The intima may not be entirely destroyed so that the clot may be incased within the vein wall rather than being attached everywhere to the vein wall.³ Such a thrombosis may extend in the direction of the current as far as the nearest large tributary from which a rapid stream is coming and it may travel distally as far as there is any stagnant blood. It is recanalized fairly quickly in three ways, first by the natural contraction away from the vein wall of the clot itself⁴, secondly by solution of the clot by enzymes from the leucocytes within the

clot itself⁵, thirdly, by regeneration of any intima that has not been destroyed.³ The end result in the vein is usually some loss of tone, some possible narrowing and some impairment of the valves.

Treatment must be based upon the principle of helping nature overcome this pathology. This is best accomplished, first, by the application of heat and rest in bed and later by an elastic support for at least several months and perhaps for life. A surprisingly large percentage of our ulcer cases are the result of neglected resolved phlebitis of the deep variety.^{1, 6} As a rule, however, this is because of the lymphatic system blockage. Veins are recanalized much more easily than lymphatics are remade or new anastomoses formed. Stagnant lymph lowers skin resistance and allows infection which is ordinarily saprophytic to become parasitic. The result is death of the skin and an ulcer.

In our opinion, if such a phlebitis follows an operation or a delivery, the surgeon or obstetrician should assume the responsibility for it and should supervise after-care as long as it is found to be necessary. So much for the phlebitis of the non-varicose variety.

The phlebitis in a varicose vein presents an entirely different situation. In the first place, embolus rarely occurs for the simple reason that the course of the blood stream is down rather than up. Usually, the phlebitis starts low down in the varicosity and progresses upward, stopping every now and then where the stream becomes somewhat more rapid at the junction of the varicosity and a communicating vein (Diagram No 2). The damage to the

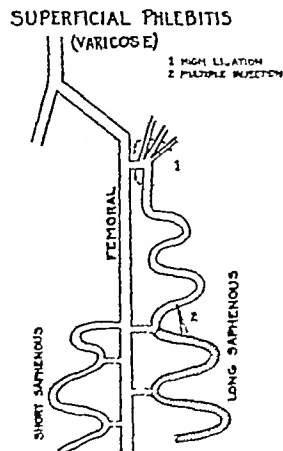

DIAGRAM NO 2 showing location of varicose vein phlebitis and areas where treatment can be instituted.

lymphatic system is not so important as it is in deep phlebitis because only some of the smaller channels, or ducts, are affected and

*Read before the Twenty-Fourth Clinical Congress of the American College of Surgeons at the Boston Dispensary October 17 1934.

†Whitney, Edward T.—Assistant Surgeon Boston Dispensary. For record and address of author see This Week's Issue page 941.

anastomosis between these smaller ducts is more frequent.

Treatment in this type of phlebitis should prevent any extension of the process up the venous system, thereby confining it within the smallest space possible. There are four ways of doing this: first, by excision of the phlebitic vein¹, secondly, by ligating either well above the affected area or just distal to the femoro-saphenous opening, thirdly by collapsing the varicosity by very tightly strapping two or three thicknesses of felt padding over the vein wall above the phlebitis, fourthly by injecting above the affected area², thereby producing what Theis³ calls a white thrombus. Such a thrombus is composed mostly of fibrinous or organizing elements and, therefore is of a

FIGURE NO. 1. A case of varicose vein phlebitis a few days old. It is being injected in five places just above the proximal border of redness and tenderness. As the difference in color between the phlebitic area and the normal area does not appear in a photograph a crescentic line has been superimposed indicating the proximal border of the phlebitis.

more permanent nature than the red or mixed thrombus of the phlebitis. Any one of the latter three obliterations practically immobilizes the phlebitic process and causes it to quiet down within a very few days. The method of choice, where possible, is the injection as it is of a fairly permanent nature and does not necessitate any operative procedure. These patients formerly were kept in bed for from three to six or seven weeks with an icebag on the affected part, but we know now that this is not necessary, because, aside from the theoretical considerations, a great many of these patients come into the clinic with a phlebitis of many days or weeks' standing and no harm has come to them.

Having confined or put at rest the phlebitic

process, our next step should be to eliminate the underlying pathology which caused the phlebitis. This pathology consists of a chronic passive congestion due to varicosities and a toxic or infectious element. The chronic passive con-

FIGURE NO. 2. Same leg as in figure no. 1. After a lapse of two weeks following injection.

gestion is treated by further injection, ligation if indicated, and support, and the focus of infection whether local or distant, should be eliminated.

This method of treating phlebitis in varicose veins prevents a three to six weeks' period of total disability confines the phlebitic or infectious process to the smallest possible space, prevents chronicity or the recurrence of phlebitis after recanalization and prevents future ulceration.

HIGH LIGATION IN THE TREATMENT OF VARICOSE VEINS*

BY WALTER S. LEVENSON, M.D.†

A FEW years ago the injection treatment of varicose veins became popular in this country. Its popularity was due in a great measure to the fact that a conservative ambulatory procedure was offered in place of a radical surgical operation, necessitating hospitalization and disability. We shared this wave of popularity and enthusiastically entertained visions of relieving a great mass of patients suffering from varicose veins who, for one reason or another, could not absent themselves from their occupations, and who had for years received palliation by numberless procedures. Aside from these considerations, we felt that reports from other clinics here and abroad showed results at least as satisfactory as those to be hoped for by surgery. As time went on, it became quite obvious in our own clinic, as well as in others, that in a certain percentage of cases permanent results were not being obtained, and that patients were returning to the clinic for treatments over a surprisingly long period. Various sclerosing agents and various techniques were used, but it became quite apparent that more radical measures were indicated.

Mindful of the suggestions of De Takats and McPheeters and others, we decided to combine with injection treatment the high ligation of the saphenous vein in selected cases. At the same time, a series of cases was to be treated by the multiple injection method, discussed elsewhere. It was felt that because of the hydrostatic pressure continuously present in the saphenous vein, particularly in the thigh, sometimes injection in those large varices did not work to their best advantage, and that apparently well thrombosed veins recanalized and small branches dilated in from three months to a year.

Therefore, patients with saphenous veins with incompetent valves, but with competent perforating veins, were selected for ligation. New patients and patients who had been previously injected were included.

TECHNIQUE

Under the usual aseptic technique, infiltration anesthesia with one per cent novocaine solution is obtained. Usually not more than ten to fifteen cc is necessary. An incision is made about two inches long, two fingers below and parallel to the inguinal ligament with the center over the saphenous vein where it dips through the fossa ovalis. The junction of the saphenous vein and the femoral vein is exposed and the saphenous vein held up by means of a tape moistened in saline solution. Three or four tributaries which are usually constant are isolated and doubly ligated with fine silk and cut between the ligatures. Directly at the junction of the saphenous vein and the femoral vein, the saphenous vein is doubly ligated with number 6 black silk. The saphenous vein is then clamped across distal to these ligatures and transected between the ligatures and the clamp. At this point, the distal segment of the saphenous vein can be injected with ten to thirty cc. of a mixture of dextrose and sodium chloride. After the injection, the saphenous vein is ligated with silk below the clamp and a segment of vein about one-half inch long is removed. The subcutaneous structures are approximated with fine, plain catgut and the skin with interrupted dermol or clips. A collodion dressing is applied and compressed with adhesive plaster and flat gauze sponges. In twenty-four hours the patient is allowed up out of bed and usually goes home in about four to five hours after that, making a total hospital stay after operation of about thirty hours. Ace bandages are applied to the extremity, and the patient is seen again in the clinic in about three days.

Surprisingly little pain is complained of by these patients postoperatively, if no injection is made at the time of operation. At most, only moderate pain is noted if injection of the lower segment is carried out as described above. It is satisfying to observe that even after this operative procedure has been carried out without injection of the saphenous vein in the thigh, a vein which previous to operation was easily palpable is difficult to find, indicating that the back pressure has been controlled. About one week after operation, injections are started again according to our accepted techniques.

THE MULTIPLE INJECTION METHOD OF
TREATING VARICOSE VEINS*

BY S. SEYMOUR HORLICK, M.D.†

BY the multiple injection method we refer to the procedure described by McPheeters¹ in his book "Varicose Veins." This method has as its basis the injection of a sclerosing solution into many points along the course of varicose veins, at a single sitting, to produce massive obliteration of their lumina. The advantages in using this method are primarily to reduce time over which treatment is necessary and, secondarily to make for more efficient obliteration of these pathologic veins.

Statistical data as to the length of time over which treatment is given are lacking in the literature of varicose veins. Faxon's² carefully prepared report of 314 cases at the Massachusetts General Hospital shows an average of about seven injections per patient, with two or three injections per visit. This particular report shows sixty three per cent recurrence. From our experience, the number of injections would account in good part for the large percentage of recurrence. It is almost inconceivable that one can obliterate the entire system of varicose veins with an average of seven injections.

From our observation of the other clinics in Boston, we find that the patient makes periodic visits spaced from one to four weeks and, usually, then receives only a single injection and that into the most prominent, or most easily found, varicose vein. At the next visit, the treatment may have no relation to the preceding one and this haphazard method is pursued until the patient no longer returns because he is either tired of so many injections or satisfied since the most noticeable veins have disappeared. We found certain patients who had returned at intervals for five years and were still being treated. This makes us feel that a definite plan of procedure should be mapped out at the first visit and carried out to its completion as promptly as possible.

Theoretically, there is only one absolute contraindication to the injection treatment. That is inadequacy of the deep circulation. There are, however, more contraindications to the use of multiple injections. From a routine examination, one may find that the patient has diabetes, in which case sugar solutions should not be used. The patient may have nephritis, in which case concentrated salines should not be injected in large amounts. Patients with heart disease are often benefited by obliteration

of their varicose veins but as a rule should not be subjected to multiple injections because the treatment is a long one, one-half hour or more, and may tire them excessively. The treatment is further contraindicated in neurotic patients because of cramps and venitis, which is often incident to good obliteration. Also in cases of active phlebitis of infectious origin. It has aptly been stated³ "Never treat any patient with varicose veins by the injection method so radically, completely or extensively that she will be incapacitated or bedridden, for, in so doing, one great advantage, that of being an ambulatory treatment, is lost."

Given a patient suitable for multiple injections, the technique is not difficult, but it requires considerable attention to details. An assistant greatly facilitates the work. The time consumed at each visit is necessarily long but the results compensate for it.

Our technique is that described by McPheeters¹ except for a few minor variations. Briefly it is as follows. The patient is placed in an erect position and the points where injections are to be made are marked with mercurochrome solution or tincture of iodine so that one may know where to inject when the veins are subsequently collapsed. The patient lies down and the extremity to be treated is elevated and stripped of blood. Two tourniquets are applied about six to eight inches apart, starting at the foot or ankle. These must not be applied so tightly as to cut off the deep circulation, for serious trouble might ensue from the sclerosing solution finding its way to a corresponding segment of the deep circulation. After this, the leg is lowered and the points previously marked are injected between the tourniquets with the solution to be used. Pads of gauze are strapped over each puncture wound. This done, the distal of the two tourniquets is removed and the leg again elevated and stripped of blood. The tourniquet previously removed is then applied about six to eight inches above the one left in place and the leg lowered. This segment is then injected as was the lower one. This procedure is followed up the leg and thigh until the veins are injected to the groin. The most proximal of the tourniquets is left in place and the whole extremity is firmly and evenly bandaged from toes to groin. The ace or elastoplast bandage is ideal for this purpose. In our clinic because the cost of these latter is prohibitive, we use sheet wadding and ordinary bandage with satisfactory results. When the bandage is applied the tourniquet is removed. By this means the veins have been injected while collapsed and have been kept collapsed, as near

*Read before the Twenty Fourth Clinical Congress of the American College of Surgeons at the Boston Dispensary October 17, 1924.

†Horlick, S. Seymour—Junior Assistant Surgeon, Boston Dispensary and Beth Israel Hospital. For record and address of author see "This Week's Issue" page 931.

ly as possible, by the bandage. The resulting thrombi will thus be smaller in diameter. It is advisable to keep the bandage in place until the next visit to the clinic. At the ensuing visit, small varicose veins, so-called "pick-ups", missed at first, may be individually injected without the use of tourniquets. If the veins of both legs were varicose and only one done at the first visit, the other may be done at the same time as the "pick-ups".

It is important to obliterate the internal saphenous vein thoroughly. This may frequently be found, when not palpable or seen, by the technique described by McPheeters¹, the so-called "percussion pulse transmitted". This is obtained by percussing a distended loop in the calf or lower thigh with one hand while the other is held flat over the location of the internal saphenous vein. A distinct fluid wave is produced within the vein which is felt by the palpating hand.

A vein, size 3* or 4* in McPheeters' classification, when treated by single injection while distended, will more readily recanalize than the same vein collapsed. In general, it may be stated that the greater the diameter and the shorter the length of the thrombus, the greater will be the probability of recanalization. This is due to pressure created by the weight of a column of blood above the thrombus. If the whole column of blood was thrombosed at the same time in a collapsed system of veins, recanalization is lessened because the thrombus would be narrower, more extensive and, therefore, more resistant to the back pressure.

The patients chosen for multiple injections in our clinic have been those with extensive varicose veins, who showed no signs of heart or kidney disease, active phlebitis or neurosis. Many of those who were barred may well have been treated had it not been for the limitations of facilities for handling large numbers of long treatment cases.

The solutions used in our series of cases were twenty per cent sodium chloride, five per cent sodium morrhuate and seventy-five per cent invert sugar. Needless to say, sclerosing solutions that are toxic in moderate or large dosage, such as quinine hydrochloride and urethane, or the salicylates, must not be used. Quinine hydrochloride and urethane has been used for injecting the "pick-up" veins missed at the multiple treatment. We found that ten cc of sodium morrhuate in one fourth to one half cc dosage at each point is suitable for the average case. In more severe cases we supplement this with twenty per cent sodium chloride solution. The

latter solution gives an excellent firm thrombus but, because of the severe cramps it causes, we prefer the sodium morrhuate. We have not seen toxic manifestations from this large amount of the morrhuate solution. None of these solutions will produce a slough if the technique is properly executed, and *any of them may produce a slough* if the solution finds its way outside the vein lumen.

One point not sufficiently recognized should here be emphasized. The destructive action of the sclerosing solution on the vein wall continues as long as the solution is in contact with it. The longer the action, the greater the destruction. Hence, it is important to keep the solution localized in a segment of vein just long enough to produce damage to the intima and not erosion through it to destroy the thinned-out media. It is in these cases that one sees severe perivenitis and slough, even though the surgeon was certain he was within the vein.

It is gratifying to note that patients who receive multiple injections suffered less post-injection discomfort. This is probably due to the support afforded by the bandage. Cosmetically the results are superior to those produced by the single injection method.

In an attempt to compare the duration of time consumed in treating patients by the single and multiple injection method, fifty cases of the former, picked at random from the records of the vein clinic of the Boston Dispensary, have been classified. Those records which showed the patients to have advanced myocardial disease, nephritis in any form, neurosis or active phlebitis were excluded. Fifty-one consecutive cases, treated both privately and in the Boston Dispensary Clinic by the multiple injection method, were similarly classified. The private cases were treated by the same technique, with the same solutions and by the same operator as were the clinic patients. Only those records were analyzed which showed that the patient was discharged except for follow-up.

From this analysis, the average patient by the single method received 19.52 injections at 21.76 visits, covering a span of 82.22 weeks. By the multiple injection method, it was found that the patient did receive an average of 44.11 injections at 4.76 visits, covering 4.17 weeks.

In this series of fifty-one cases treated by multiple injections, there were four recurrences and only in those who showed a double Trendelenburg. Patient No. 5 of the Multiple Schedule showed slight recurrence in twelve months. Patient No. 8 showed recurrence in sixteen months. Patient No. 25 showed slight recurrence after twelve months. Patient No. 51 showed slight recurrence after eight months. Excluding three patients who had not received follow-up examinations, the recurrence rate is 8.33 per cent.

NEW ENGLAND SURGICAL SOCIETY

PERSONAL EXPERIENCES WITH TUMOR OF
THE BLADDER*

BY J DELLINGER BARNEY, M D †

THE literature of tumor of the bladder is already extensive and is growing rapidly. Many studies have been made of large series of cases, the largest and most recent being that collected and analyzed by the Carcinoma Registry of the American Urological Association (*J Urol* 31 423 [April] 1934). The conclusion of most urologists of experience is essentially the same, namely that recurrence, no matter what the treatment, is very frequent, that five-year cures are relatively few in number (15 to 30 per cent), and that there is a high operative mortality. A further point of agreement, perhaps one of the most important is that it is uncommon to see a case in its earliest and therefore most favorable stage.

In view of all this I do not feel that what I shall have to say will contribute anything new or strikingly different from what has already been reported. I do feel, however, that an experience of about twenty-five years with a series of some 250 cases enables me to express an opinion on certain aspects of the question.

Although this is to be by no means a statistical study, a few figures must be given to impress certain old truths upon you. That tumors of the bladder are seen infrequently even by the urologist is shown by the fact that they comprise only about three per cent of all urological cases. Most are seen first by the family doctor, by the internist, or by the general surgeon. I have already stated that it is common experience to find many of these patients with well-advanced cancer before they are finally seen. It is important, therefore, to consider the possibility of improving on this situation. It is not unfair to say that the blame for delay rests partly on the doctor and partly on the patient. To anticipate a little let me say that all studies of such cases show that hematuria, gross or microscopic, intermittent or constant, is the initial and presenting symptom in about eighty per cent. It is also important to know that in various studies of cases of hematuria as a symptom, malignant disease of some part of the urinary tract is responsible in about seventy-five per cent. It follows not only that we must be constantly on the watch for blood in the urine, but also that we must advise the patient to have the source of bleeding investigated. In the event of microscopic

blood, involving as it does for its discovery a careful microscopic examination of the sediment, it is not enough to attribute it to a "cold" or a "strain" or some such unlikely cause. We must bear in mind its possible significance, thereby giving the patient the unquestionable advantage of early interference with a situation fraught with disastrous possibilities. Too often are all concerned lulled into a sense of false security by the fact that the bleeding stops after the administration of medicine, or by a period of rest. Experience shows clearly that the bleeding from bladder tumor is very frequently intermittent, and will let up spontaneously for a greater or less length of time. Not only this but there is no drug yet discovered which will influence hematuria favorably. The physician however is handicapped by the fact that the patient may not realize that there is blood in the urine, even sometimes in considerable quantity, therefore and quite naturally not seeking advice. It is also a fact that human nature, being what it is, many patients shrink from consulting the doctor because of their fear of being hurt or of being told some unpleasant news. The situation is difficult, and the only solution I can suggest is (a) more widespread use of the annual or semi-annual routine physical examination, and (b) more frequent and more forceful spread of the facts before both the profession and the laity.

Many other writers have shown the apparently unnecessary delay in making the diagnosis in tumors of the bladder. In my own cases sixty-six patients said they had had symptoms, consisting not alone of hematuria, but also of dysuria, frequency, loss of weight, et cetera, lasting anywhere from one to twenty years, in a smaller number symptoms had been noted for many months. In a series of 902 cases reviewed by the Carcinoma Registry of the American Urological Association, a diagnosis based on complete examination was made within one month from the beginning of symptoms in only 10.8 per cent, while in 48.3 per cent the diagnosis was delayed for more than a year. Such a situation would appear to be wholly unnecessary in view of the diagnostic and therapeutic attainments of today. Let us all work together for its improvement.

But there are other symptoms, almost as common, which, together with hematuria, characterize tumor of the bladder. I refer to frequency of urination, occurring in over seventy per cent of my cases, and dysuria, found in over

*Read by title at a meeting of the New England Surgical Society, Manchester, N. H., September 28, 1935.

†Barney J. Dellinger—Chief of Service, Urological Department, Massachusetts General Hospital. For record and address of author see *This Week's Issue*, page 991.

forty per cent. We have, therefore a very definite diagnostic triad, with hematuria forming the largest leg, on which to base a probable diagnosis, and one which can be confirmed sometimes by abdominal examination, more often by rectal or vaginal examination, and always by cystoscopic study. As a matter of fact in my own series of 250 cases, rectal examination in the male was suggestive or definitely indicative of tumor by way of induration, nodularity or thickening in forty six per cent, vaginal examination yielded similarly positive findings in forty four per cent. In this connection it is also desirable to emphasize the importance of bimanual examination, either rectal or vaginal as in twenty nine per cent of my cases this showed evidences of a mass in the bladder.

In the series of 902 cases already referred to loss of weight was noted in 251 or 27.8 per cent, and gastro-intestinal symptoms in 128 or 14.1 per cent.

The hematuria, gross or microscopic of bladder tumor is frequently referred to as a "painless hematuria." And so it is in many instances especially in the early stages of the disease. When found it is almost pathognomonic. But we have also seen that it is accompanied in many cases by other significant symptoms, the natural history of which I would like to dwell upon for a moment. It is easy to see how such a highly vascular structure, often rapidly growing, as a bladder tumor should bleed. Frequency and dysuria are the natural sequences being induced by necrosis of the growth with subsequent infection, which involves not only the neoplasm but the bladder as well. This condition is shown by the fact that not only blood but also pus and albumin are found in more than half of any group of cases.

That the bladder symptoms are probably induced not only by infection, but also by the position of the tumor is demonstrated by the fact that these tumors originate in the trigonum in from one-quarter to one-third of the cases, and on the lateral walls and bladder neck in from one-third to one-half of the cases. That the position of the tumor near or actually within what one might call in rough language the "business end" of the bladder is an important contributing factor to the disturbance of urinary function, is shown by the fact that in those rather infrequent instances where the neoplasm is in the vault of the bladder (about 7.5 per cent), urinary symptoms, even hematuria, are far less conspicuous until the disease is well advanced.

From what has gone before it is now possible to see why we find loss of weight and gastrointestinal disturbances so frequent a factor in these cases. Long-continued hematuria, in juxtaposition with exacerbations of sometimes marked severity, together with infection are factors sufficiently important. But in addition

to this we have another element and that is kidney damage. That this is not infrequent has long been recognized, more especially in recent years, since the advent of intravenous pyelography. By this method of investigation one can readily establish not only its presence, but also its extent, and whether one or both kidneys share in the destructive process. Not only is renal involvement demonstrated in this way, but it is also shown by the fact that the nonprotein nitrogen or urea nitrogen figure is abnormally high in the great majority of cases. In the 902 cases already mentioned the blood chemistry was investigated in 546. In 472 the results were indicative of serious kidney damage sometimes excessive. Further evidence of renal impairment is borne out by autopsy observations. In the series mentioned there were seventy nine postmortems of which twenty-six showed infection or dilatation or both of one or both kidneys and ureters. As additional evidence I cite the statement by Smith and Mintz (*Am J Surg* 20:55 [April] 1933) that in "86 cases in which the condition of the kidneys was shown at autopsy, both kidneys were normal in but nine."

Various factors contribute to this destruction of the upper urinary tract. That actual obstruction of the ureter by the pressure or actual invasion of the growth is a factor is shown by the fact that it was found in eleven of the seventy nine autopsies referred to. Where actual mechanical obstruction cannot be found the changes may well be induced by severe infection, by obstructing lesions at the bladder neck, and by cicatrization both of the latter conditions sometimes resulting from the operation.

Here therefore is a partial explanation of a high operative mortality thirty per cent or more. Other factors in the order of their frequency are circulatory accidents, pneumonia, peritonitis, shock and sepsis. Before proceeding to the next phase of this problem I can only emphasize again the enormous importance of an early diagnosis if we are to enable the patient to escape the disasters which are bound to overtake him if he waits long enough. Delay in the recognition of these tumors is a prime factor in this very high operative mortality.

Throughout my remarks I have referred to "tumors" of the bladder, meaning by this carcinoma. I think it is generally accepted that all epithelial tumors of the bladder are at least potentially malignant, regardless of their apparently benign appearance under the microscope. Although these are classified as Grade I, II, III, or IV according to their content of differentiated and undifferentiated epithelium, experience shows that the grade of malignancy by this classification seems to bear no definite relation to their tendency to metastasize. It seems to be a fact, however, that cancer of the vault of the

bladder is generally of a higher grade of malignancy than that elsewhere. For this reason and because through lack of symptoms they are apt to be well advanced when discovered, the prognosis is less favorable than for those in other parts of the bladder. It also seems to be a fact that the papillary type of carcinoma is far less likely to form metastases than the squamous type. Furthermore experience shows that while "less than half of the tumors" in the trigone, bladder neck and lateral walls are "highly malignant", seventy-five per cent of those in the vault show the higher grades of malignancy. Still another point to be emphasized is that while about one-third of all bladder tumors are multiple and that only about one out of three of these is highly malignant, almost one-half of the single tumors (these constituting about two-thirds of any given series) are of grades III or IV.

In this connection and before proceeding to other phases of this important subject, it is worthy of note that in the series of 902 cases studied by the Carcinoma Registry nearly half of the tumors had attained a diameter of more than 5 cm when they were first observed. Here again is an indication of delay in their recognition, for to reach such a size the tumor must have existed over a considerable period of time. This, together with the fact that experience has shown that the results in tumors of less than 2 cm are much more favorable, offers still another argument for prompt diagnosis and early intervention.

Although it has generally been believed that bladder tumors metastasize infrequently or only late in the disease, autopsy observations and recent intensive studies by various authorities show that metastases occur in at least ten per cent of cases. In a series of thirty-four autopsies reported by Smith and Mintz, metastases were found sixteen times (47 per cent). We do not yet know the entire story, for even the relatively few who come to autopsy can be so thoroughly examined as to be sure that no metastases exist. These deposits are found far more frequently in the bones than elsewhere, with the lungs, regional lymph nodes, liver, retroperitoneal nodes and peritoneum next in order of frequency. Nor is it impossible to exclude metastases, even though the tumor of the bladder has at least been temporarily eradicated. A patient of mine, a physician, died of metastatic cancer of the brain some months after his third operation for cancer of the bladder and when a recent cystoscopy showed no evidence of recurrence.

Treatment of cancer of the bladder resolves itself into five categories. A very few small lesions, sometimes accidentally discovered, of the pedunculated and so-called benign epithelial group can be cured by fulguration through the

cystoscope. These may be or may become multiple. I have had several of these definitely cured as shown by the elapse of more than five years without recurrence. Only recently however I saw a woman whose tumor I fulgurated five years ago, and who now, after complete freedom from neoplasm, has developed two small growths similar to those first seen.

In very unusual instances a sessile or infiltrating growth of small size (not over 1 cm in diameter) and in a readily accessible position may be cured by the cystoscopic implantation into its base of one, two or three radon seeds. Although I have had a few such cases result favorably to date, I feel it is justifiable to advise an operation as offering greater chance of permanent cure.

The external application of roentgen rays has been tried in certain cases both as a therapeutic measure and as a preoperative procedure with the idea that it will retard growth and by the production of a fibrosis make metastases at least by way of the lymph channels less likely. While the last word has not yet been said on this method of treatment, I think it is of little value and should be abandoned unless as a last and sole resort. It is, however, of considerable value in relieving the distressing cystitis of advanced cases, and the pain produced by metastases.

Wide resection of the growth with ample margins of healthy tissue is, when possible, the best method of removal. It does, however, result in a mortality of about thirty per cent and cannot be applied in those cases where the tumor is located in the trigone, bladder neck or low lateral wall.

Fulguration, by which I mean removal of the growth with the cauterizing loop, with or without the implantation of radium seeds in the base, carries a somewhat lower mortality but gives no greater prospect of cure than resection. This method of treatment is peculiarly suited to those tumors which are found in situations not suited for wide resection and which we have seen form the bulk of the cases.

The highest mortality (about 40 per cent) seems to occur where chief reliance is placed on the implantation of radium seeds in large numbers and where only that portion of the tumor which protrudes above the level of the bladder mucosa can be removed by cauterizing loop or knife. Here we have various factors contributing to the mortality among which toxemia both from radium necrosis and from sepsis are the most important. Not only this but even if the patient does not die, he may be made wretched by the severity and long duration of the radium burns.

As a matter of fact the final results do not seem to be better by one method of treatment than another, and in approaching a case the surgeon must be prepared to make use of any

or all of the procedures touched upon. When we realize that a recurrence of nearly fifty per cent takes place after any form of treatment, that only about one-third of the cases treated survive for five years or more, and that there is an operative mortality of over thirty per cent, we realize that a very real problem confronts us. Because of this we must give it our most serious thought. Not infrequently the most unfavorable sort of a case will turn out most satisfactorily, on the other hand what seems to be a more easily controlled tumor will prove to be of the most vicious variety.

Before closing I wish to say a word about total cystectomy which, theoretically speaking, should offer a satisfactory solution of our problem. But like all other apparently good things it has its drawbacks. Even in the supposedly favorable case there may be undemonstrable metastases. Then, too, when we say cystectomy we mean also one or two additional preliminary and major operations for the diversion of the

urinary stream. Having survived these ordeals removal of the bladder itself may tip the scales, coming as it does in the footsteps of other surgical procedures of real magnitude. In spite of this I think we are all convinced that it offers the only definite hope of cure in certain carefully selected cases. After all, the patient will surely die if he is not cured of cancer, and in the process will drag out a most wretched existence. Should we not therefore give him all the chance that surgery offers to obtain definite and permanent relief?

The length of time required and difficulties encountered in the follow up of patients, whether private or hospital cases, is well known. While this undertaking has been begun it is by no means complete. Not only this but it involves a good deal more than a mere statement as to how long a patient lived after operation. This aspect of the subject will therefore be dealt with at a later time in another communication.

NEW HAMPSHIRE MEDICAL SOCIETY

PRESIDENT'S ADDRESS*

BY FREDERICK P. LORD, M.D.†

ONE of the temptations of an occasion like this, where opportunity is given me or is forced upon me, to talk before the members of this Society with no discussion to follow, is to get rid of any wild and pot ideas which I may be harboring. There is no lack of such of course, on my part, but I have decided to resist this special manner of suicide.

The logical procedure would be for me to talk about the one thing concerning which I may be supposed to speak with some authority. As I thought of you listening to a long paper on some anatomical subject, in which I should be enthusiastically interested, I tried to picture your state of mind, feeling you were brought back again to your medical school days. I feared I should need to ask to have the doors locked before I could finish the paper.

Then there is the perennial subject, a vitally important one, to which you have frequently listened at this annual meeting and elsewhere, The Socialization of Medicine. Certainly I have my own ideas on the subject, and here is a chance to recount them. But can I give you anything really vital and conclusive on this highly debatable subject, concerning which an eminent authority is going to speak to you later? I am inclined to think that I may even

receive your thanks if I do not venture on this broad field at this time.

The experiences of the recent years during which I have had considerable to do with this Society, and especially for this past year, as I have met with various committees, visited many of the county societies and tried to understand the problems and questions that have come up for consideration, have caused me to ponder about this Society, its organization, its membership its history, its past policies, its present trend and its future course.

Historically it is an old institution, dating back almost to the year of the signing of the Constitution of this country, and thus it possesses the strength, and perhaps the weakness, of such a tradition.

In size it is small, as such societies run, with less than five hundred members on its roster. We live in a rather sparsely settled and agricultural region, having but few cities, none of them of any great size. I presume that the average doctor works in a place where there are no more than two other doctors close at hand, and it is only occasionally that he sees other medical men than those in his own town. The time and opportunity for such practitioners to meet other doctors, with whom to discuss medical matters, give and receive ideas with respect to their profession, are not very common. Most of them have to be decidedly sufficient unto themselves, and they must carry on

*Presented at the Annual Meeting of the New Hampshire Medical Society at Manchester N. H., May 7, 1931.
†Lord, Frederick P.—Professor of Anatomy, Dartmouth College Medical School, 1931.—For record and address of author see This Week's Issue, page 931.

largely on their own momentum, so to speak. Vacations are not frequent or long and are often nonexistent, it is hard to get away from their patients, and for one reason or another they rarely close the office door for more than an occasional day off. Such a life leads to a very real sense of responsibility to their work and their patients, and it also tends to make the doctors somewhat individualistic, relying upon their own efforts, their own judgments and their own ideas and information.

With this background this Society's membership is naturally a more or less loosely bound organization, meeting as a whole but once a year, and in its county units, often not more than twice. Unlike a Rotary Club, for example, which meets every week, it is not reasonable to expect that our smaller groups or the whole Society would be as unified or as active in its functions or policies as the former. And men so occupied with their exacting and arduous daily life, seldom have an opportunity to work shoulder to shoulder with men of their own special interests and training and do not naturally make these rare gatherings a vital factor in their existence. Time is not offered for the exchange of ideas, the formulation of policies, opportunity is not available for ironing out individual differences or making reasonable compromises toward some special end, all of which are necessary for any creative and cooperative results.

The organization of this body, due to its size, and to the few opportunities for assembling, has necessarily been so devised that the greater part of its legislative and deliberative functions is carried out by a group of about thirty men, elected representatives from each local group. Such functions cannot be carried out by a sort of town meeting among several hundred members gathering once a year. The executive work is done by a few special officers and a considerable number of committees. Information of what is done by the House of Delegates and by the special officers and committees is given out by an annual report, issued a year after the meeting has taken place, by monthly publication in a medical journal and at times may be given by special bulletins from the Secretary.

The long history, the character of our membership, and the type of organization of this Society, it seems to me, tend to make it difficult for timely, effective and speedy action where such action may be needed. Also it is not reasonable to expect that such a body would be highly efficient in bringing about a common attitude or its expression on any particular subject.

What the situation has been in the past in this regard is a fair question to ask. Our one gathering each year, such as the present occasion, brings us together to hear a splendid med-

ical program, which we all enjoy, and from which we profit professionally, there is no doubt of that.

Our legislative body meets, adjusts its constitution and by-laws, elects its officers and committees, discusses routine affairs, entertains propositions from its committees, passes resolutions, deplores this or that tendency, recommends certain procedures, some of them of decided value and importance and adjourns for a year, necessarily leaving to its committees the function of carrying out its wishes. So far as the rest of the Society is concerned this usually seems to be the end of it. Some committees meet and work conscientiously, others less so, but all are handicapped by the fact that there seems little general knowledge on the part of the members of the Society, and perhaps too little interest, in what they are trying to do. Little help from among the members seems to be available, considerable opposition seems evident in some cases, and the next year seems to begin about where things were the year before.

I question whether as a group we have not been several laps behind the rest of our State in general, whether we have not preferred to continue things as they have been, without much thought as to what are the demands and wishes of the public, their reasons therefor, whether we have not preferred to let others go ahead, against our opposition or indifference, rather than to study the matters in question, enter into the public discussion, and attempt to use our influence along the lines in which our special training and experience would naturally make us leaders.

If various projects, that have to do with things medical, have been carried on by others than ourselves and in ways which we think are unwise or improperly handled, have we been willing to accept the existing fact that these procedures are in being, and to do our part as citizens as well as specialists in bettering them? Have we been feeling that we belong to a profession which requires perhaps the most laborious and extended period of preparation of any, which carries a tremendous individual responsibility, which is more generous of its time and skill than perhaps any other, and that our position for these reasons is sacrosanct? Have we been feeling that our practices and traditions are to be left as they are, need no adaptation to a changing world, that others should accept our attitude without question, and, if they do not, we should ignore the fact and go on as ever? I ask these questions as being healthy for ourselves, for it is often well that we make examination along the lines where we feel the most secure. Sometimes it comes out under such a process that we can readjust our perspective a little and see even our familiar and accepted path under a different light.

One can easily say that a doctor who is not today carrying on medical practice is not a

suitable person to carry on such queries let alone to pass judgment on such matters. This is a natural comment to which I can only answer that my recollections of my struggles for several years in the practice of medicine are by no means forgotten, that my regular work is in teaching young men who are to make their living as practicing physicians, and that my deep interest is and always has been in my profession ever since the days when I first studied medicine. My experiences during this past year with many of the problems that have come to the practitioner have brought close to me their significance to other doctors who are making their living by active practice.

If I am painting a somber and discouraging picture of the New Hampshire Medical Society, it is not with the idea of trying to point out any personal feeling that matters are necessarily hopeless or too discouraging, but rather that I feel there are signs of a very definite improvement already along some lines and there are possibilities for much further progress. It is for this reason that I have taken the liberty to speak so frankly at the outset.

I want to say at this time that, as I have seen our organization in recent years in a sort of close-up view, I feel certain that we do not lack men, able, informed, interested and willing to work along with the rest toward an improvement of conditions, where such seem to be needed. The heterogeneity and individualism of our Society is not by any means a factor that is altogether harmful or that cannot be overcome where it is a hindrance. What then can be done and along what lines can we make further and more definite progress?

Let me call your attention to certain far-reaching tendencies that have appeared in the last few years in our Society. When this State launched its Relief Program there were many new problems and many new procedures were established, some of which were a cause for great dissatisfaction on the part of our profession. We might have allowed things to remain in that situation, individually harboring feelings of injustice, or we might have passed a resolution, letting it go at that. Instead there was instituted a committee, headed by our able president of last year, which worked hard and long over the new regulations, doing its best to point out the difficulties, to correct them as much as possible, attempting to inform the medical men of the State as to the meaning of the more vague provisions, and to explain as far as possible where explanation could be made. This committee not only acted as interpreter to our profession, but it went to the State authorities, who had the matter in charge, doing its best to alter and improve in so far as they were able to do so.

At the same time there was introduced an other new factor, namely a Special County Com-

mittee in each County Society, whose function it was to handle this problem in its details in its own province, to keep in touch with the State Committees of their Society, and at times to clean house in its own County, where evidence was forthcoming that any individual member was not following properly the regulations which the rest of us were trying to carry through.

Many mistakes were made in the administration of this new law, no one will deny that many injustices and inequalities were present, and a deal of unhappy feeling was stirred up. I am not attempting to pass judgment in any way upon Bill 417, or upon its administration in detail, even if I felt more competent to do so. That particular law is a thing of the past. What I do want to call attention to is the fact that in our relation to this law we have set up what is practically a new procedure.

During the past year this device has again been resorted to by our Society in two other similar instances, namely in regard to Child Health and to Maternity and Infancy Work of a medical nature relating to pre-school and school children and also to maternal and infant care, is being done by agencies of this State other than our own profession, agencies which we rather presumptuously call lay groups. In both cases there was formed a special committee of this Society whose function was to work with these lay officials. I might add that in one case at least such a committee from our organization was asked for by the lay body which was to carry out the work in order that they might have the benefit of the advice and help of the medical profession. It is a good guess that such a request, the desire for such cooperation, would never have occurred had it not been for the work of the Committee on State Medical Relief of the previous year.

In the hurried and state wide work on Child Health, County Society Committees were also established in each of the ten Counties, as in the case of the Welfare work, and for the same reason. The County machinery was new and not always simple to use. While in some Counties it was not availed of, in other Counties these committees were active and made real accomplishments. Again I want to state that I am not attempting here to judge the details of these procedures, but I feel that the plan helped, that there was a very real cooperation and that in the work of the Department of Education, with the aid of our Society, the task was simplified and friction was lessened by means of our new and somewhat creaky machinery.

It may well be that many or all of these State lay projects were not altogether what they might have been, the work of the various committees was not entirely satisfactory to the members themselves, or to many of the members of this

Society, the difficulties were certainly many. Nevertheless, this development on the part of the New Hampshire Medical Society of coordinating committees of this nature, to work with organizations outside our own is packed with possibilities of the greatest value to the future, both for our organization, and, I dare hope, for the public in general.

There is being brought to the attention of our members at this annual meeting a tentative plan of schedules and regulations, which it is hoped will help to carry out the administration of State Relief in the future. This plan has been worked out by our representatives in conference with the State Relief Commission and representatives of the County Commissioners. Again I do not wish to discuss here the provisions of that agreement—you will hear of them at another time—but I wish to point out that it is the result of a deliberate and careful attempt on the part of our own committee to present the case for the medical profession to the officials having this relief in charge, and an attempt on their part to meet our suggestions and advice as presented to them by active practitioners who know the history of the past two years in this matter and who are acquainted with the opinions and feelings of our profession throughout the State. This sort of co-operation, with the desire on both sides to come to a fair agreement, is inherent in this set-up, and I think we are entitled to feel that it has in it germs of real benefit to all concerned.

Although it may not be entirely satisfactory to any one—what arrangements of this sort ever can be so?—it promises well and carries with it a chance for further alterations where they may be needed. It seems to be the logical and only proper way by which such a measure can be carried along to its fitting conclusion. Where mistakes are made, where injustice is done, there exists through the machinery of the County and State Committees on Relief of our Society an opportunity to call attention to them and to have them considered on their merits, with hopes for remedy.

At this point I want to speak of what I believe is a necessary further step which we must always be ready to take, if we are to do our own part in making such a scheme successful. I think I feel as strongly as does any one here that the members of our profession as a rule are willing to do their part, as they always have in this less remunerative portion of their work, that they are intending to act fairly and to work with the machinery that is set up by the State. If there are any among us who, through misinformation or through deliberate intent, do not carry on their work fairly or who may be tempted to utilize the existing system for selfish ends, I think our organization ought to be willing to correct the one who is misinformed

and to censure or penalize the one who is remiss. If we are not willing to do this, we are not doing our part in this group with which the State is working. It means that our County and State Committees may need on occasion to use frank and direct means. I do not surmise that such situations will often arise, but when they do we should be ready to do our part.

The benefits of this procedure where the two parties concerned, the State or lay group and this profession, have gone over the ground together is shown in the recognition of certain factors concerning which there has been much said during the past two years. As regards Welfare for example, the patient, if it is an acute case, is allowed to have the privilege of choosing his own physician, he may receive the first visit without having to wait for special permission from a third party, and as an acute case he may continue with his own doctor at the hospital. The physician does not have to ring up a local official when making his first call on a relief case. Reasonable fees for his work are proposed for the doctor, who in many cases of this nature would formerly have received nothing, and opportunity is offered for adjustment of fees in special cases where question arises.

These provisions represent a reasonable set-up in the care of relief cases by the doctors of this State, and they provide means for further change if, and when, such changes seem desirable. Once more, I am not trying to evaluate in detail the scheme here referred to, but I am calling attention to the fact that this Society has now in existence and actually at work machinery which has been successful to a degree, at least, and which has not as a rule been previously much used or to such good effect. This machinery is capable of further usefulness, both to institute and modify existing arrangements, and similar machinery can be set up for other and new purposes when this is needed.

How does all this bear on the future? We are all well aware that other innovations are being discussed which may affect profoundly the practice of medicine. During the past year the officers of this Society have given much consideration to these problems and have attempted to learn what is the opinion of its members. To that end there have been many meetings of the Committee on Public Relations, Public Policy and Legislation, other members, representing the Society more widely, have been called for a special meeting, discussions have been held among the County Societies, and finally it was thought that these matters were sufficiently important and imminent to call an extra session of the House of Delegates to consider these vital questions.

The officers have attempted, by special bulletins to the members, to call their attention to these problems and some of the evidence bear-

ing upon them, to record the official decisions of the House of Delegates, to interpret to the public our opinions in so far as we can interpret them, and to see that at least the public is aware of the fact that we are interested in such things and are carefully studying them. The officers realize that they are your representatives, and that, even if they should wish to move faster, they cannot rightly make any head way unless the Society as a whole moves with them. The officers are not ashamed of their intent and they have found it difficult going. The rightful interpretation of five hundred minds on burning questions is no simple thing and if your officers have made mistakes we trust you will tell them.

We may not expect that the various new proposals for Socialized Medicine, Sickness Insurance, etc., will become law, or we may feel that they will surely be in existence within a relatively short time. We may like or dislike them. We may do our best to prevent their coming into being or we may wish to expedite the process. It may be, as some have said, that it will make no difference what we think or do as to the final outcome of such measures. I am not inclined to think that this statement is entirely true.

In so far as we have a collective opinion in regard to the proposed measure of Socialized Medicine let us state these opinions and do so where it will have the greatest effect. It is not unnatural that we, as a profession should feel that in such matters we have not only a right to voice our beliefs, but that we have a definite obligation to do so as being a group who are especially and peculiarly familiar with many of the problems that arise in regard to Sickness Insurance, for example.

What further can we do? I think that what we have already done, the machinery that we have already set up and used, is the clear and self respecting answer to this question. After the preliminary stages of discussion are over and when this Country or State decides to embark upon any form of Sickness Insurance then is the time for us to give our advice and cooperation through our constituted representatives.

These representatives will work with the State authorities we certainly will make an effort to that end—attempting to use our best wisdom in helping to direct the manner in which the laws shall be carried out. Where unfairness and injury are present we can by this means have a real chance to remedy such conditions, to speak for the best interests of those who are most concerned, and to carry on our fundamental work, which is to do all we can for the better health of our patients, who are the people of this State and who I do not hesitate to say need and I hope desire our services.

I hope that this partial attempt to analyze our Society, its history, its membership and

its organization, will not be regarded as too unkind or too pessimistic. Such a backward glance seemed to me to be a necessary step in order to bring out our difficulties, and to show the means we have been utilizing to overcome so far as possible these difficulties. It points the way also to what can further be done along these lines toward keeping all of our members better informed, in closer touch with each other and with their elected officials toward the erection and maintenance of a proper organization which can cause us to be heard, and toward the use of representatives who will keep us in close and friendly touch with the other agencies with whom we may desire to work.

I do not mean that such a device should be used simply to line our own pocketbooks, although I feel it is only fair and right that our interests should be vigorously presented and worked for, but if we physicians wish that our profession be advanced, that public health be best looked after that we have an opportunity to make ourselves felt through our own organization, it is well that we examine into our own official body as carefully as we do into that of a patient, that we look into all the facts that bear on the case, make our diagnosis and be prepared to institute methods of treatment which will do the most good.

RECENT DEATHS

SNOW—SAMUEL DRYDEN SNOW M.D., aged sixty five medical referee of Carroll County was found dead at his home in North Conway on September 20 1935. He had lived alone since the death of his wife, Louise (Berry) Snow last December.

Dr Snow had been a resident of North Conway for the past thirty years, going there originally as resident physician at the tuberculosis sanatorium. He graduated from the Dartmouth Medical School in 1897.

One son Dryden Snow who is educational adviser at the Glen CCC camp survives him.

TOWLE—GEORGE H TOWLE, M.D., was born in Deerfield, N. H., August 7 1873 a son of Dr George H and Panthia (Tucker) Towle. He received his early education in the Deerfield public schools and prepared for Dartmouth at Coe's Northwood Academy and Tilton School. He studied medicine at Dartmouth and later pursued his medical studies at both Bowdoin Medical School and the University of Vermont. He received his M.D. from the latter institution in 1900.

Dr Towle had practiced in Newmarket for thirty three years at the time of his death October 29 1935 and had been one of its prominent citizens. He was deeply interested in civic affairs and was a member of the Board of Selectmen. He also served as a member of the School Board which position he was holding at the time of his death.

Survivors are the widow a brother in Manchester and a sister in Deerfield.

CASE 21461

PRESENTATION OF CASE

The patient, a white American girl about twenty years of age, complained of fever and abdominal discomfort

She became ill while attending a boarding school and was admitted to the school infirmary with slight fever and malaise. She improved after a few days and was permitted to resume her studies in preparation for graduation. Several days later, however, she again became ill with mild diarrhea, vague upper abdominal discomfort, occasional emesis and complete anorexia. Shortly afterward she developed weakness in both hands and feet which progressed rapidly to a point where she was unable to feed herself. She was sent home, where her temperature ranged daily between 100° and 103° and the pulse varied erratically from 90 to 130. Her gastrointestinal symptoms gradually increased in severity.

At the end of two weeks, physical examination showed a thin, pale, apprehensive girl in no apparent discomfort. There was slight puffiness of her upper eyelids. The ears were normal. The throat exhibited nothing of significance. There were no palpable nodes in the neck. The breasts were normal. Other than a few transient atelectatic râles the lungs were negative. The heart was not enlarged. A soft systolic murmur was heard along the left sternal margin. The blood pressure was 90/64. Examination of the abdomen was negative and no pelvic examination was done. There was bilateral wrist and foot drop with atrophy of the extensor muscles of these parts. The reflexes were normal. The specific reflexes elicited were not recorded.

Examination of the blood showed a red cell count of 3,500,000 to 4,000,000. The white cell count was 14,000 to 23,000. A blood smear showed moderate achromia and an apparent increase in platelets. There were 45 to 60 per cent eosinophils. A stool examination was negative for pus, blood and parasites. Blood cultures showed no growth. The spinal fluid contained two cells per cubic millimeter. There was no increase in the protein content. The globu-

lin and Wassermann tests were negative. Sections of gastrocnemius muscle were negative for trichinosis.

After six weeks the patient's fever fell by lysis but the pulse continued to range widely between 90 and 130. When she had been afebrile for two weeks she was permitted to sit upon the edge of her bed. Gentle massage was instituted for the wrist and foot drop and she was carried out-of-doors once daily. She began to gain weight and obviously became stronger. Her appetite improved although she vomited once and had a short spell of mild diarrhea. One morning she was suddenly seized with a series of convulsive attacks and, died before medical attention could be obtained.

DIFFERENTIAL DIAGNOSIS

DR ALFRED KRANES This history suggests several possibilities, none of them too convincingly. The first thing that comes to mind, because of the symptoms of generalized infection and bilateral weakness of the hands and feet, is poliomyelitis, of course. There are, however, a number of things here that seem to be somewhat against that. In the first place, it says that she was preparing for graduation. I take it that that was some time in the spring of the year which would make it unusual for poliomyelitis, although it does occur. Secondly, she does not have any headache or pains in the extremities which we associate with poliomyelitis and which most cases do have, and then again the apparent severity of the gastrointestinal symptoms after the paralysis had developed is against it.

Another possibility is poisoning of some kind. Arsenic for instance produces a rather severe gastroenteritis and also peripheral neuritis, but we have no history for that. The onset is rather gradual and not sudden as one would expect with a case of arsenic poisoning. The peripheral neuritis of arsenic poisoning is just as much a sensory neuritis as a motor neuritis, so I think that is probably unlikely.

Can this be a paralysis or peripheral neuritis secondary to deficiency or avitaminosis which we occasionally see in cases of ulcerative colitis? I think that is exceedingly improbable because the peripheral weakness was too marked and there was not enough in the way of gastrointestinal symptoms, not enough diarrhea to account for this degree of weakness. There is nothing else that I can suggest from that history.

It would be a little more helpful if we were told something about the sensory examination. Inasmuch as that is not mentioned here and since she has no sensory symptoms I shall assume that there was no sensory impairment whatsoever. Aside from the bilateral foot and wrist drop the other important feature in that

history is the hypotension which is somewhat unusual for a girl of that age. Poliomyelitis does occasionally produce a hypotension when it involves the vasomotor center, but we have no evidence in this case of any medullary involvement. I think that is probably not the case. The hypotension of course suggests the possibility of Addison's disease. She does have gastrointestinal symptoms, weakness and hypotension but that is all there is in favor of it. There is no pigmentation. The rather rapid onset with fever and the weakness described here is not the usual type of weakness one would expect in a case of Addison's disease, so I think that is also very unlikely.

Nothing is said about the hemoglobin. Of course, the startling thing in the laboratory examination is the very striking eosinophilia. The lumbar puncture, done apparently two weeks after the onset of her illness, does not really rule out poliomyelitis. The spinal fluid might have been abnormal to start with and returned to normal but the other things I mentioned seem to make it improbable. The eosinophilia is very interesting and there are really very few diseases with which I am acquainted which will produce that striking degree of eosinophilia. The most common cause is trichinosis. I think if we knew nothing else except that the patient had 45 to 60 per cent eosinophils and made a diagnosis of trichinosis we would be right in a vast majority of cases. The other, though far more unusual cause is periarteritis nodosa and there are a number of things in this picture that such a diagnosis might explain.

This is a rather unusual story, a distinctly unusual mode of death for a girl of twenty. I do not know that I can offer any explanation for this picture but I think that in our differential diagnosis we have to keep in mind that this patient was suffering from a disease which affected her gastrointestinal tract, her neuromuscular system, possibly her cardiovascular system and which in addition produced a fever, leukocytosis and a very high eosinophilia. As far as I know there are only two diseases which are at all consistent with that clinical picture and they are trichinosis and periarteritis nodosa, one a rather common disease of known etiology which is not usually fatal and which produces this variegated picture by the dissemination of the larvae throughout the body by the blood stream, the other a rare disease of unknown etiology which produces very bizarre clinical pictures and is practically always fatal. I think I will have to confine myself to the discussion of these two possibilities. I do not know anything else that would give this picture.

Can it be periarteritis nodosa? She had gastrointestinal symptoms and central nervous system involvement and this high eosinophilia. This certainly is not the usual picture of periarteritis

nodosa, if one may speak of "a usual picture" in such a rare disease. They usually have a longer course and rarely die within eight weeks as this patient did, usually from four to eight months up to a year and sometimes even longer. So that that seems to be against it. She does not have what most of the patients with periarteritis nodosa have, that is severe pain in the extremities, muscular cramps. She does have what appears to be a peripheral neuritis although we are not quite sure of that. The peripheral neuritis of periarteritis nodosa is mainly a sensory affair and rarely leads to wrist drop and motor signs. The abdominal pain of periarteritis is usually different from this, usually severe abdominal cramps and not mild discomfort and diarrhea. She has none of the urinary findings and none of the cardiovascular findings. They frequently have angina which this patient does not have. Can periarteritis produce this sudden type of death? I think it could with involvement of the cerebral blood vessels. The patient with this disease occasionally dies rather suddenly with profuse subarachnoid hemorrhage, but even with severe subarachnoid hemorrhage one would not expect the patient to die quite so rapidly. On the whole I think that diagnosis is unlikely.

Can trichinosis explain this picture? I do not see anything in there that is inconsistent with that diagnosis. This patient has a number of complaints that people with trichinosis frequently have, abdominal discomfort and diarrhea, fever, malaise and the very high eosinophilia, also puffiness of the eyelids. Is there anything there against the diagnosis of trichinosis? The one thing we usually expect our patients with trichinosis to have is rather severe pain in the extremities, just as in periarteritis, but I have seen a number of them that had no pain whatever. I can recall several who have had no pain but who were later proved to have trichinosis by biopsy and skin test. I do not think that rules it out. As a matter of fact trichinosis is picked up so very commonly when hunted for routinely at postmortem examination that the series ranges all the way from seventeen to thirty per cent in routine autopsy reports. These patients rarely present a history of trichine infection. How about the negative biopsy? I do not think that rules it out either because we have had patients on whom the diagnosis was eventually established who have had negative biopsies. I recall one we had on the West Medical service who had four biopsies before the diagnosis was established so that a patient can have trichinosis and a negative muscle biopsy. The unusual bilateral foot and wrist drop we do not associate with trichinosis and yet there have been patients with just that symptom. One patient at the City Hospital was thought to have poliomyelitis for a while and later turned out to have trichinosis. She had bilateral wrist and foot

drip and as one reads the stories of the German epidemics this very severe muscular weakness is not uncommon in severe cases. Some of them become so severe that the patient is unable to sit up in bed not because of pain but because of very profound muscular weakness. So that I think that can fit in with trichinosis. Just what the mechanism of that weakness or paralysis is, is not very clear. Apparently it was not a real peripheral neuritis, that is the nerves themselves are not involved. It seems to be entirely a muscular affair.

If this patient did have trichinosis, how do we account for that rather sudden death? Trichinosis ordinarily does not do that. She died in a series of convulsions which leads us to think there must be some involvement of the central nervous system. Up to that time there was no indication of any involvement at all—negative spinal fluid, no reflex changes and probably no sensory changes, although I cannot be sure of that. We know that the trichinae are occasionally found in the central nervous system. They have been recovered from the cerebrospinal fluid and the brain substance itself and cases have been described where patients died of diffuse encephalitis, but there is no evidence of such a process here. Patients who die with encephalitis in the course of trichinosis usually present the picture of coma, delirium and ocular palsy, none of which this patient had. Trichinosis also produces thrombosis of the peripheral blood vessels and one wonders if it cannot do the same thing in the brain with the cerebral blood vessels and there again I must mention the fact that cases of trichinosis have been described during the course of which the patients have had hemiplegia the nature of which has not adequately been explained. But this is not the picture of cerebral thrombosis and I do not think anything will be found in the brain to account for this type of death. The usual mode of exitus in patients with trichinosis is diffuse myocarditis and we do have some evidence here that there is myocardial involvement. There is that single isolated low blood pressure. It would be extremely interesting to have more blood pressures during the convalescence of this patient. The fact that this patient had a pulse of 90 to 130 while afebrile makes one wonder about the possibility of myocardial involvement in this case. I think it also would be of interest if we had an electrocardiogram some time during the course of the disease because patients with trichinosis frequently show striking cardiographic changes which later return to normal with convalescence. I think this death could have been caused by a sudden acute myocardial failure. If the patient had trichinosis I believe it would be a logical type of death. Trichinae are frequently found in the myocardium if properly digested though not usually in microscopic sections but the myocar-

dial changes are almost always found. That is about the best explanation I have to offer.

DR TRACY B. MALLORY: We have given Dr. Kranes the compliment of a very difficult case and I think his discussion is so complete there is nothing to add.

DR JAMES H. MEANS: May I add one thing in the list of differential diagnoses? We have seen at least one very bizarre leukemia with extraordinary eosinophilia with cells that were abnormal. I think that is unlikely but I merely mention it as being worthy of the list of diagnoses to be considered.

DR ALFRED KRANES' DIAGNOSES

- (1) Trichinosis or
- (2) Periarteritis nodosa

PATHOLOGIC DIAGNOSIS

Periarteritis nodosa of the coronary arteries

PATHOLOGIC DISCUSSION

DR MALLORY: I am sorry Dr. Roy Wheeler is not here. This was his case and he himself did the autopsy outside the hospital and sent in some of the organs to me. The heart was normal in size, but as you looked at the surface you could see along the coronary arteries small beads one and two millimeters in diameter. These were separated by intervals of four or five millimeters of normal vessel and then another bead. In cutting through the arteries at the points of beading it was obvious that in some instances they were thrombosed, in other instances not. Microscopically the picture is absolutely typical of so-called periarteritis nodosa. The condition is really a pan-arteritis, the most important feature of which is necrosis of the media with the formation of mural aneurysms rather than the periarterial inflammation. A few lesions were also found in some slides of the liver. Unfortunately we did not receive specimens from the other organs, and the brain was not examined.

There is one other possibility of diagnosis in a case of this type that came to my attention within the last year from a very interesting case they had at the Faulkner Hospital with a somewhat similar history. The patient had signs of myocardial weakness with rather more pain in the muscles and rather less weakness than this patient, but some of both. He developed grossly palpable nodules along some of the arteries of the scalp. He had, like this patient, an eosinophilia of 50 per cent. I was told about the case and made of course a snap diagnosis of periarteritis nodosa and urged them to do a biopsy. They did one and the nodules from the scalp vessels proved to be perhaps the prettiest rheumatic nodules I have ever seen. The patient improved for some time and then suddenly died. Dr. Hazzard has al-

lowed me to see sections of the case and there are scattered throughout the heart very numerous Aschoff bodies. There are a few Aschoff bodies to be found in the diaphragm and in the kidney, and there are other lesions that very strongly suggest periarteritis nodosa. On the other hand the lesions of small vessels in rheumatic fever are so similar microscopically to some of the pictures in periarteritis nodosa that it would be difficult to distinguish between the two. I have been unable to make up my mind whether it is rheumatic fever plus periarteritis nodosa or whether an occasional case of atypical rheumatic fever may give that picture.

CASE 21462

PRESENTATION OF CASE

First Admission. A forty six year old Finnish laborer was admitted complaining of vomiting and lack of appetite.

He had been well until twelve weeks prior to entry when he suffered from an attack of "grippe" which confined him to bed for two days. The attack consisted only of malaise but at its termination he developed an abscess in the right groin which was incised by his physician. It continued to drain purulent material for three weeks after which it healed spontaneously. He developed anorexia which was associated with nausea, occasional emesis and a sensation of light-headedness. He returned to bed shortly after his abscess was incised and remained there for nine weeks. Vomiting, which at first occurred irregularly, increased in frequency until he vomited two to three times each day. During the ten weeks before admission he developed a nocturia of two to three times. Two weeks before admission he began to vomit everything ingested. Slight swelling of the ankles appeared. There were occasional attacks of "dizziness." He became progressively weaker and developed slight dyspnea on exertion. In the three months preceding his admission his weight had dropped from 165 to 135 pounds.

He had had incision and drainage of a left inguinal abscess forty years before entry. Seventeen years later he was seen in the Outpatient Department where he presented a story of morning cough with blood tinged sputum and pain in the chest of two years' duration. Inconstant rales at the right top and slight dullness of the left were found on examination. These findings were not confirmed subsequently and the cough gradually subsided. Because of multiple caries and apical abscesses his teeth were extracted three years before entry.

Physical examination showed a well-developed but poorly nourished man with evidence of re-

cent weight loss. His skin was dry and scaling and there was fairly marked pallor of the mucous membrane. The heart was negative except for slight accentuation of the aortic second sound. The blood pressure was 110/90. There was a sharp scoliosis of the third to fifth dorsal vertebrae with a convexity to the right. The lungs were clear. The liver edge was irregular and was found to be 3 centimeters beneath the costal margin in the midclavicular line. An ill defined globular mass which moved slightly with respiration was felt in the epigastrium just above the umbilicus. (Neither the abdominal mass nor the liver edge was demonstrable at subsequent examinations.) There were recent scars in the right inguinal region and old healed scars in the left. An eczematoid eruption was observed on the right lower leg.

The temperature was 98.6°, the pulse 84. The respirations were 20.

Examination of the urine showed a specific gravity of 1.008 and a large trace of albumin. The sediment contained three to five white blood cells, a rare red blood cell and an occasional hyaline and granular cast. A urine concentration test exhibited fixation of the specific gravity at 1.008 to 1.009. The blood showed a red cell count of 4,900,000 with a hemoglobin of 70 per cent. The white cell count was 9,500, 71 per cent polymorphonuclears. The stools were negative. A Hinton test was negative. The nonprotein nitrogen of the blood was 80 milligrams, the serum protein 4.1 grams per cent. The chlorides were equivalent to 110 cubic centimeters N/10 chloride per 100 cubic centimeters. An intravenous phenolsulphonephthalein test showed excretion of 10 per cent of the dye in two hours. An intracutaneous injection of old tuberculin in a dilution of 1:40,000 was negative. The icterus index was 2. A liver function test showed 0 to 5 per cent retention. The van den Bergh was normal.

An intravenous pyelogram was interpreted as demonstrating non-concentrating kidneys of normal size. An x ray of the gastrointestinal tract exhibited no abnormality of the esophagus, stomach or duodenum. A barium enema showed ballooning of the rectum, spasm of the sigmoid and unusually poor emptying. No lesions could be demonstrated.

The patient continued to vomit solid food at intervals but his appetite improved. On the fifth day another phenolsulphonephthalein test showed no excretion of the dye in two hours. The nonprotein nitrogen of the blood was 68 milligrams. The red blood cell count was 3,600,000, with a hemoglobin of 80 per cent. He was given glucose intravenously and the tincture of belladonna by mouth and the vomiting eventually ceased on the eighth day. The temperature, pulse and respirations remained normal throughout the hospital stay. His anorexia

and weakness subsided and he was discharged home at the end of the second week

Second Admission, two and a half months later

Shortly after his return to his home he began to vomit again with progressively increasing frequency. He became quite weak and developed an intolerable generalized itching of the skin. He was somewhat drowsy at times. Two weeks before entry a tender swelling had appeared on his right cheek at the corner of the mouth. This had grown larger, ruptured externally and exuded purulent material.

Physical examination showed a sick looking, pale, drowsy, air hungry man who scratched himself continually. The skin was dry and scaly and contained a few brownish blotches. There were scattered deposits of fine white granular material on the skin surface. Retinal edema was observed in the left fundus. Examination of the right side was not recorded. An abscess draining white creamy pus was present at the right corner of the mouth. There was an indurated tender swelling at the left corner of the mouth also. The lungs were clear. The heart was not enlarged and the sounds were distant. A basal systolic murmur was heard. The pulse was feeble. There was no edema. The blood pressure was 125/90.

The temperature was 98.8°, the pulse 95. The respirations were 20.

Examination of the blood showed a red cell count of 2,400,000, with a hemoglobin of 50 per cent. The white cell count was 20,000. There were 76 per cent polymorphonuclears, 11 per cent lymphocytes and 13 per cent eosinophils. The blood chlorides were equivalent to 115 cubic centimeters N/10 chloride per 100 cubic centimeters. The serum protein was 4.6 grams per cent, the nonprotein nitrogen of the blood 150 milligrams per cent, and the carbon dioxide combining power was 20 volumes per cent.

The patient was given 2,000 cubic centimeters of 10 per cent glucose solution intravenously. He failed rapidly, his temperature dropping to 97°, and died thirty-six hours after admission.

DIFFERENTIAL DIAGNOSIS

DR FULLER ALBRIGHT. The whole problem in this case will be to find out why he has renal insufficiency, what type, not whether he has that condition. The vomiting and lack of appetite will turn out, as we read more of the history, to be obviously due to chronic uremia.

Since his illness started with infection you immediately think of glomerulonephritis as opposed to other types of renal disease.

With a draining abscess in the groin one cannot help thinking of lymphogranuloma inguinale, which recently seems to be turning up on all sides in this hospital. It may be due to an old tuberculous gland or anything else.

With all these recurrent abscesses we are now thinking a little bit of amyloid.

Low blood pressure is against chronic glomerulonephritis.

An indefinite mass in the epigastrium usually means nothing.

"The sediment contained three to five white blood cells, a rare red blood cell and an occasional hyaline and granular cast." This pretty definitely puts it in a chronic nephritis group as opposed to various urological conditions.

We are surprised to see that the red cell count was normal.

"The nonprotein nitrogen of the blood was 80 milligrams, the serum protein 4.1 grams per cent." A kidney that has difficulty in excreting nonprotein nitrogen, and does not hold back protein. The chlorides are elevated. You would expect this value to be slightly high with the serum protein so low.

He has a very low renal function.

I do not think there is any question but that our trouble is with the kidney. I do not think he has uremia due to vomiting and dehydration alone. I think from the kidney findings that the pathology must be in the kidney. I think that all these other studies are aside from the point.

"The skin was dry and scaly and contained a few brownish blotches." Some superficial infection I imagine.

"Retinal edema was observed in the left fundus." The fundi are certainly surprisingly lacking in change.

There is no evidence of hypertension as yet. He now has very marked anemia. He undoubtedly had a lot of infection. It is not unlikely that a terminal septicemia or something set in.

It is a little hard to explain why the blood chlorides should be up to 115. He had marked terminal acidosis as so many of these patients have. I am surprised to see the chlorides that high.

I should think the most likely thing that Dr Mallory will tell us is that the kidney is of the same type primarily, as that in Dr Baker's case, a kidney about normal in size, the so called pale white kidney,—a chronic glomerulonephritis that went through a nephrotic stage and ended in typical uremia with these infections to contribute. I should not be too surprised if he told us he had amyloid disease. Consistent with this were the very low protein, the terminal rise in blood nonprotein nitrogen, and absence of eyeground changes. He had perhaps an etiology for amyloid. I think we have to consider the other insidious conditions that will destroy kidneys, multiple myeloma certainly is to be considered but with that you would expect a high serum protein rather than low. Hyperparathyroidism has to be considered but I think I would have heard of it if it had been hyperparathyroidism.

X RAY INTERPRETATION

DR. GEORGE W. HOLMES There are one or two things that I might point out. As Dr. Al. bright suggested, there is nothing of particular importance in the x ray. You can see the kidney outlines on both sides and although we are not able to state definitely the size of the kidney from x ray film, you can detect gross changes. The size here appears to be normal. This is the edge of the liver and it does not seem to be enlarged. Again the x ray evidence of enlargement of the liver is of uncertain value. The question was raised as to the presence or absence of trouble with the spine. We have lateral and anteroposterior views of the spine. They show scoliosis but no evidence of disease. Here is the film of the chest which also shows quite marked scoliosis but no evidence of disease of the lungs. In other words no primary tuberculous infection of the lungs, nothing to suggest that the other lesions were of tuberculous origin.

CLINICAL DISCUSSION

DR. ALFRED O. LUDWIG When this man first came into the wards there was a discussion as to what the diagnosis might be because of the anemia and blood pressure. We finally felt that it was chronic glomerulonephritis. He was followed for a time in the Outpatient Department and later we sent him into the house again with the opinion that he was in a terminal stage of chronic glomerulonephritis and some secondary infection. We still were concerned at that time that the blood pressure was not higher. He lacked eyeground changes.

CLINICAL DIAGNOSES

Chronic glomerulonephritis
Uremia.

DR. FULLER ALBRIGHT'S DIAGNOSES

Chronic glomerulonephritis.

ANATOMIC DIAGNOSES

Chronic amyloid nephrosis, with contracted kidneys
Bronchopneumonia.
Lymphangiectasis of the small intestine

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY Very obviously there are discrepancies in the clinical picture. The diastolic blood pressure is high, but the

systolic is quite low. The serum proteins are certainly very low for a chronic glomerulonephritis, and he did show typical retinitis.

At autopsy we found moderately shrunken kidneys. The pair weighed 150 grams. On the other hand the surface was only slightly granular, not so markedly so as one would expect, the tissue was rather firm and had a slightly waxy consistency. The sections have served only to increase the mystery a bit more. The picture is a peculiar one in that the most striking feature of the kidney is the persistence of glomeruli, which are all hyalinized, and almost complete absence of convoluted tubules. Ordinarily when the glomerulus is sclerosed and hyalinized in chronic nephritis, it eventually disappears, the time of disappearance probably taking two or three years. As it loses its function the corresponding tubules atrophy and disappear, and one is left with a fibrous scar which is usually rather densely infiltrated with lymphocytes. Not only the convoluted tubule but the corresponding Henle's loop and collecting tubule disappear. In this man, however, Henle's loops were well preserved, the collecting tubules seem actually to have proliferated a bit and the convoluted tubules are all gone. With ordinary stains the glomeruli are apparently characteristic of amyloid disease but with the amyloid reaction they give a very feeble and not entirely characteristic stain. There is no amyloid in the follicles of the spleen, the commonest place, and none in the liver. On the other hand the adrenals are full of amyloid. The renal picture suggests that at some time in the past something has specifically knocked out the convoluted tubules. The findings seem to fit the assumption of a contracted kidney based on an old tubular nephritis, a diagnosis that was often made fifteen years ago but which has gone completely out of fashion now.

It should be remembered, moreover, that in amyloid nephrosis the tubules regularly show more or less severe lipid degeneration, a condition which might well be followed by atrophy. Fahr as a matter of fact, describes "amyloid Schrumpfneure" in which the shrinkage is due to tubular atrophy, and such a diagnosis is, I think, our best bet on this case.

This man did have some pathology in the gastrointestinal tract in the form of multiple polypoid projections which on section seem to be greatly dilated lymphatics in the small intestine. He had a terminal bronchopneumonia, a normal sized heart. The other organs were essentially negative.

COLLEGIATE PREMEDICAL EDUCATIONS

THE proposal of the Board of Registration in Medicine that the requirements for premedical education shall be raised from mere high school to include two years of collegiate work takes one back to 1918 when this requirement was generally adopted for approved medical schools. The previous formal step had been taken in 1914 when one year of college became the requirement.

It is interesting to note that although the evaluating bodies whose opinion is generally accepted have not raised their formal requirements since 1918, many medical schools require more than two years of premedical collegiate work for their own students and a very considerable number of candidates for medical school present four years of college credits and the baccalaureate degree. This raising of the in-

formal requirements so high above the formal, is due to the great demand for medical education, far greater than medical schools now in existence can supply.

The specific content of the two collegiate years is often not stated except that it shall include physics, chemistry, and biology. These subjects were formerly taught, in so far as they were taught, in the medical curriculum. At least as far back as 1893, they came to be formally, though not universally, relegated to the premedical schools. By 1922, the conviction had become so widespread, that the physician should have at least an acquaintance with these fundamental sciences, that Massachusetts became aware of the situation, and there were introduced into the list of statutory subjects for examination these three, physics, chemistry and biology. As a high school education became a requirement at the same time, a mere casual familiarity with science was deemed sufficient.

If one reviews the laws of the states, one finds that only eight have failed to make statutory provision for the two years of college. In six of the eight, however, the boards of registration have, under the statute and in the exercise of their discretion, refused to accept graduates of schools which do not have this requirement. Massachusetts stands almost alone in clinging to the low standards which, over forty years ago, nearly half a century, enlightened institutions outgrew.

With the progress of knowledge, the burden of knowledge and training on the medical student and the physician has become heavier, to such an extent that few, if any, are able to become well-qualified physicians without the formal education now generally required. The day has gone by, when anyone without formal training in physics, chemistry and biology can provide for himself an adequate foundation for his work in the medical school.

There is another consideration to which more explicit attention should be given. Why has medicine made such rapid progress in recent years? The reasons may be summarized briefly in the statement that the closer association of the university departments of these premedical sciences with the medical schools and the application of their ideas to medicine have resulted in a remarkable fertilization in both the preclinical sciences and in their application in practice. Indeed the result of the impact of science on the art of medicine in the past twenty-five years has been one of the remarkable phenomena of the twentieth century. It is now impossible to understand modern medicine without insight into the introductory and basic sciences.

Since this formal education in science is necessary and is so regarded by the State, Massachusetts should also require that it be more nearly adequate, that is, of collegiate grade.

CELSUS DE MEDICINA

Of the three great medical figures of the Classical Period—Hippocrates, Galen and Celsus—the least is known about the life of the latter. The author of a great medical treatise, which profoundly affected the practice of medicine throughout the ages and even down to our time, may not have been even a practitioner of the art. Quintilian states that he wrote on many other subjects than medicine and from this statement it has been inferred that Celsus was merely a general editor of an encyclopaedia, perhaps not even the author of *De Medicina*. Dr. W. G. Spencer, who has recently translated the first four books of *De Medicina** takes the view, based on a number of passages in his work that Celsus was "a learned and experienced medical practitioner" even allowing for the less sharp distinction drawn between the professional and amateur in his day. The book would "seem to indicate that he himself regularly attended patients, and wrote with the authority of a practising physician."

Whatever views we may hold about the authorship of *De Medicina*, all agree that the book has had great influence as a text of medical practice. A number of manuscripts exist testifying to its popularity before the days of printed books. Before 1600, moreover it was printed four times, the *editio princeps* at Florence in 1478. Three of these incunables are in the Boston Medical Library in the Bulfinch Collection. When printing became more common, edition after edition came off the presses forty-nine before 1841. The best translations before Spencer's, were those by James Greive in many issues, and by G. F. Collier. Required reading for applicants for license by the Royal College of Surgeons, many interlinear translations were printed in the eighteenth and nineteenth centuries in England. Scholarly comments on Celsus have been written by Daremberg, Marx and others, much of interest about the man, his book and his time will be found in Albinus's *Greek Medicine in Rome* and in Payne's article on Roman medicine in the *Cambridge Companion to Latin Studies*. Finally we have the readable translation by the London surgeon, W. G. Spencer, a worthy addition to that section of the medical historian's library of *Celsusiana*.

**Celsus De Medicina* with an English Translation by W. G. Spencer. In two volumes. Volume I. Loeb Classical Library. Cambridge, Mass. Harvard University Press, 1928. XIV 493 pages.

THIS WEEK'S ISSUE

CONTAINS articles by the following named authors

DEROW, HARRY A. M.B., M.D. Boston University School of Medicine 1927. Assistant Physician Beth Israel Hospital. Instructor in

Medicine, Harvard University Medical School. Address 475 Commonwealth Avenue, Boston. Associated with him is

ALTSCHULE, MARK D. B.S. M.D. Harvard University Medical School 1933. Assistant in Medicine, Harvard University Medical School. Resident in Medical Research, Beth Israel Hospital. Address 330 Brookline Avenue, Boston. Their subject is "Malignant Hypertension." Page 951.

SHELDON, WILLIAM M. A.B., M.D. Harvard University Medical School 1920. F.A.C.S. Assistant in Anatomy, Harvard University Medical School. Instructor in Surgery, Tufts College Medical School. Assistant Surgeon to Out-Patients, Massachusetts General Hospital. Chief of Tumor Clinic, Boston Dispensary. Address 270 Commonwealth Avenue, Boston. Associated with him is

CONTRACEPTION AND STERILITY

One of the striking things that appears in the study of sterility is the increase in its frequency which has occurred during the last decade or two. Statistics are unreliable at best but it seems fair to say that there has been an increase from 10 per cent to 15 per cent, or even 17 per cent. Such a change deserves careful study. Unfortunately the statistical sources of our information are so uncertain as to be practically worthless, but the impression which one gathers from talking with both members of many sterile couples may at least indicate the trends, if not the causes, of this phenomenon.

Of these sterile couples there is hardly a single one nowadays that has not employed some measure designed to prevent conception. Twenty years ago this was not the case though even at that time probably 50 per cent, or two-thirds of the couples, had done so. This immediately

raises the question whether the prolonged use of any contraceptive technique, no matter how carefully employed, may not, by denying the natural changes in the woman's pelvic organs which pregnancy initiates, produce a sort of functional sterility. It is my firm belief that it does. It is also my belief that the longer birth control has been practiced, the longer this period of functional sterility will last. This is a common experience with those couples who eventually do conceive without assistance. In most instances it is temporary but in some, where a minor catarrh develops in the cervical canal, where there is congestion from a retroversion, or where other such minor conditions arise, such a functional sterility becomes permanent unless treated. The great increase in numbers of women who, though menstruating regularly, rarely ovulate would seem to postulate hormone changes as possibly resulting from a denial of pregnancy while the sexual stimulation of marriage still persists. In other cases changes in the life of the woman from great activity in business to the relative ease of keeping house for two people, together with dietary indiscretions, predispose toward great changes in nutrition or metabolism, and thus often affects fertility. Then, too, there is the effect of time and business cares on male fertility. In many cases of which we have careful records male fertility has decreased to a dangerously low level under the stress and strain of modern business conditions in a relatively short time.

If we can accept these trends as following from prolonged use of birth control early in marriage, it would seem that we as physicians had a duty to broadcast this information. As far as one can judge from numerous conversations with young people who are about to become married there is practically speaking not a single couple, unless forbidden by religion, that does not contemplate postponement of having a family. Quite apart from whatever our attitude may be as to the morality of such a course, it would seem imperative for us to protest against the possible consequences of sterility and ill health which may, and often do, follow.

THIRD ANNUAL POSTGRADUATE MEDICAL EXTENSION COURSE

The following sessions have been arranged by the Committee for the week beginning November 17

Barnstable

Sunday, November 17, at 4 00 P.M., at the Cape Cod Hospital, Hyannis. Subject: Kidney and Bladder Diseases, A (Medical) Acute Nephritis — Etiology, Diagnosis and Treatment. Nephrosis and Its Treatment. Instructor L. B. Ellis J. I. B. Vail, Chairman.

*A series of short selected articles by members of the Section is being published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the Section.

Bristol South (Fall River Section)

Monday November 18 at 4 00 P.M. at the Stevens Clinic of the Union Hospital Fall River Subject Lung Diseases (a) Differential Diagnosis and Treatment of Lobar Pneumonia (b) The Surgical Problems of Empyema. Instructors Maxwell Finland and H F Newton. Eugene A. McCarthy Sub-Chairman

Essex North

Friday November 22 at 4 00 P.M., at the Hotel Bartlett, 95 Main Street, Haverhill. Subject Kidney and Bladder Diseases A (Surgical) Hematuria Its Significance in Surgical Diseases of Kidney and Bladder Instructor F H. Colby Francis W Anthony Chairman.

Essex South

Tuesday November 19 at 4 00 P.M., in the Nurses' Home of the Salem Hospital Salem Subject Diseases of the Liver Surgical Problems in Diagnosis of Acute Disease of Gall Bladder and Liver Instructors C M Jones and L S McKittrick Walter G Phippen, Chairman

Hampden

Thursday November 21 at 4 00 P.M. at the Academy of Medicine Professional Building 20 Maple Street, Springfield and at 8 00 P.M., at the Holyoke City Hospital, Holyoke. Subject Lung Diseases (a) Differential Diagnosis and Treatment of Lobar Pneumonia. (b) The Surgical Problems of Empyema Instructors R. H. Sweet and D S King George L. Schadt and George D Henderson Chairmen

Hampshire

Wednesday November 20 at 4 15 P.M., in the Nurses Home of the Cooley Dickinson Hospital Northampton Subject Pediatric Abdominal Disease in Childhood Medical and Surgical Aspects Instructors P H. Sylvester and T H. Lanman. Robert B. Brigham, Chairman.

Middlesex South

Tuesday November 19 at 4 15 P.M. at the Cambridge Hospital, Cambridge Subject Cancer of Breast and Uterus Sarcomas of Bone Lymphoma and Leukemia. Their Early Diagnosis Discussion of Life History of Cancer and Grades of Malignancy Instructors J V Meigs, C. E. Dumas and Dudley Merrill. Edmund H. Robbins Chairman.

Norfolk South

Monday November 18 at 8 30 P.M. at the Quincy City Hospital Quincy Subject Pediatrics The Neonatal State and Its Diseases Medical and Surgical Aspects Instructors J L. Morse and W E. Ladd. David L. Belding Chairmen.

Plymouth

Tuesday November 19 at 4 00 P.M., at the Brockton Hospital, Brockton Subject Arthritis (e) Medical Care of Patient in the Home (b) Orthopedic Treatment in Hospital and Aids in Home Treatment. Instructors R. T. Monroe and W T Green. W H. Pulsifer Chairman.

Worcester North

Friday November 22, at 4 30 P.M., at the Burbank Hospital Fitchburg Subject Psychiatry Management of Psychotic States in the Care of General Diseases Especially Chronic Disorders Subpsychotic States Instructors G O. Caner and Maurice Fremont Smith. Edward A. Adams Chairman.

MISCELLANY

MEDICAL HISTORICAL PAGEANT

A public performance of the fifth annual medical historical pageant presented by medical students of Tufts College Medical School under the direction of Dr Benjamin Spector will be given at the Boston Medical Library on Monday evening November 18 at eight o'clock.

The performance will be under the auspices of the Boston Medical History Club and a demonstration of manuscripts and books having to do with the characters in the play will be made by James F. Ballard Director of the Boston Medical Library

These pageants are unique in their method of preparation and presentation. The students write their own scripts after parts have been assigned to them by Dr Spector. The characters are costumed in the correct dress of the periods which they represent.

The current pageant has to do with the quotation "Story of Early Medicine in Massachusetts" which is divided into three epochs: the Colonial (1620-1700) the Pre-Revolutionary period (1700-1775) and the Post-Revolutionary period (1775-1846)

In the Colonial Period will be found the Indian Medicine Man, Deacon Samuel Fuller of Plymouth, the two Governors Winthrop and the Reverend Thomas Thatcher of Boston.

The Pre-Revolutionary Period is subdivided into Smallpox Inoculation Midwifery and Obstetrics and Apprenticeship in Medicine

The Post-Revolutionary Period is also subdivided into Cowpox Vaccination the Ether Demonstration, and Oliver Wendell Holmes and Puerperal Fever

All interested persons and their friends are cordially invited to attend the performance at the Boston Medical Library

A RESOLUTION ADOPTED BY THE MASSACHUSETTS MEDICO-LEGAL SOCIETY

Whereas The sale by druggists and dispensing by physicians of strychnine alone or incorporated with other drugs in laxative and tonic tablets with

chocolate or sugar coatings has resulted in many fatalities among children, innocent of their potency and attracted by the candied coatings, and

Whereas, The known therapeutic value of strychnine in no wise justifies such loss of life, suffering, and sorrow,

Be it, by the Massachusetts Medico Legal Society in regular meeting assembled

Resolved, 1 That it go on record as discountenancing the sale or dispensing of strychnine in any form which covers or conceals its taste or without being clearly labeled as to name, amount, in each dose, and the warning "poison" if dosage is exceeded, and treatment if excess is accidentally taken

2 That the copies of this resolution be published in *The New England Journal of Medicine* and that the Massachusetts Pharmaceutical Society and the Massachusetts Medical Society be invited to cooperate in preventing the sale or dispensing of this drug in concealed, dangerous form

HEALTH SURVEY*

MEMORANDUM FOR THE MASSACHUSETTS MEDICAL SOCIETY

Plans have been prepared for a survey of the extent of disabling illness and a study of public

health and medical facilities in nineteen States. The survey is to be conducted under the auspices of the United States Public Health Service as a project financed by the Works Progress Administration.

The survey follows closely the well-established policy of the Public Health Service and employs essentially the same methods which have long been used by the Service. It is, in fact, a continuation of activities which have been carried on from time to time over a period of nearly twenty years. Examples of these activities are

1. Surveys of State, city and county health departments at the request of State or local communities
2. Epidemiological studies. Frequently these studies have embraced a more detailed inquiry into economic, industrial, racial, and other influences affecting the spread of disease than that contemplated in the present study.
3. Numerous reports based upon physical examinations of school children and industrial workers to determine the extent of disease and physical impairment. These studies were limited to certain diseases and to certain groups of population and, therefore, only partially depict the true health situation.
4. Morbidity studies. These studies were first undertaken fifteen years ago and relate to selected groups of the population or to selected areas. In the first as well as the later studies local physicians cooperated fully with the Service in checking statements concerning the nature of illness reported to field enumerators by the families surveyed.

The foregoing activities are embodied for the most part in the larger and more comprehensive surveys now being made. Methods that have proved successful in the activities listed above have been adapted and refined for application to that part of the present study which has to do with the collecting of data on the prevalence and distribution of the chronic disabling illnesses among representative groups of the general population. Until now such data have been very meagre or wholly lacking.

The program has been prepared and revised following a conference held by the Surgeon General with Drs. Leland and Bauer of the American Medical Association.

The purpose of this memorandum is to acquaint the members of your Society with the objects of the survey and solicit their cooperation in the checking of statements concerning illnesses reported to our enumerators. The cooperation of the medical profession in the areas selected for study is vital to the successful conduct of the study and to the ultimate value of the material collected.

A typical schedule will be sent to the family physician with the request that he check the precise or provisional diagnosis. Physicians will receive

*Submitted by the Public Health Service

twenty five cents for each schedule properly filled out.

NOTE A copy of the schedule may be consulted in advance of its distribution at the office of Dr. Begg, 8 Fenway Boston Mass. It also appears in the *Journal of the American Medical Association*, October 5 1935

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR SEPTEMBER, 1935

Disease	Sept. 1935	Sept. 1934	5 Yr. Average*
Anterior Poliomyelitis	540	8	159
Chicken Pox	99	101	89
Diphtheria	10	37	95
Dog Bites	793	756	539
Epidemic Cerebrospinal Meningitis	7	5	9
German Measles	49	19	24
Gonorrhea	553	556	512
Lobar Pneumonia	105	90	87
Measles	51	43	88
Mumps	215	75	99
Scarlet Fever	218	273	305
Syphilis	463	284	331
Tuberculosis, Pulmonary	291	376	295
Tuberculosis, Other Forms	33	88	41
Typhoid Fever	14	22	29
Undulant Fever	3	1	
Whooping Cough	254	506	474

RARE DISEASES

Anterior poliomyelitis—540 cases (see weekly lists)

Dysentery (amebic) was reported from Fitchburg 1 Middleboro 1 total, 2

Dysentery (bacillary) was reported from Boston 5 Falmouth 1 Worcester 1 total, 7

Encephalitis lethargica was reported from Lynn 1 Uxbridge 1 total 2

Epidemic cerebrospinal meningitis was reported from Boston, 1 Cambridge, 1 Salem 1 Shrewsbury 1 Stockbridge, 1 Taunton 1 West Bridgewater 1 total 7

Malaria was reported from Chelsea, 1 Revere 1 total, 2

Pellagra was reported from Boston 2

Septic sore throat was reported from Boston 9 Lynn 1 Mansfield, 1 total 11

Tetanus was reported from Great Barrington 1 Medford 1 Salem 1 total 3

Trachoma was reported from Boston 2 Cambridge, 1 total 3

Trichinosis was reported from Arlington, 1 Boston 1 Falmouth 1 total 3

Undulant fever was reported from Auburn, 1 Clinton, 1 Worcester 1 total 3

Based on the figures for the preceding 5 years.

Infantile paralysis is now on the decline, having had a September peak.

Diphtheria with the lowest monthly figure ever reported is running 50 per cent lower than in 1934

Lobar pneumonia for the sixth month in a row was reported slightly over last year's figure.

German measles had a September morbidity somewhat over the five-year average. It may be that we are in for another year of increased incidence.

Mumps is running higher than in 1934

Measles, scarlet fever typhoid fever pulmonary tuberculosis tuberculosis other forms and whooping cough were all reported at a lower level than in 1934

Chicken pox and epidemic cerebrospinal meningitis were not remarkable

CORRESPONDENCE

ELECTROSURGICAL CHOLECYSTECTOMY

Editor, *New England Journal of Medicine*

In the October issue of your valued *Journal* (No. 14) there appeared an article by Dr. Lester R. Whitaker on "Electrosurgical Cholecystectomy" which discusses my operation. Accuracy demands that I correct certain statements in the article referred to and I hope these comments will be allotted space in your valued column.

Whitaker used a modification of Pribram's procedure in sixteen cases. His results disclose an operative mortality of 18.46 per cent, 31 per cent of infections, and above 50 per cent of bile leaks a decidedly worse record than is obtained from removing the gallbladder with the knife which shows about 2 per cent mortality in selected and a global mortality of 99 per cent in complicated cases.

In other words twice as many people succumbed at the hands of Whitaker as in the worst cases operated on by surgeons elsewhere. This statement is based on the exhaustive studies of 12,144 cases of Enderlien and Hots.

I regret to note that in his discussion of my operation (which, by the way I have performed to date on 148 consecutive unselected patients without a single fatality) Dr. Whitaker failed to grasp the rationale and principles underlying my procedure which are as follows:

1. An understanding of the differences between fulguration, carbonization and coagulation is a sine qua non.

2. The appreciation of the fact that drains are inimical to electrosurgically treated surfaces. This has been pointed out time and again by a number of observers (Kuntzen and Vogel and others) and corroborated by my own researches. Even Pribram whose method Whitaker used admonishes not to drain. I believe Whitaker's disregard for this fundamental rule is in a great measure responsible for his failures.

Electrocoagulated surfaces within the abdomen agglutinate with contiguous serous surfaces within about three hours after operation. If a drain is introduced, agglutination is frustrated and infection ensues. Electrocoagulated surfaces within the abdomen heal by encapsulation and absorption. Superimposition of the falciform ligament, as is practiced in my operation, helps in accomplishing this result.^{2, 3}

Experience contradicts Whitaker's conclusions on the behavior of electrocoagulated tissues.

3 Whitaker's observations are diametrically opposed to those of Baker on the question of postoperative biliary leakage.

4 Whitaker has apparently not read Schörcher's exhaustive studies on the "why" of the absence of shock in electrosurgical maneuvers.⁴

5 In discussing my operation Whitaker says, "Thorek depends upon the collapse and coagulation of the vessel walls to prevent postoperative hemorrhage. It is doubtful that with the cystic artery and its larger branches this would always be sufficient."

The coagulum is likely to loosen sooner than the tie. The fact is that I never coagulate the cystic artery but always ligate it. Again, the coagulum never loosens in undrained, properly performed operations but becomes absorbed.

6 Careful scrutiny of the sixteen cases recorded by Whitaker forces the conclusion that unless one is equipped with a thorough knowledge of the principles underlying electrosurgical methods he had better hold on to the time-honored cold scalpel in surgery of the gallbladder.

MAX THOREK, M.D., Professor of Surgery,
Cook County Graduate School
of Medicine, Chicago

A CRITICISM OF AN EDITORIAL ON "POLIO VACCINES"

Editor, *New England Journal of Medicine*,

The *Journal* of October 3 carries an editorial headed "Polio Vaccines." In referring to vaccines, it says, "Thousands of mothers beg for its trial, and the supply of vaccine is limited. Before we again let our eagerness confuse our reason, it may be well to consider some of the facts in the matter."

The editorial then proceeds to make statements that are incorrect and not in accord with the latest work done on "polio" vaccine. The information thus conveyed is incorrect, misleading and not up-to-date.

The editorial states, "If we remember their (Harvard Infantile Paralysis Commission) laboratory experiences correctly, it would seem that the infec-

tion of subinfective amounts of living virulent virus, repeated many times, failed to produce sufficient active immunity to protect a susceptible monkey against subsequent inoculation with a fatal dose of virus."

Flexner and Lewis in 1910¹ reported the successful vaccination of monkeys with subcutaneous and intracutaneous injections of living virus or mixtures of virus and immune serum.

In 1927, Aycock and Kagan² did a great deal of work on monkeys, with a virus attenuated with phenol, glycerine and drying. They found that about 25 per cent of the animals were protected, but in another 25 per cent infection developed from the vaccine. In 1933, Kolmer and Rule³ succeeded in vaccinating one monkey partially and two completely, out of a series of six monkeys by subcutaneous and intracutaneous injections of 2 per cent poliomyelitic cord in 10 per cent sodium ricinoleate. In 1934, Kolmer and Rule vaccinated 18 *Macacus rhesus* monkeys successfully against acute infantile paralysis with subcutaneous and intracutaneous injections of vaccine of living but attenuated virus. The vaccine was composed of 4 per cent suspensions of poliomyelitic monkey spinal cord in sterile 1 per cent solution of sodium ricinoleate.

These 18 monkeys were all immunized without the slightest ill effect and protected completely against infection following the intracerebral injection of about eighteen minimal infective doses of virus given under ether anesthesia about one month after the last dose of vaccine. The disease developed in the unvaccinated controls in from five to nine days after inoculation.

In 1934, Brodie⁴ showed by work on monkeys

- 1 A single subinfective intracutaneous inoculation of active poliomyelitis virus containing cord tissue gives rise to an immunity which appears at or soon after the sixth day and reaches its height by the twentieth day.
- 2 The immunity lasts a considerable time, being still present a year later.
- 3 Two doses of active cord tissue given at ten to twenty day intervals give rise to a higher degree of immunity than exists after mild or severe forms of the disease.

Both Kolmer and Brodie tried many methods of making a vaccine, safe for human beings, Brodie finally developing a vaccine from a formaldehyde treated monkey cord, Kolmer developing his from monkey cord using sodium ricinoleate as an attenuating agent.

The Brodie vaccine is a formaldehyde killed virus, the Kolmer, a living, attenuated virus.

After Kolmer had successfully vaccinated 18 monkeys and protected them against injections of virulent polio virus, without any ill effects whatsoever from the vaccine, he felt sure enough of his vaccine to start human work.

He proceeded to do this human work on himself and his co-worker, Anna Rule. First, he took some of his own serum, mixed it with living virus, and

after letting it stand for a time injected it into monkeys intracerebrally. He did the same with the serum of Anna Rule and for controls used salt solution plus the same polio virus. All of the animals developed polio. He then proceeded to vaccinate himself and his associates. Two weeks after the third dose, he performed the serum neutralization tests again. Monkeys were injected as before with his serum plus polio virus, another group with her serum plus polio virus and the control group with salt solution plus the polio virus. The Kolmer serum and the Rule serum absolutely protected their monkeys from any illness. The controls developed polio.

He had thus proved that the vaccine had developed in their blood some antiviral substance which protected the monkeys.

The work of both Kolmer and of Brodie has been carefully checked and controlled. I am referring more to the work of Kolmer because I am more familiar with it and have used his vaccine.

Kolmer next proceeded to administer the vaccine to 25 children. Both before and after the vaccination, serum neutralization tests were done to test for antiviral substance in the blood.

These serum neutralization tests were done by mixing 0.5 cc. of serum with 0.5 of 10 per cent suspension of virus. This mixture was allowed to stand about two hours in a water bath at 37° C. and then injected intracerebrally into monkeys under ether anesthesia. For controls 0.5 cc. of sterile saline was used with 0.5 cc. of virus let stand in the water bath and used in the same manner.

There were no ill effects from the vaccine except slight fever in some of the children 100.2 the highest, and a few slightly sore arms.

Of fifteen children showing no antibody before vaccination 75 per cent showed sufficient antibody following vaccination to protect the monkey. Serum of the ten children showing the presence of antiviral substance in their blood before vaccination showed much more after vaccination as their serum now protected the monkeys against an intracerebral injection of 50 per cent suspension of virus.

The serum neutralization test on monkeys' has so far proved the only test of value in determining whether the blood of the individual contains antibodies. Serum colloidal gold, complement fixation precipitation' and skin tests' have been shown to be without value.

"The question of fundamental importance," says Kolmer, "is whether antibody in the blood of human beings for monkey passage virus is protective against human virus."

About 30 per cent of 1.6 cases of persons recovering from polio showed no antibody in their sera by monkey virus tests. This report is from the added results of eight different observers and suggests that immunity to the disease can be present without demonstrable amounts of antibody in the blood.

Kolmer states "These results indicate that possi-

bility that antibody in the blood of human beings for monkey passage virus may not protect against human virus and if such should subsequently be proved it would render the present serum neutralization test worthless as an index or measure of resistance to poliomyelitis among human beings."

However Kolmer has found that antibody developed in children by three doses of Kolmer vaccine has completely neutralized a human virus from the 1934 California epidemic.

The editorial proceeds to call attention to a question of simple arithmetic and gives an equation involving monkeys. Mathematics is an exact science but this mathematical problem is based on a false premise.

To quote the editorial "Since for the production of vaccine by present methods one monkey furnishes at the most, sufficient vaccine for ten injections then each single injection would require one-tenth monkey."

Kolmer hoped to be able to prepare vaccine from brain tissue so that a greater amount would be available but experiments showed that virus was absent or in insufficient amounts in brain tissue of monkeys dying of polio so that the source of supply is limited to monkey spinal cord.

However Kolmer states' that the spinal cord of one monkey furnishes about 150 cc. of vaccine which is sufficient for the immunization of from forty to seventy-five children depending on age and dosage. As three doses are required for each immunization, each single injection would require from one one-hundred-and-twentieth to one-two-hundred-and-twenty-fifth monkey instead of one-tenth.

Of course it would be impossible to do monkey neutralization tests on all cases before and after vaccinations. It is practical however to do such tests on a percentage of the whole group vaccinated and thus the results could be roughly figured out.

Kolmer's work indicates that the majority of children under ten years of age are devoid of antiviral antibody and probably susceptible.

Because of the fact that polio is a disease that hits only a small percentage of the population and because the disease rarely hits any locality in the same degree two successive years it will take a long time to prove positively the value of any preventive measure.

So far there is no knowledge of anyone carrying antibody in the blood, as shown by serum neutralization tests developing infantile paralysis but as yet only 318 sera have been reported on. On the other hand polio has occurred in individuals known to have an antibody in the blood prior to the disease and Kolmer has had one such case.

There is no doubt that all physicians are reluctant to inject a living though attenuated virus into human beings. In a letter dated September 3 Kolmer states that he and his associates have vaccinated over 6,000 cases—only mild reactions developed or none at all. Immunity develops very rapidly in at least 90 per cent.

My own experience is limited to twenty cases. No monkey neutralization tests were done and therefore the cases are of little value. However, it is of interest to note that not one of the cases showed the least constitutional reaction and the local reaction was so slight as to be unimportant.

The editorial ends, "But we hope that our eagerness will be tempered with reason and that any trial of any preventive or curative agent will be conducted with full and rigid controls, so that we may be spared the disappointment that has too often followed some of our earlier attempts."

I should like to point out that the work of both Kolmer and Brodie¹⁰ has been carefully done and controlled so far as humanly possible.

It is best that we move forward rapidly in an endeavor to prove or disprove the value of the vaccine. It is true that we want to be spared the disappointment if it should fail, but it would be better to risk that disappointment than to proceed too slowly and cautiously, and later awake to find that we have been delaying in the use of a valuable preventive measure.

It would seem logical to select two adjacent primary schools, in several of our cities where epidemiological studies suggest that an infantile paralysis epidemic may occur next year. In the spring vaccinate the children in one school, use the other as a control. School has always adjourned for the summer before the disease becomes prevalent, and the children in adjoining districts would be in contact with each other during the summer. In this manner, the practical value of the vaccine could be determined in the shortest period.

EDITORIAL NOTE The editorial on "polio" vaccines which appeared in the *Journal* of October 3, 1935, asks that the eagerness with which we grasp at any proffered solution of the poliomyelitis problem be tempered with reason. The writer of this editorial feels that merely recommending the trial of a vaccine (even though no assurance of efficacy be given) will be seized upon as a "cure" in view of the recurring surges of alarm. He would have wished for a more convincing demonstration of the efficacy and safety of the vaccine in the experimental animal

before it was released for human use, and rightly goes on to point out some of the statistical difficulties in arriving at a prompt answer to the question of the efficacy of the vaccine.

Dr. Casey, on the other hand, in his criticism of the editorial, seems to accept the experimental evidence proffered by the proponents of the vaccine as sufficient justification for its human use, urging that we move forward rapidly in testing it out on children. Unfortunately, the scheme which he proposes to accomplish this—testing out the vaccine in communities shortly to be visited by infantile paralysis—would not be easy of fulfillment.

His own experience with twenty individuals, none of whom showed any general or local reaction to the vaccine, has little bearing on the main question involved, namely, whether the vaccine is a practicable means of preventing infantile paralysis.

IS LYMPHOCYTIC MENINGITIS SYMPTOMATIC OF A SYSTEMIC DISEASE?

October 25, 1935

Editor, *New England Journal of Medicine*,

Your editorial entitled "Acute Lymphocytic Meningitis" which appeared in the *Journal*, September 19, 1935, is of considerable importance and the subject is of particular interest to me.

In 1929 when Viets and Watts¹ first reported the syndrome of "acute aseptic meningitis," I was fortunate enough to follow very closely a case with many similar characteristics at the Boston Psychopathic Hospital. This patient showing cerebral symptoms of an organic nature was found to have the typical signs and the blood picture of infectious mononucleosis commonly known as "acute glandular fever," originally described by Longcope² in 1922. Because of the uniqueness of the condition this case was reported in detail and published by Dameshek and myself³ in the *Journal* in 1931 under the title of "Involvement of the Central Nervous System in a Case of Glandular Fever." Reference was made in that article to the earlier communication of Viets and Watts regarding acute lymphocytic meningitis and it was stated that "it is possible that the increase of lymphocytes in the spinal fluid (in such cases) may be associated with a lymphocytosis in the blood although as yet this has not been demonstrated." It was further stated that "the concept of an aseptic meningitis is at best a vague one and almost as all inclusive as the term encephalitis." The concept was emphasized in that article that these conditions were symptomatic of some systemic disease and the suggestion was made that acute lymphocytic meningitis and infectious mononucleosis might be one and the same disease.

During the past few years a number of reports have appeared in the literature concerning the occurrence of this syndrome, variously called aseptic, idiopathic, epidemic and acute lymphocytic meningitis. So far as I am aware there have been no detailed blood studies in such cases and, therefore, it cannot be denied that there may be an etiological

relationship between acute lymphocytic meningitis and infectious mononucleosis. At the same time typical cases of the latter disease have been seen not infrequently and among these there have been no observations on the spinal fluid.

Considerable interest in the subject has developed recently as the result of some experimental investigations on the etiology of acute lymphocytic meningitis. The work of Armstrong¹ of the United States Public Health Service and of Rivers and Scott² of the Rockefeller Institute indicates that a filtrable virus is the causative agent of this disease tending to show that the disease is a clinical entity.

It seems to me that the crux of the whole problem lies in the larger concept of various systemic diseases of known and unknown causes, giving rise to changes in the central nervous system. I am inclined to believe that such diseases as infectious mononucleosis still of unknown etiology may produce cerebral changes and conversely so-called acute lymphocytic meningitis like certain of the encephalides is merely symptomatic of some as yet unknown systemic disease.

Very truly yours

SAMUEL H. EUSTICE, M.D.

ARTICLES ACCEPTED BY THE AMERICAN MEDICAL ASSOCIATION COUNCIL ON PHARMACY AND CHEMISTRY

Editor *New England Journal of Medicine*,

In addition to the articles enumerated in our letter of September 5 the following have been accepted

Abbott Laboratories

Procaine Hydrochloride — Abbott Tablets 1.14 grains (0.07 Gm.)

Procaine Hydrochloride — Abbott Tablets 3.28 grains (0.15 Gm.)

Ampoules Bismuth Subsalicylate with Butyn—D. R. L. 1 cc.

Robert A. Bernhard

Saf-T-Top 5% Ferrous Chloride in 50% Glycerine 2 cc. and 15 cc.

Saf-T-Top Isopropyl Alcohol, 98% 2 cc. and 15 cc.

Saf-T-Top Mercurochrome 2 per cent Solution 15 cc.

Saf-T-Top Mercurochrome 2 per cent in 25 per cent Glycerine 2 cc. and 15 cc.

Saf-T-Top Tincture Metaphen, 2 cc. and 15 cc.

Lee Laboratories

Rabies Vaccine Simple Method (Lee)

Lederle Laboratories, Inc.

Scarlet Fever Streptococcus Antitoxin, "Globulin-Lederle-Modified"

Refined Diphtheria Toxoid (Alum Precipitated) — Lederle 0.5 cc. vial packages

Wm. S. Merrell Co.

Vioosterol in Oil—Merrell Spertol Process

Ampules Dithane 0.5% in Solution of Sodium Chloride 0.5% 6 cc.

Winthrop Chemical Co., Inc.

Salvarsan 1.2 Gm. tubes

The following products have been accepted by the Council for inclusion in the List of Articles and Brands Accepted by the Council But Not Described in N. N. R. (New and Nonofficial Remedies 1935 p. 445)

Robert A. Bernhard

Saf-T-Top Tincture Iodine, USP 2 cc. and 15 cc.

Saf-T-Top Tincture Iodine U. S. P., 3½% 2 cc. and 15 cc.

Yours sincerely

PAUL NICHOLAS LAFON, Secretary

Council on Pharmacy and Chemistry

RECENT DEATHS

TUCKER—WILLIS LEROY TUCKER, M.D., of Hinsdale, Massachusetts, died at his home November 7, 1935. He was born in 1872, graduated from the University of Illinois College of Medicine in 1898 and had practiced in Hinsdale for many years.

He served in the World War and had been a member of the board of selectmen and of the school committee in Hinsdale.

ANDREWS—FREDMAN W. ANDREWS, M.D., of 50 Poterboro Street, Boston, died at the Forest Hills Hospital, November 8, 1935.

He was born in Boston the son of Clifford F. and Addie (Appleton) Andrews in 1896.

He first qualified as an osteopathic practitioner and is recorded as a physician in the Directory of the American Medical Association but without a record of having an M.D. degree.

He served as official physician to the Back Bay Police Station. He is survived by his widow Mrs. Audrey H. Andrews and a daughter.

OBITUARY

RESOLUTIONS IN COMMEMORATION OF DR. WALTER A. POLLANO

ADOPTED AT THE NINETY-FOURTH QUARTERLY MEETING
OF THE ESSEX NORTH DISTRICT MEDICAL SOCIETY

Whereas Dr. Walter A. Pollano died suddenly on June 25, 1935, at his home at 233 Haverhill Street, Lawrence, Mass., from a heart attack.

Dr. Pollano was born in Sessa Aurunca, Italy, on April 6, 1879, and he came to Lawrence when he was twenty-one years old. He was educated in Italy

where he attended the University of Naples. In 1915 he became a registered pharmacist and from that time was actively interested in one of the Lawrence drug stores. He later studied medicine and received his degree of M.D. from the Middlesex College of Medicine and Surgery in 1922. He served his internship at the Lying-In Hospital in New York. Dr. Pollano was affiliated with the American Medical Association, and the Massachusetts Medical Society becoming a member in 1928. He was also an active member of the Greater Lawrence Medical Association.

Whereas, in the death of Dr. Walter A. Pollano, the Massachusetts Medical Society has lost an honored and efficient member, and one held in high esteem and,

Whereas, we keenly feel our loss, and we desire to express some appreciation of his high qualities, his loyalty to his profession, and his friends and,

Whereas, we desire to express our heartfelt sympathy to his widow and his two small children,

Therefore, be it resolved that this resolution be entered upon the records of the Society, and that copies be sent to his widow, and to *The New England Journal of Medicine*

Signed

N. F. DeCesare, M.D.

N. J. Scarito, M.D.

JOSEPH A. SINOLITICO, M.D.

NOTICES

BOSTON UNIVERSITY SCHOOL OF MEDICINE SURGICAL CLINIC AT THE BOSTON CITY HOSPITAL

Friday, November 15, 12-1, Cheever amphitheatre

Dr. William R. Morrison, Associate Professor of Surgery, Boston University School of Medicine, will present the following cases:

1. Intestinal obstruction, with ileostomy
2. Fracture of both bones of forearm
3. Hypertrophied prostate with multiple urinary calculi

Physicians and medical students are invited

THE EDWARD K. DUNHAM LECTURESHIP

In 1923 there was founded in memory of Doctor Edward K. Dunham (M.D., Harvard, 1886), the Edward K. Dunham Lectureship for the Promotion of the Medical Sciences. Among the useful purposes for which the Foundation was established was that of binding closer "the bonds of fellowship and understanding between students and investigators in this and foreign countries." The lecturers are chosen from "eminent investigators and teachers in one of the branches of the Medical Sciences, or of the basic Sciences which contribute toward the advance of Medical Science in the broadest sense." The lectures, which are given annually, are "free and open to the faculty and students of the Harvard Medical School and College, and all other interested professional persons who may profit by them."

The Faculty of Medicine of Harvard University has issued invitations to attend three lectures to be given under the Edward K. Dunham Lectureship for the Promotion of the Medical Sciences on "Recent Studies on the Functions of the Hypophysis."

Friday, November 22, "What We Have Learned from the Toad Concerning Hypophyseal Functions"

Monday, November 25, "Metabolic Functions of the Hypophysis"

Wednesday, November 27, "The Hypophysis and Diabetes"

At five o'clock at the Harvard Medical School Amphitheater, Building C, by Bernard A. Housay, M.D., Professor of Physiology and Director of the Institute of Physiology, University of Buenos Aires

MEDICAL CLINIC AND STAFF ROUNDS AT THE PETER BENT BRIGHAM HOSPITAL

At 3:30 P.M. on Thursday, November 21, in the amphitheater of the Peter Bent Brigham Hospital, Dr. Henry A. Christian, Physician in Chief, Hersey Professor of the Theory and Practice of Physic in the Harvard Medical School, will give a medical clinic. To it are cordially invited practitioners and medical students.

On Saturdays in the wards of the Peter Bent Brigham Hospital, from 10 to 12, staff rounds will be conducted by Dr. Christian.

UNITED STATES CIVIL SERVICE EXAMINATIONS

The United States Civil Service Commission has announced open competitive examination as follows:

Public Health Consultants

Applications for various grades of public health consultants, and for public health research assistant, must be on file with the U. S. Civil Service Commission, Washington, D.C., not later than November 25, 1935.

Optional subjects for the consultant positions are maternal and child health, general public health practice, and orthopedics. The specialty for the research assistant is maternal and child health.

Vacancies in these positions in the Children's Bureau, Department of Labor, and in the U. S. Public Health Service, Treasury Department, both in Washington, D.C., and in the field, will be filled from these examinations.

Social Economists

Applications for various grades of social economist positions, Children's Bureau, Department of Labor, must be on file with the U. S. Civil Service Commission, Washington, D.C., not later than November 18, 1935.

Optional subjects are Child welfare administration, social service for physically handicapped children, research and demonstration in the prevention and treatment of juvenile delinquency, and research in problems of child dependency and neglect, or social provision for crippled children. Certain education and experience are required.

Full information may be obtained from the Secretary of the United States Civil Service Board of Examiners at the post office or customhouse in any city which has a post office of the first or the second class or from the United States Civil Service Commission Washington D. C.

REPORTS AND NOTICES OF MEETINGS

WORCESTER NORTH DISTRICT MEDICAL SOCIETY

The Worcester North District Medical Society held the most largely attended and most enthusiastic meeting in its history at the State Colony in Gardner Wednesday October 23. The Society was signally honored by the presence of Dr. Charles E. Mongan, President of the Massachusetts Medical Society. Dr. Alexander S. Begg, Secretary of the Massachusetts Medical Society. Dr. William Morrison, Chairman of the Committee of Arrangements for the next annual meeting of the Society, and Dr. M. A. Tighe, Chairman of the Committee on Social Legislation and Insurance, a subcommittee of the Public Relations Committee of the Massachusetts Medical Society. There were about one hundred and forty present. Dr. George P. Norton, President of the Worcester North Society, introduced the speakers and referred to the great honor conferred on the Society by the distinguished guests.

Dr. Mongan showed an intimate knowledge of the history of the local society and recalled that the late Dr. Alfred O. Hitchcock of this city had been President of the state society in 1869 and that Dr. F. H. Thompson Sr., of this city had been a vice-president. He paid a fine tribute to the efforts of the late Dr. Alfred H. Quesey in defeating the Sheppard-Towner bill.

Dr. Mongan said that the state society needs the help of all medical men. The doctor must become politically minded, he said. He no longer can refuse to do his share in great movements many of which cannot be successfully worked out without the cooperation of the physicians.

He argued that conditions in Massachusetts are different from those in many other states and we should work out our own problems.

"The idealist wants to abolish poverty but it can not be accomplished," he said. "Those who would attempt to carry out their plans along these lines forget that the spirit of America is based on manhood and the acceptance of opportunities. The first movement came from Europe and from Oriental countries where all reliance is placed in the head of the country thereby stifling initiative."

"But even in this country the morale has broken down to some extent and persons who a few years ago would spurn government aid now consider it as one of their rights. England has a fine sense of propriety and the English are willing to give for their country. The medical men can do much to

check the present tendency of affairs for they go from home to home, are asked advice and frequently give it.

He asked the members to go to their state representatives or congressmen to prevent bad legislation.

"There is no need of compulsory health insurance in this state, for the doctors have always given the highest type of service. There is a difference between public health and private health. Compulsory health insurance means that everyone with a salary of \$3000 per year or less must have health insurance, the employer and employee each to pay 40 per cent and the state 20 per cent of the cost."

He called for concerted action by the public to defeat the enforcement of the provisions of the compulsory health insurance act.

Dr. Tighe said that the two influences aiding the passage of the compulsory health act were the report of a committee of four appointed by the administration, no one of which committee was a doctor, and the depression.

"This letter was duck-soup for the idealists," he said. It was what they were waiting for. As a result, President Roosevelt appointed a national security committee whose task was to cure all the social evils. Since no doctors were on this committee the secretary of labor, Miss Perkins, appointed her own group, three of whom were doctors but they are slack of their jobs already.

The delegates of the American Medical Association oppose this feature. The Councilors of the Massachusetts Medical Society have joined them in their opposition and the Public Relations Committee has set out on a program of publicity and education of the people to mould public opinion against this iniquitous bill."

Dr. Alexander S. Begg, Secretary of the State Medical Society, gave a brief talk, congratulating the members on the splendid attendance, despite the heavy rainfall.

Dr. Morrison, Chairman of the Committee of Arrangements of the next Annual Meeting of the State Society to be held in Springfield, June 8, 9 and 10, gave a résumé of the plans.

Dr. Thomas R. Donovan, Supervisor of the Board of Censors, announced that the next meeting of the Censors would be held at the Burbank Hospital Thursday November 7 at 4 P.M.

Dr. Edward A. Adams told of the courses given in postgraduate instruction in the district. A motion by Dr. Walter F. Sawyer was passed whereby the cancer clinics of the district will be operated separately.

A splendid buffet lunch was served and a vote of thanks given to the speakers.

FRANCIS W. McMURRAY, M.D., Secretary

MASSACHUSETTS PSYCHIATRIC SOCIETY

The eleventh annual meeting of the Massachusetts Psychiatric Society was held on October 29, 1935 at the Parker House, Boston.

The following officers were elected for the coming year

President, Dr Charles E Thompson.

Vice President, Dr Oscar J Raeder

Secretary Treasurer, Dr W Franklin Wood

Councillors, Dr C Macfie Campbell, Dr Joseph E Barrett.

A large attendance listened with keen interest to Dr George Sarton's illuminating address on "Genius" He showed in the development of his subject the necessity of discounting the psychopathic tendencies in the various types of genius He emphasized the point that the now popular type of "de bunking" biography often lays too much stress on these psychopathic traits and does not sufficiently feature the extraordinary talent of the particular genius, for which alone he is interesting He said that all the traits of such a great man can be imitated except his genius—that is peculiarly his own

OSCAR J RAEDER, M D, *Secretary-Treasurer*

ESSEX SOUTH DISTRICT MEDICAL SOCIETY

A stated meeting of Essex South District Medical Society was held at the Beverly Hospital, November 6, 1935

An interesting and instructive clinic was held at 5 P M, followed by a dinner at 7 P M The guest speakers, at the evening meeting, were Dr Charles E Mongan, President of the Massachusetts Medical Society, Dr Michael A Tighe, Chairman of the Committee on Social Legislation and Insurance, a subcommittee of the Public Relations Committee of the Massachusetts Medical Society and Dr Alexander S Begg, Secretary of the Massachusetts Medical Society

Dr Mongan reminded the members of their splendid professional heritage and of their consequent responsibility for good influence in the community and interest in the community welfare His appeal was for careful appraisal of so-called "economic security", supporting the good in it and preventing the bad

He also appealed for the profession, as a whole, to become professionally and politically conscious for the benefit of the country

Dr Tighe, of Lowell, Mass, reviewed briefly the history of "Compulsory Sickness Insurance" in England and Germany

Citing the vote of the American Medical Association to disapprove all Compulsory Sickness Insurance and the approval of this stand by the Massachusetts Medical Society, he called especial attention to the fact that the Massachusetts Medical Society had initiated a campaign of public education concerning Compulsory Sickness Insurance

He expressed his absolute faith in public opinion when rightly informed and was confident that a high degree of interest in public good existed among the laity and that the press could always be relied upon correctly to interpret this interest, without political bias

Dr Begg complimented the Staff of the Beverly Hospital for the valuable clinic presented to the medical society and graciously offered the facilities of his office in any way that might benefit any district society NATHANIEL POPE BREED, M.D., *Reporter*

HAMPDEN DISTRICT MEDICAL SOCIETY

From eighty to ninety members and guests attended a meeting of the Hampden District Medical Society held at the Academy of Medicine, Springfield, October 29, 1935 The President, Dr Theodore S Bacon, presided

The paper for the afternoon was on "Recent Advances in Medicine", by Dr Reginald Fitz, of Boston

Dr Fitz touched rather briefly on the question of State Medicine, its possibilities and its disadvantages He praised the high degree of efficiency attained by organized medicine in the American Expeditionary Forces in the World War He cited diseases formerly considered rather hopeless in which recent advances have radically changed our attitude, e g, arthritis, hypertension, especially of the functional type, and certain formerly obscure endocrine disturbances, also the anemias and cardiovascular renal disease He mentioned dietetics as a field in which marked advances had been made through careful observation and experimental work He is of the opinion that the state of adolescence will yield a rich return if carefully studied It is here that the apparent results of endocrine therapy may be misleading Methods recently introduced for the clinical study of the peripheral circulation and of the blood and blood forming organs in the anemias were mentioned and the present status of classification of the anemias, which fall roughly into well defined groups and a borderline one, more or less composite Some recent surgical methods developed in the treatment of conditions formerly regarded as entirely medical were referred to and the work of the Mayo and Lahey Clinics and of a surgical group in Michigan Dr Fitz believes that at no time has the medical profession been more alive and forward looking than at present

After a standing vote of thanks to Dr Fitz the meeting adjourned and a buffet supper was served

ANDREW PETERS, M D, *Reporter*

CLOVER HILL HOSPITAL

Lawrence, Mass

The next medical meeting of the Clover Hill Hospital will be held in the reception room of the hospital at 161 Berkeley Street, Lawrence, on Thursday afternoon, November 21, 1935, at 4 30 P M

Speaker George R Minot, M D, Professor of Medicine at Harvard University

Subject "The Etiology, Diagnosis and Treatment of Nutritional Deficiency Anemias"

The lecture will be illustrated with lantern slides Discussion will follow A clinical exhibition arranged by Lawrence physicians may be seen following the lecture All physicians of Lawrence and vicinity are cordially invited to attend

EDWARD MAOK SMITH, M D, *Chairman*

THE BOSTON HEALTH LEAGUE AND THE MASSACHUSETTS CENTRAL HEALTH COUNCIL

A Luncheon Meeting of the Boston Health League and the Massachusetts Central Health Council will be held at The Parker House Boston on Thursday November 21 1935 at 12 30 P.M.

Dr Carl Buck Field Director of the American Public Health Association will speak on 'New Horizons in Public Health Work'

NEW ENGLAND PHYSICAL THERAPY SOCIETY

The New England Physical Therapy Society will meet at 8 P.M. on Wednesday November 20 at the Hotel Kenmore 490 Commonwealth Avenue, Boston.

PROGRAM

Treatment of Prostate Pathology George C Pratner M.D., Boston George E. Percy M.D. Salem

Opening comments by DeWitt G. Wilcox M.D., Newton, and William D. McFee M.D., Boston followed by general discussion

Special dinner arrangements have been made for a table in the Empire Room of the Kenmore at 8 30 P.M. Members and guests are urged to take advantage of this social hour

The council will meet at 6 P.M.

All members of the medical profession are cordially invited to attend

WILLIAM D. McFEE, M.D., Secretary

41 Bay State Road
Boston Mass

NEW ENGLAND HEART ASSOCIATION

Boston City Hospital

Amphitheatre of the Mallory Institute of Pathology (Entrance at 784 Massachusetts Avenue)

Monday November 25 at 8 15 P.M.

PROGRAM

- 1 Demonstration of Pathological Specimens
- 2 Amyloid Heart. Dr G. Kenneth Mallory
- 3 The Mechanism and Treatment of Postural Hypertension. Dr L. B. Ellis and Dr Florence Haynes
- 4 The Significance of Precordial Leads in Cardiac Infarction — Clinical Pathological Correlation. Dr James M. Faulkner
- 5 Recent Observations on the Functional Properties of the Vascular System and on the Hemodynamics in Arterial Hypertension. Dr Soma Weiss
- 6 The Nature of the Peripheral Resistance in Arterial Hypertension with Special Reference to the Vasomotor System. Dr Myron Prinzmetal and Dr Clifford Wilson.
- 7 The Electrocardiogram in Bacterial Endocarditis as Contrasted with Rheumatic Carditis. Dr Maurice S. Segal.
8. The Significance of Differential Venous Pressure Measurements. Dr Eugenio B. Ferris, Jr. Presented by Dr Robert W. Wilkins

- 9 Malignant Hypertension of the Pulmonary Circuit (?) Dr Frederic Parker Jr., and Dr Soma Weiss

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held in the Peter Bent Brigham Hospital Amphitheatre (Shattuck Street Entrance) Tuesday evening November 26 at 8 15 P.M.

PROGRAM

Presentation of Cases.

The Mechanism and Effects of Abdominal Compression in the Treatment of Pulmonary Tuberculosis. By Dr Burgess Gordon, Associate Professor of Medicine Jefferson Medical College

Medical students and physicians are cordially invited to attend.

MARSHALL N. FULTON, M.D., Secretary

CARNEY HOSPITAL

CLINICAL MEETING

A Clinical Meeting of the Carney Hospital will be held at 8 30 P.M. on Monday November 18

PROGRAM

Blood Transfusion By Dr Lewis S. Plicher (Lantern Slides)

The Routine Management of Diabetic Patients By Dr C. W. Finnerty

Physicians and medical students are invited.

SOCIETY MEETINGS CONGRESSES AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING MONDAY NOVEMBER 18, 1935

Monday November 18—

- 9 10 A.M. Boston Dispensary, 25 Bennett Street, Boston. Blood Clinic. Dr William Dameshek
8 P.M. Medical Historical Pageant. Boston Medical Library, 18 Fenway
8 30 P.M. Carney Hospital Clinical Meeting

Tuesday November 19—

- 9 10 A.M. Boston Dispensary 25 Bennett Street, Boston. Back Strain—Sciatica. Dr F. R. Ober
13 Noon South End Medical Club office of the Boston Tuberculosis Association 554 Columbus Avenue Boston
2 30 P.M. Pediatric Ward Visit. Massachusetts Eye and Ear Infirmary
7 45 P.M. Gardner Auditorium State House, Boston. "The Child and the Modern World." Lawson G. Lowrey, M.D.

Wednesday November 20—

- 9 10 A.M. Boston Dispensary 25 Bennett Street, Boston. Ward Cases. Dr B. J. Thannhauser
11 30 A.M. Clinico-Pathological Conference. Children's Hospital
1 P.M. Massachusetts Society for Mental Hygiene Twentieth Century Club Boston
8 P.M. New England Physical Therapy Society Hotel Kenmore, Boston

Thursday November 21—

- 8 30 9 30 A.M. Clinic Surgical Staff of the Peter Bent Brigham Hospital, at the Peter Bent Brigham Hospital
9 10 A.M. Boston Dispensary, 25 Bennett Street, Boston. "Interviewing a Patient." Professor Edson Mayo.

12 30 P M The Boston Health League and the Massachusetts Central Health Council. The Parker House, Boston.

*3 30 P M. Medical Clinic at the Peter Bent Brigham Hospital

5 P M. Lecture on "The Care of the Patient," Harvard Medical School, Amphitheatre C

Friday, November 22—

*9-10 A.M. Boston Dispensary, 25 Bennet Street, Boston Ward Cases Dr S J Thannhauser

12 M Clinical Meeting of the Children's Medical Staff. Ether Dome, Massachusetts General Hospital

5 P M. The Edward K. Dunham Lectures Harvard Medical School Amphitheatre, Building C

Saturday, November 23—

*9-10 A.M. Boston Dispensary, 25 Bennet Street, Boston. Liver Disease (Continued.) Dr S J Thannhauser

*10-12 Staff rounds at the Peter Bent Brigham Hospital.

*Open to the medical profession

†Open to Fellows of the Massachusetts Medical Society

BOOK REVIEW

New and Supplementary Facts and Figures About Tuberculosis Jessamine S Whitney 46 pp New York National Tuberculosis Association \$50

This pamphlet, published in June, 1935, by the National Tuberculosis Association, is complementary to an earlier compilation of facts and figures about tuberculosis issued in 1931. It consists of forty-nine elaborate tables including a group of tables of great importance on tuberculous infection.

To those who are investigating and writing on the mortality and morbidity of tuberculosis and who need statistical information of any kind whatsoever on this subject, this booklet will prove a veritable mine of useful, accurate and up-to-date information

TORSION OF THE APPENDIX TESTIS* (HYDATID OF MORGAGNI)

Report of Two Cases

BY JOHN B. RHODES, M.D.†

TORSION of the appendix testis is so rare that the condition is seldom thought of in the differential diagnosis of lesions of the scrotum. No description of the condition can be found in textbooks on Urology with the exception of Hinman's recently published book.¹ The signs and symptoms are very similar to those seen in other acute diseases of the scrotum.

The first case report of torsion of the appendix testis was recorded by Colt² who in 1922 described a case seen in the Royal Infirmary at Aberdeen, Scotland in August 1921. Albert Mouchet³, a Frenchman, is credited with the first detailed pathological description of this condition and in 1928 he reported three personal cases. Dix⁴ in a review of the literature in 1931, collected forty seven cases. To date only two cases have been recorded in the North American literature, both from the Boston Children's Hospital by Foshee⁵ in 1932. Since September 1934 two cases have been seen at the Massachusetts General Hospital.

The appendix testis is a remnant of the cephalic end of the Mullerian duct. It is a pea sized structure, usually sessile but occasionally pedunculated, located near the upper pole of the testicle and is present in the majority of individuals. Normally, it is cystic, containing transparent liquid and is lined with cylindrical epithelium.⁶

REPORT OF CASES

CASE 1. O. Z., a thirty nine year old Greek poultry raiser, came to the hospital September 17, 1934 with the story that four weeks before entry he had been "kicked in the scrotum by a pet rooster." He immediately had severe pain in the left side of the scrotum accompanied by dizziness and nausea and found it necessary to lie on the ground for a few min-

utes. Throbbing pain in the left testicle kept him awake that night but was less severe on the following day. At this time the patient noticed swelling of the left part of the scrotum. His doctor advised rest in bed and ice packs to the scrotum. The pain gradually subsided but the swelling persisted and the patient was referred to the hospital. There were no urinary symptoms.

On examination the left side of the scrotum was enlarged four to five times its normal size. It was tense smooth and did not transmit light. The testicle and epididymis could not be distinguished. There was very slight tenderness. The urine was negative and the temperature was normal.

Hematocele was thought to be the most likely diagnosis. Operation was done under spinal anesthesia. The scrotum was incised and the tunica vaginalis was freed and delivered. When opened three to four ounces of dark blood and blood clot escaped. A round mass the size of an English walnut and thought to be a necrotic testicle was exposed. An orchidectomy was done by amputating the cord at the external inguinal ring. The scrotum was closed except for a small rubber drain.

Further examination revealed that the structure taken to be testicle was really the appendix testis. The tunica albuginea was thickened and covered with fibrin but the testicle and epididymis were normal.

CASE 2. I. G., a Jewish boy of eleven years, entered the hospital April 6, 1935 complaining of severe pain in the left lower quadrant and left side of the scrotum of forty-eight hours duration. There was no history of trauma. There had been no nausea or vomiting and no change in bowel habits. The temperature was 100 and the white blood count 11,200.

On examination the left side of the scrotum was found to be enlarged twice its normal size and the overlying skin was reddened. The cord was not thickened. The child would not tolerate examination of the testicle because of tenderness.

A diagnosis of torsion of the testicle was made and operation was performed immediately under ether anesthesia. The tunica vaginalis was exposed and opened. About one ounce of clear yellowish fluid was expelled. The testicle and epididymis were grossly normal. Near the upper pole of the testicle there was found a pedunculated whitish, oblong mass about the size of an almond (Fig. 1). The twisted pedicle was clamped, ligated and divided and the mass removed. The scrotum was closed without drainage. Convalescence was uneventful and the child was discharged after five days.

†Read at the meeting of the New England Branch of the American Urological Association, Boston, April 28, 1935.

†Rhodes, John B.—Resident Urologist, Massachusetts General Hospital. For record and address of author see "This Week's Issue," page 1018.

ETIOLOGY

The etiology of torsion of the appendix testis is obscure. The lesion occurs in individuals in whom this structure is pedunculated. Foshee⁶ has suggested that a sudden and violent ere-

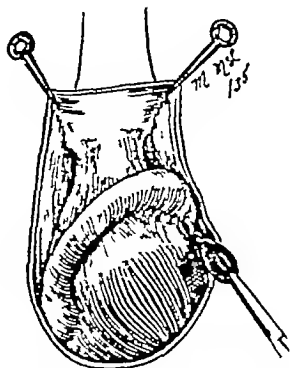

FIG 1 The gangrenous appendix testis is held in the forceps

masteric reflex is the probable cause of torsion of the pedicle. The history of trauma may be lacking.

INCIDENCE

The age incidence in sixty-one cases, of which fifty-nine have been collected from the literature, has varied between eleven months and sixty-six years. Only three cases have been more than sixteen years of age.

PATHOLOGY

Torsion of the pedicle results in necrosis due to the loss of blood supply. Foshee has described edema of the testicle and epididymis. In the two cases observed by the author there was no gross evidence of any change in the testicle or epididymis and in Case 1 these structures were microscopically normal. There is usually an accumulation of clear fluid within the tunica vaginalis. This fluid may be bloody as in Case 1. Culture of the fluid removed in Case 2 gave no growth. Necrosis was too advanced to permit histological study of the specimens from either of our cases. The gangrenous appendix testis may become detached from the testicle and be found floating free within the tunica vaginalis.⁸

SIGNS AND SYMPTOMS

The common symptoms are the sudden onset of pain in the scrotum which may radiate into the groin. The pain may be accompanied by dizziness and nausea and is usually followed by swelling and retraction of the scrotum on the affected side. The overlying skin may become reddened. There is often slight rise in

the temperature and white blood count during the early acute stage. The symptoms are not always severe. Mouchet has described a case in which retraction of the affected side of the scrotum and syncope were the only signs.

DIAGNOSIS

The diagnosis of torsion of the appendix testis is difficult and seldom made before operation. This condition may be confused with acute epididymitis, orchitis or torsion of the testicle. Careful palpation, when tolerated by the patient, may reveal a small, tender nodule located near the upper pole of the testicle and distinct from the epididymis and testicle. The signs of inflammation and the elevation of temperature are usually more marked in acute epididymitis and orchitis. Both orchitis and acute epididymitis commonly occur in the presence of infection elsewhere, either in the urinary tract or in other parts of the body. Torsion of the testicle is likely to result in greater thickening of the spermatic cord.

TREATMENT

Granting that a diagnosis can be made without operation, the acute symptoms may be expected to subside gradually under palliative treatment. Early operation will confirm the diagnosis and hasten convalescence. The incision may be made in the inguinal region or over the scrotum as the operator chooses. In addition to the removal of the gangrenous appendix testis, excision of the redundant tunica vaginalis is desirable in the presence of a large amount of hydrocele fluid.

CONCLUSIONS

1. Two additional cases of torsion of the appendix testis are described.
2. The diagnosis is difficult and should be considered in all acute lesions of the scrotum, especially through the age of adolescence.
3. Operative removal of the strangulated appendix testis is the treatment of choice.

EXPERIMENTAL AND CLINICAL OBSERVATIONS
ON URINARY CALCULI*

NY O C HIGGINS, M.D.†

NUMEROUS clinical observations have been made which support the contention that a relationship exists between the formation of urinary calculi and a deficiency in the diet. The clinical observations of McCarrison¹ of India indicate that stone areas occur in parts of that country where a properly balanced diet is not followed. Similar observations have been made by Fujimaki² and other observers. In the United States, stone areas are said to exist in southern Florida and southern California, and in England, Joly³ states that calculous disease is more prevalent in Westmoreland and Derbyshire. Joly also has stated that in countries where progress in the knowledge of diet and nutrition has occurred, we have been rewarded by a decrease in calculous disease in children, while in countries where the children do not have a well balanced diet calculous disease still is quite prevalent. Osborne and Mendel⁴, in the course of a series of investigations dealing with dietary problems, noted that calculi developed in a certain percentage of the experimental animals. This was true, however, only of the rats that have been on a diet deficient in vitamin A during some part of the experiment.

I should like to review briefly the experimental work that we have been doing for the past four years.

The effect of the withdrawal or of a deficiency in the various vitamins was studied to determine the exact relationship between the production of calculi and a deficiency in the specific vitamins. Likewise, the effect of inadequate amounts of fat, protein, carbohydrate and the various salts was studied. In experimental work with dietary problems, extreme care must be taken in the preparation of the foods or a misinterpretation in results will occur. It is essential that the necessary proteins, fats and carbohydrates and the various salts be included in the diet and the food must contain the required number of calories and it must also be palatable.

After the rats have been maintained on a diet deficient in vitamin A for twenty-nine days the first signs of vitamin A deficiency which are manifested are xerophthalmia, loss of weight and if small amounts of vitamin A are not restored to the diet at this time, the rats become cannibalistic, the stronger rats prey on the weaker and some die from intercurrent infection.

The incidence of urinary calculi that can be

formed in the white rat that is maintained on a diet deficient in vitamin A is shown in the following table

EXPERIMENTAL PRODUCTION OF URINARY CALCULI

200 ALBINO RATS—25 CONTROLS			
Number of Rats	Duration of Experiment Days	Bladder Calculi	Per Cent
30	1-30	1	3
28	30-60	4	14
42	60-90	18	88
28	90-130	20	71
80	180-190	26	86
17	180-250	15	88

Twenty-five controls 1 showed sand in bladder

EXPERIMENTAL PRODUCTION OF URINARY CALCULI

Number of Rats	Duration of Experiment Days	Kidney Calculi	Per Cent
80	1-30	0	0
28	30-60	0	0
42	60-90	6	14
28	90-130	8	28
30	180-190	9	80
17	180-250	7	41

Twenty-five controls No renal calculi

EXPERIMENTAL PRODUCTION OF BILIARY CALCULI

Number of Rats	Duration of Experiment Days	Biliary Calculi	Per Cent
30	1-30	0	0
28	30-60	0	0
42	60-90	0	0
28	90-180	2	7
30	180-190	4	18
17	180-250	4	14

Twenty-five control rats No biliary calculi

It will be noted that bladder calculi form at an earlier period than do kidney calculi. Likewise, at the end of 250 days, small stones are found in the livers of these animals in from twelve to fourteen per cent of the cases.

The question also arises as to the possible relationship between infection and the formation of urinary calculi. In our experimental work it was found that the incidence of infection was practically equal to that of the calculus formation. The chemical analysis of stones showed that they were composed of calcium and magnesium phosphate with traces of carbonate. Neither uric acid nor oxalates were found to be present. There was also a small amount of mucoid substance.

When it had been demonstrated that stones could be produced by a diet deficient in vitamin

Read at the meeting of the New England Branch of the American Urological Association, Boston, April 29, 1939.
Higgins, C. C.—Member of the Surgical Staff, Cleveland Clinic. For record and address of author see "This Week's Issue," page 1492.

A and that they could be prevented by the addition of vitamin A to the deficiency diet, the question arose regarding whether stones could be caused to undergo solution when vitamin A was restored to the diet. A group of rats, therefore, was maintained on a deficiency diet for a sufficient period of time to allow the stones to be demonstrated roentgenographically. These rats were then maintained on the same diet but cod liver oil was given daily by mouth by means of a medicine dropper. In every instance, if the rat survived for a sufficient period of time, the stones underwent complete solution and when autopsy was performed, no evidence of a calculus remained. The time required to cause a dissolution of the stone, however, seemed to depend directly upon the degree of infection present in the kidney and likewise upon the amount of kidney damage present which reduced the function of the individual kidney. In the absence of infection or any degree of renal damage, the stones underwent solution with considerable rapidity.

At this time, we decided to determine whether an alteration of the constituents of the diet would cause a change in the chemistry of the calculi which were produced. As I reported in previous communications^{5, 6}, when the phosphorus was reduced to a minimum, in comparison with the calcium present in the diet, the chemistry of the stones which were produced was changed considerably. The stones produced after the phosphorus intake was reduced were composed chiefly of calcium carbonate with traces of calcium magnesium phosphates. Again no uric acid or oxalates were present. We then decided to attempt to produce calculi in other animals whose diet had been deficient in vitamin A and a group of dogs was therefore studied. I was fortunate in seeing with a veterinarian a dog which had had stones in the bladder at frequent intervals and had had two previous cystotomies with the removal of stones from the bladder. Upon analyzing the diet of this dog, it was found that his diet was definitely deficient in vitamin A. Stones removed from the bladder were composed chiefly of calcium and magnesium phosphate with only traces of carbonate. In our experimental work with other dogs, after they had been maintained on a deficiency diet for a period of seven and one-half months, a cystotomy was performed. In four of the seven dogs that have been operated upon up to the present time, multiple stones were found in the bladder in three instances. One stone was allowed to remain in the bladder which was then closed in the usual manner as was the abdominal wall. These dogs are now on a diet high in vitamin A in an attempt to determine whether the stones produced in the dogs also will undergo solution.

At the present time, the work of the production of uric acid stones is being studied. This

work is carried out on chickens and pure bred Dalmatian dogs, and a report of this will be published in a later communication.

From this experimental work, it seemed that we had sufficient data to permit us to apply our results in clinical cases. After considerable deliberation, we decided that the cases in the following groups might be suitable for medical treatment:

1 Cases in which the patient refused removal of the calculus by surgery.

2 Cases in which bilateral renal calculi were present but in which surgical intervention was not deemed advisable.

3 Cases in which calculi were present in one of the calices of the kidney but were not producing obstruction.

4 Cases in which small calculi were present in the renal pelvis but did not produce obstruction.

5 Cases in which calculi were passed at frequent intervals but could not be demonstrated roentgenographically.

6 Cases in which calculi were of sufficient size to require nephrectomy.

7 In orthopedic cases such as osteomyelitis or fractures where the recumbent position was required for a long period of time. It is known definitely that calculi may form under such conditions.

8 Cases in which prevention of the recurrence of lithiasis following operative removal of stones was desired.

The following routine has been adopted in cases where medical treatment is anticipated. The patients are hospitalized for a period of from three to seven days while the necessary examinations of the blood and urine and x-ray studies are made.

A plain roentgenogram and stereoscopic study is first made. These show whether stones are actually present, whether they are unilateral or bilateral, and whether coexisting stones are present in the ureter or the bladder. This is followed by a cystoscopic examination. After visualization of the bladder, catheters are passed to both kidney pelves. Specimens are taken in glucose brain broth for culture. Likewise, a specimen is collected in order that we may have a stained slide of the sediment. Two cubic centimeters more are collected for pH determination and the usual cytological examination. A fractional phenolsulphonphthalein function test is made.

In all cases, a catheterized specimen of urine is taken from each kidney for a pH determination. This is done in view of the fact that we have found in some instances (17 cases) a definite difference in the pH of the urine from a kidney containing a stone, especially if the stone is of the calcium-phosphate type. In

one instance, the pH of the urine from the kidney in which a stone was located was 8.4 and triple phosphato crystals were present, while in the normal kidney, the pH was 5.2 and no phosphate crystals were present. Therefore it can readily be seen that the pH of the bladder urine is not always a true interpretation of the acidity or alkalinity of the urine as it comes from the kidney.

The following day after the spasm of the ureters which results from the passage of the catheters has subsided, an intravenous urogram is done. This shows whether a stone is producing an obstruction and also gives additional information regarding the function of the kidney. If it is obvious that a definite obstruction is present or that the patient is having sufficient discomfort and pain from the presence of a stone, surgical intervention is necessary. It certainly would be unwise to temporize with an obstructive lesion of the upper urinary tract and to sacrifice the renal parenchyma while the patient is on the dietary régime.

Certain blood examinations are quite important. Calcium, phosphorus, phosphatase, urea, uric acid, creatinin and sugar determinations are made routinely. If an elevation of the blood calcium is found and a lowered blood phosphorus, our attention is drawn to the possibility of the presence of parathyroid disease and the patient is studied more closely along this line. Likewise, if there is an elevation of the blood uric acid, naturally it is important that the purines and the various foods in the diet that tend to elevate the blood uric acid be minimized. If the patient has passed a calculus previously, this is analyzed in our chemical laboratories. A routine Jeans test is made in order to determine whether clinical evidence of vitamin A deficiency is present.

After all these data have been secured, we can tell whether the patient is suitable for conservative treatment and the high vitamin A acid ash diet is prescribed. Vitamin A is given in the form of two Carotene-in-oil capsules three times a day for a period of one month. After this time, one capsule is taken each morning and night.

Patients must follow the diet for a considerable period of time. Because it is so essential that the patient should understand the principles of the diet, the dietitian visits him daily while he is in the hospital to discuss with him why certain foods are allowed and others restricted. She also explains in detail the sample menus which the patient is given to follow when he leaves the hospital. It is impressed upon the patient that if satisfactory results are to be secured, the diet must be followed as closely as a diabetic patient adheres to his diabetic régime.

No specific diet can be used in all cases but the diet must be prescribed in each individual case depending upon the pH determinations of

the urine and the blood chemistry. As a general rule, we start with an excess of acid or alkaline ash of approximately 17.3 cc. depending upon the pH of the urine from the kidney harboring the calculus. However, in the presence of a protein infection or of poor renal function, it frequently is necessary to change this to twenty or thirty cc. during the first few days of hospitalization. Likewise, in some instances, it is necessary to administer ammonium chloride in enteric coated tablets to reduce the pH of the urine to a point from 4.9 to 5.2. Since acetone, diacetic acid or beta-oxybutyric acid are not present in the urine, the patient can be maintained on this diet for a considerable period of time.

The patient also is taught to make his own pH determinations which are done one half hour before lunch in order to avoid the effect of the alkaline tide. A simple and inexpensive apparatus* may be purchased which gives a result of sufficient accuracy that it can be used to follow the patient's progress and to determine whether his diet must be altered or the medication must be increased to maintain the desired pH.

If the pH of the urine remains at the desired level for a period from five to six days, the patient is discharged from the hospital and told to report the daily pH determination to the family physician every two weeks.

I now have six patients in whom I was unable to reduce the pH of the urine below 6.8 or 7.0. In all six of these patients, large bilateral stones, very poor kidney function and a protein infection were present. In spite of an excess acid ash of twenty-eight to thirty cc. and forty grams of ammonium chloride daily by mouth, I was unable to reduce the pH to the desired level during the patient's stay in the hospital. In four instances however, between three and five weeks after the patient was discharged, the pH gradually was reduced to approximately 5.2. All these patients had been treated elsewhere previously with the ketogenic diet by excellent men and the pH had not been reduced to the acid side in any of them.

The following cases are a few in which satisfactory results have been secured by the use of the high vitamin A acid ash diet.

CASE 1. The patient was a woman fifty-two years of age, who had large bilateral renal calculi. In spite of marked kidney damage she was able to carry on her daily duties and the blood urea was forty-five mg. per hundred cubic centimeters. When I first saw this patient, seven and one-half months ago, a stone had never been passed. Since that time, she has followed the diet and more than 273 small calculi have been passed. It is interesting to note that these patients have very little discomfort when the calculi which resemble a jelly like mass are passed. If however this mass is allowed to stand on filter paper and dehydration occurs, a small accumulation of sand and stone is found. When this patient was last seen a roentgenogram revealed a marked decrease in the size of the calculi.

*This may be purchased from the LaMotte Chemical Products Company, Baltimore, Md.

CASE 2 The patient was a man fifty two years of age whose condition had been diagnosed as arthritis before he entered the Clinic

A plain roentgenogram showed that a large stone filled the entire right kidney. Operation was advised but the patient refused. The high vitamin A acid-ash was prescribed and five and one-half months later, more than 300 small calculi had been passed. While the stone was undergoing solution roentgen examination revealed the breaking up of the solid mass until it was decreased in size by at least fifty per cent. Unfortunately, at this time, the patient was killed in an automobile accident and we were unable to secure the kidney for examination.

CASE 3 The patient was a young girl who had a small stone at the ureteropelvic junction. Inasmuch as she did not wish to discontinue her school work, nonoperative treatment was advised. I was able to dislodge the stone with a ureteral catheter causing it to fall back into the kidney pelvis.

The high vitamin A acid-ash diet was followed and in a period of five and one-half months, the stone disappeared entirely.

CASE 4 The patient was a physician who had two recurrent stones in the right kidney. One stone produced a definite obstruction and operation was advised. However, two previous operations had been performed on this kidney and any further surgical procedure was refused.

The high vitamin A acid-ash diet was prescribed and three and one-half months later, the large stone in the lower calyx of the kidney had entirely disappeared, and the stone in the pelvis of the kidney was definitely smaller.

CASE 5 This patient was a physician also.

A plain roentgenogram revealed nine stones in the left kidney. The high vitamin A acid-ash diet was followed for seven and one-half months and the stones disappeared entirely.

CONCLUSIONS

The following results have been secured by the use of the high vitamin A acid-ash diet in the treatment of urinary calculi.

1 We now have collected a series of twenty-three cases in which stones which were too large to pass spontaneously from the kidney have undergone complete solution as indicated by radiographic studies and by pyelography.

2 We have a group of seventeen patients who passed calculi at frequent intervals. After the high vitamin A acid-ash diet had been followed, all have been entirely free from symptoms for more than two years.

3 During the past two and one-half years, we have had only one instance of recurrent stone formation following operative removal of stones from the upper urinary tract. In this case, the patient did not follow the routine that was outlined for him. I do not wish to infer that postoperatively we only use the high vitamin A acid-ash diet. This is prescribed in addition to the other therapeutic measures that we always have used such as eradication of infection and elimination of stasis. Since this régime has been used the incidence of recurrent stone formation has been reduced from 16.4 to 4.7 per cent in our cases.

4 We also have a series of cases in which

the stones have diminished in size, but insufficient time has elapsed to warrant their complete solution.

5 In other cases, we have been unable as yet to note any decrease in the size of the calculi although the patients have followed the diet for a period of from four to five months. It is impossible to determine whether a noticeable decrease in the size of stones will occur after the diet has been followed for longer periods of time. We do believe, however, that if the stone is not producing definite renal damage, and is not disabling the patient from pain, conservative treatment should be attempted.

6 We are quite certain that, if in addition to the other therapeutic measures which have been used previously, a carefully planned diet is prescribed to which vitamin A is added postoperatively, the recurrent formation of stones can be reduced to a minimum.

DISCUSSION

DR. FLETCHER H. COLBY I want to congratulate Dr. Higgins very highly on his presentation and his subject which shows, whether you believe it or not, that a great deal of hard and progressive work has been done. There are certain questions that are not clear to me. First, we find stone formation in this part of the country and it is very difficult for us to believe that the average patient is deficient in vitamins of any sort. That, I believe, applies to the average ward patient that we have in our hospitals. Certainly, it would seem to apply to the private patients that we have. If there is no vitamin deficiency, it is difficult to see how feeding vitamin A is going to affect the stones.

Another point is this: in the cases of stones that have resulted from parathyroid disease, we have found at the Massachusetts General Hospital, all these patients have been carefully observed following the removal of the parathyroid tumor to see if there would be any effect on the stone, if the stone would get smaller or possibly dissolve in the spectacular manner that some of these cases we have seen tonight have. In the few instances in which that was done, where the patients were observed, no change, so far as I know, was present or could be determined in the structure of the stone itself. Here is an instance where the etiological factor has been removed, definitely metabolic in character, and I think it would be fair to assume that there might be some change in these patients' stones.

I have enjoyed Dr. Higgins' paper very much and want to thank him a great deal for coming, on and talking to us.

DR. E. GRANVILLE CRANTREE I have a patient who has a series of mishaps, the first of which was an overdose of radium affecting the bladder and rectum, as a result of which I implanted the ureters. One of these resulted in a nephrectomy because it

had to be planted in an unusual place as I could not approach the sigmoid because of extensive adhesions from previous operations. She has lived with one kidney which has functioned perfectly well for nine years. Beginning six months ago there was a change in this patient. She began to have loss of weight, pain and an intravenous pyelogram showed a great degree of dilatation of the ureter far down to its insertion into the sigmoid. In addition to that it showed stones in the kidney pelvis. The kidney pelvis was opened and a mass of soft stones the analysis of which has not yet been completed, was removed. The kidney was placed on nephrotomy drainage as a temporary measure after demonstrating that the junction between the ureter and the sigmoid was perfectly normal and would admit a large sized bougie. Our difficulty however has been the question of persistent alkaline urine on that side as tested by the urinary flow from the catheter drain in her kidney. The infection is a proteus and I was hoping to get some help from Dr. Higgins about acidifying this urine as we have been unable to do it by any measures so far employed.

DR. ALFRED SHORL. I came here to listen and to learn. By no stretch of the imagination can I be considered a urologist. Dr. Deming tried to teach me some things about urology once but I am afraid it didn't take. I was associated with him once in an attempt to modify the acidity of the urine in various ways. Perhaps he will tell you about the methods you can employ best in changing the acidity of the urine and what results to expect.

Speaking as a chemist, there is no question that uric acid is soluble in alkalies. As far as the cystine oxalates are concerned the most acid urine one can obtain would be approximately the condition for the precipitation of cystine.

I am naturally very much interested in the question of vitamin A deficiency in relation to stone formation and very often I have seen these calcium salts. I have no doubt that the acidity of urine can be influenced by the diet but I am still in doubt, however, as to how much importance one must lay to the acidity factor and how much to the vitamin A. As far as I know vitamin A deficiency in human beings is not widespread at least in this country but where vitamin A deficiency occurs it is not invariably associated with calculi.

On the question of measurement of the acidity of the urine by the colorimeter I agree with Dr. Higgins. With hundreds of determinations so far as I know no practical difference has been made out in any type of urine between the electrometric and the colorimetric measures. It is true that there is a definite salt effect on the indicators but I do not think that is ordinarily of sufficient magnitude to vitiate any result that may be determined by colorimetric determinations of the urine. I think Dr. Albright's ideas with regard to phosphate are well taken and any attempt to acidify the urine by phosphates is perhaps a step in the wrong direction.

I would like to ask Dr. Higgins the diets with which he produced pure calcium carbonate stones in rats.

DR. E. L. PRINSON. I would like to know what happens to stones in rats if they are put on an acid diet without vitamin A at all.

DR. ROBERT R. BALDWIN. I would like to ask Dr. Higgins whether the dissolving of stones in cases where infection was present had any effect on the infection whether the infection persisted or not.

DR. THOMAS N. HETURN. I have known of Dr. Higgins' excellent work by his published papers and I came up from Hartford to hear it personally presented because I thought it of such value. Also I wished to see his pictures of dissolving kidney stones certainly a most dramatic presentation. I have been equally charmed by the convincing work the group in Boston has done at the Massachusetts General Hospital on disturbed metabolism as a result of hyperparathyroidism.

For a number of years I have removed stones from the kidneys and I am astonished at my good fortune that so many of them have not recurred. I recall twenty five or thirty years ago when dietary treatment for the prevention of stones was a prevalent medical concept. I remember the uncertainty which many of us felt who were conscious of our ignorance of the metabolic processes involved. I remember how we were told some stones would form with acid urine and some with alkaline urine. Naturally there was a revolt by my generation against accepting such poorly proved theories.

Now shall we accept as proved these more recent theories? We must keep in mind that a large proportion of stones are unilateral and that without resorting to any complicated metabolic diet or parathyroidectomy at least sixty per cent of our stones do not recur. Is concentrating the attention of the poor human stone victim on the fact that he may reform stones good treatment when sixty per cent go along rather happily without recurrence? I have felt and feel now my gross ignorance on this subject, my incapacity to judge except in a relatively small group which stones are metabolic and which stones are the result of dietary deficiency. I hope that as a result of this work, urologists will better understand the etiology and treatment of kidney stones resulting from dietary or glandular errors. I also hope that the minds of urologists will not be so centered on the complex phases of this lesser group that they will make all their patients too stone-conscious unless they are quite sure to which group of stone makers they belong.

One thing has not been mentioned to which attention should be paid and that is the value of good drainage of the kidneys at the time of operation and to the value of foreign fluids where you are uncertain as to what the etiology of the stone is. Those of us who are not fortunate enough to have metabolic laboratories at our command and are afflicted with a staghorn skepticism will do well if we keep the urine very dilute with forced fluids and be sure at the time of the operation that there is not some obstruction area of a mild character. Adequate kidney drainage is still probably the best corrective for renal infection. Remember that the majority of these patients will not reform stones and they should not have to carry in their minds always the feeling that they are handicapped by having to stick to special diets and probably only a very small group should be trained to examine their urine frequently as diabetics do and so become always conscious of their disability.

I do not wish to convey the impression that I am not properly grateful and appreciative of the very splendid work that is being done by our metabolic chemists and by our food experts. I speak only for the encouragement of urologists who are not clear in their minds regarding this complicated process and for the benefit of the morale of the majority of those human beings who have had or will suffer from a kidney stone.

DR. CLYDE L. DEMING. I would like to ask Dr. Higgins two questions. It is considered that vitamin A is having somewhat the opposite effect from vitamin A, that is cod liver oil and I wonder if Dr. Higgins has seen any stone formations in orthopedic

cases that have had viosterol. In using his acid-ash diet, does he follow pretty closely the diet as outlined by Dr Keezer?

DR C C HIGGINS Of course, the discussion of the etiologic factors involved in the formation of urinary calculi could be prolonged indefinitely. Probably no single factor is instrumental in the production of all stones, however, by our experimental work in vitamin A deficiency, conditions are produced which explain satisfactorily the mechanism of calculous formation. There is likewise no doubt but that hyperparathyroidism is associated with the formation of calculi in some instances.

In the series of cases of urinary calculi that I have studied, I have not noted a single case associated with hyperparathyroidism and the blood calcium and phosphorus determinations always have been within normal limits. We have operated upon three parathyroid tumors, however, which were associated with hyperparathyroidism and in which there were no evidences of calculi.

In a communication with Dr Max Ballin of Detroit, he told me that in the cases which he reported, in no instance were urinary calculi found. If cystoscopic examination is performed on a female dog every three or four days, and the region just in front of the trigone is transected with a wire, an ulceration is produced. If the urine of the dog then is rendered strongly alkaline, you will notice a deposition of phosphates on the ulcerated surface which becomes further united by the fibrin which exudes from the raw surface. If this deposit then drops into the base of the bladder and the alkalinity of the urine is continued, the gradual development of a calculus can be followed.

The question has been asked as to whether vitamin A deficiency is a common clinical finding. It is a very simple matter to make a diagnosis of extreme avitaminosis. However, in many cases, it is difficult to determine whether a mild degree of deficiency is present. After all, you cannot overlook the statistics of Jeans which were published in the *Journal of the American Medical Association* a short time ago. He found that approximately twenty per cent of the children who entered the dispensary of Iowa State University for diagnosis and treatment were deficient in vitamin A. Obviously, if a marked degree of avitaminosis is present, the condition is recognized and treatment is instituted. Therefore, for the production of urinary calculi, both in patients and in experimental animals, only a very mild degree of deficiency must exist over a long period of time.

The question is asked, how much vitamin A do we secure in our food? The usual food sources of vitamin A are milk, butter, eggs and green vegetables. The vitamin A value of animal foodstuffs varies considerably with the diet of the animal. This is especially true of dairy products such as milk, cream, butter and eggs. The Ohio State Experimental Station has found that when cows are on winter feeding, some milk contains less than half as much vitamin A as when the cows are on summer feeding in pasture. Thus the variation in vitamin A content of dairy products is markedly affected. Likewise, eggs toward the end of the laying season frequently contain only half the vitamin A content that they do in the earlier part of the year. Of course, carrots contain a large amount of vitamin A, but unfortunately, people are not especially fond of them.

With regard to the action of viosterol. About two years ago, we started working on the effect of viosterol in rats to ascertain whether calculi could be produced. In ten of fifty experimental animals, calcification was found in the renal paren-

chyma, however, no calculi were evident. In view of other experimental work that has been done, I do not feel that preparations which contain viosterol should be utilized over a long period of time. As stated previously, the stones which first formed experimentally in the white rat were composed of calcium magnesium phosphate with traces of carbonates. No oxalates or uric acid were present. We found later that by decreasing the phosphorus in the diet in relation to the calcium, a reversal in the chemistry of the stones occurred. Now they were composed chiefly of calcium carbonate with only traces of phosphates.

Is the alkalinity of the urine the chief factor in the production of stones? When the white rats are maintained on a diet deficient in vitamin A, the urine becomes alkaline. If, however, small amounts of ammonium chloride are given and the urine remains approximately neutral, calculi can be produced but it requires a longer period of time. After the stones have been formed experimentally, acidifying the urine alone does not cause a solution of the stone. Likewise you cannot prevent the recurrence of calculous formation due to the fact that the lesions in the mucosa of the genitourinary tract are still present. We know that vitamin A has a specific effect on the epithelium and is a most useful medication to promote its healing.

In the work reported on calculi associated with hyperparathyroidism, the point that has interested me is that the calculi were phosphatic in type and were produced in an alkaline urine. I am waiting anxiously to see such a patient to determine whether by the use of the high vitamin A acid ash diet alone, a solution of the stone can be accomplished before operation is performed on the parathyroid glands, or whether a positive Jeans' test is present. The clinical findings in these cases, that is, the phosphatic stones and the alkaline urine, are similar to those which we made in our dietary work. It may be true that the LaMotte apparatus does not give an absolutely accurate determination of the pH of the urine, however, it is sufficiently accurate to warrant its adoption to follow the progress of these patients. As we follow the progress of a patient with diabetes by a blood sugar examination, likewise we follow the progress of patients on the high vitamin A acid ash diet by a pH determination of the urine.

The effect of diet on infection. A short time ago in St. Louis at the meeting of the Southwestern Branch of the American Urological Association, I was asked if I had noticed that in many instances the renal infection had subsided after the patient had been on the high vitamin A acid ash diet for a period of time. I noticed that in a few cases, but did not pay a great deal of attention to it. It has been stated that the bactericidal effect of the urine on a patient who is following the ketogenic diet is due to the beta oxybutyric acid. This, of course, is not present in the urine of the patient on the high vitamin A acid ash diet. If the urine has bactericidal properties, therefore, it must be due to the fact that the pH of the urine is at a level which is not favorable for the growth of bacteria and is maintained at this level for a considerable period of time.

I will not go into detail about the discussion of the cystine stones. They are rather unusual. However, I feel certain that a cystine calculus can be formed experimentally just as easily as a phosphatic stone if we can produce a constant cystinuria for a long period of time and maintain the experimental animal on a vitamin A deficiency diet. Likewise, I believe an oxalate stone can be produced experimentally if we can produce an oxaluria in an experimental animal for a considerable period of time and maintain it on a diet deficient in vitamin A.

MASSACHUSETTS MEDICO LEGAL SOCIETY

A REVIEW OF THE VARIETY OF POISONS WHICH HAVE
CAUSED DEATH IN THE MASSACHUSETTS STATE
HOSPITALS FOR MENTAL DISEASE*

BY ANNA M. ALLEN, M.D.†

DURING the twenty years, from 1914 to 1934 which this review covers, the number of deaths caused by poisoning (exclusive of alcohol) in the State Hospital of Massachusetts for mental diseases reaches the surprisingly low figure of forty one, in twenty two of these cases the poison was ingested before admission. The hospital's population is between 22,000 to 24,000 patients. In this period there were approximately 2,600 cases which came under the jurisdiction of the Medical Examiner thus giving us a figure of somewhat over 1.5 per cent for the incidence of poisoning in the sudden or unexpected deaths in the forty-one cases.

As can be seen from the accompanying table, the poisons fall into a great variety of categories

Corrosive poisons	Lye	4 cases
Non-metallic poisons	Iodine	3
	Phosphorus	1
	Fluorine	1
Metallic poisons	Arsenic	7
	Mercury	4
	Lead	2
	Antimony	1
	Carbon Monoxide	4
Alkaloidal poisons	Morphine	2
	Nicotine	1
Non-alkaloidal organic poisons	Cresols	4
	Phenols	3
	Phenobarbital	3
	Cyanide	1
	Tri-ortho-cresyl phosphate	1

Of the corrosive poisons lye is easily accessible used as it is, so frequently in kitchen work. All of the four deaths caused by this substance were suicidal. The most rapid of these deaths occurred thirteen hours after ingestion of the lye and postmortem examination showed an intense hemorrhagic necrosis of the gastrointestinal tract, including the mucosa of the mouth, esophagus, stomach and extending a few feet into the small intestine. There were several perforations in the esophagus and stomach. It was not possible to determine the exact amount taken by this patient, but in the case of another patient who died in thirty

nine days, it was estimated that one ounce of lye was consumed.

Tincture of Iodine caused death in two individuals. A seventy year old woman drank approximately three and one half ounces, became very cyanosed, and died in one hour. Autopsy showed edema of the glottis and necrosis of the gastric mucosa.

Phosphorus in the form of a tube of Bisnit Rat poison was spread on chocolate and consumed by a twenty four year old male who felt guilty over an illicit love affair. He suffered from nausea and epigastric pain, and died in thirty-one hours. Autopsy showed pulmonary edema and congestion, necrosis of the epithelium of the esophagus and a characteristic odor from the abdominal cavity.

An accidental death occurred in one hospital when roach powder, a mixture of sodium fluoride and sodium silicofluoride was mistaken for powdered sugar and used in making hard sauce to go with the noontime dessert. The patient who was mixing the sauce tasted it on several occasions, and then complained of weakness and nausea. He vomited copiously and lapsed into a state of mild shock which responded well to treatment though generalized weakness and muscular cramps continued. Some five hours later he complained of dyspnea, and expired almost immediately. Autopsy showed subpleural and epicardial hemorrhages, as well as extravasations of blood into the lung tissue and intense hyperemia of the kidneys. The blood was liquid throughout and when examined for calcium by Mr. E. H. Stotz, Dept. of Biochemistry, Harvard Medical School it contained only 5.8 mg./100 cc., instead of the normal 10 mg./100 cc.—the tetany level is approximately 7 mg./100 cc. Dr. William F. Boos, toxicologist, found fluorides present in all the organs, as well as in the heart's blood. In this case death was presumably due to an artificial tetany brought about by the fluoride combining with the blood calcium to form a calcium fluoride which is of extremely low solubility. Since this fatality, all the roach powder used in the Massachusetts State Hospitals for Mental Disease is colored so that a similar mistake will not recur.

Of the Metallic Poisons arsenic caused the most deaths—seven fatalities. In this group, however, are listed four cases who died while undergoing treatment for syphilis, two of these were caused by the administration of un-

Read before the Massachusetts Medico-Legal Society February 6, 1935.

†Allen, Anna M.—Pathologist, Danvers State Hospital and Department of Mental Diseases. For record and address of author see "This Week's Issue" page 1010.

neutralized arsphenamine, and two died shortly after an injection of sulpharsphenamine, presumably because of an idiosyncrasy for this substance. The other three deaths were suicidal and the arsenic was taken before admission to the mental hospital. It was ingested in the form of Paris green (copper acetoarsenite). A sixty-eight year old man took six tablespoonfuls of Paris green, mixed it with milk, and drank it. He lapsed into a state of shock, later became cyanotic, and died five hours and twenty minutes after taking the poison. At autopsy there were numerous particles of bright green material in the stomach. The mucosa of the stomach was swollen and hemorrhagic. Subpleural and subepicardial hemorrhages were common.

Mercury, in the form of bichloride tablets, caused death in three cases. A depressed male patient, whose wife had taken him on visit from the hospital against advice, took six tablets. He lived eight days with almost complete suppression of urine. Another patient smuggled in some tablets of bichloride of mercury, after returning from a visit to her home. She ate several and died three and one-half days later. Autopsy showed hemorrhages into the mucosa of the stomach, ileum and colon, as well as an acute toxic nephritis. A forty-two year old patient suffering from the effects of chronic alcoholism drank approximately three ounces of a 5 per cent solution of mercurochrome. He died forty days later. Autopsy showed pulmonary tuberculosis, also an acute nephritis. The skin of the body was pinkish-white and definite pink staining was noted in the lungs, liver and bladder.

Two cases of occupational lead poisoning developed psychoses, and died in State Mental Hospitals with the usual syndrome of generalized intoxication.

Antimony Trichloride was used as a means of suicide in the case of a thirty-five year old cabinet worker. He drank about 40 cc of paint remover containing butter of antimony and suffered from severe pain in the throat and epigastrium. He died in twenty hours. Autopsy permission was refused but a quantity of spinal fluid was removed at the suggestion of Dr. Myrtelle M. Canavan, and this when tested by Dr. William F. Boos, toxicologist, was found to contain antimony, the first time antimony has been recovered from the spinal fluid.

Deaths from gaseous poisons numbered four, all of which were suicidal attempts before admission and in which death was caused by carbon monoxide. Illuminating gas was the method employed in three cases, and the gas from the exhaust of an automobile engine in the fourth case. This latter mode was used by a twenty-four year old male, who died in fifteen hours. No autopsy was performed on any of these cases.

Of the deaths from alkaloidal poisons, it was questionable whether morphine was the prime

agent in the two listed as such. It was known that both of these patients had used this drug for some time before admission, but the manner of death and the signs before death were not conclusive. There was a probability of poisonous alcohol being a factor in the death of one of these, and organic heart disease was definitely diagnosed in the other.

Nicotine caused death within fifteen minutes in the case of a forty year old man who drank an unknown quantity of an insecticide containing this alkaloid. He developed convulsions, frothed at the mouth, became rapidly cyanosed, and died. Autopsy showed the blood, fluid throughout, and the stomach contained a green liquid with a heavy precipitate and characteristic odor.

Under the non-alkaloidal organic poisons are listed four cases of suicide due to cresols, creolin 2, lysol 1 and sulphonaphthol 1. A thirty-eight year old woman drank approximately seven ounces of creolin. She died in two days. The other creolin poisoning case consumed an unknown quantity and lived six days, showing at autopsy acute gastritis, nephritis and bronchopneumonia. A twenty-three year old syphilitic woman drank the contents of a three-ounce bottle labelled Lysol. She was unconscious within a few minutes, showed signs of pulmonary edema, and died within one hour. The sixty-one year old widow who drank sulphonaphthol had also cut her left wrist, and throat from ear to ear. She lived for four days.

Phenol was taken in the form of carbolic acid by a forty-eight year old man, who died fifteen minutes after it was discovered that he had taken the poison. Six to eight ounces of an insecticide containing phenol and kerosene was drunk by a 50 year old woman. She became cyanosed and comatose, dying within six hours of drinking the fluid. Indelible ink which contained phenol was taken by an insane woman, who died one hour and forty minutes later.

Phenobarbital or Luminal caused three deaths. In two of these approximately seventy-two grains were administered in mistake for magnesium sulphate. Deep coma resulted and a rise in temperature, as high as 105°F. Pulse and respirations were also markedly increased in rate, and there was evidence of pulmonary edema. One man died in fifty-four hours, the other in sixty-four hours. The other death from luminal was suicidal. It occurred in an epileptic girl who took an unknown quantity and was found unconscious. She received drastic treatment but remained inert until her death some sixty hours after taking the drug. Autopsy showed little of note, except pulmonary edema, an enlarged liver (2175 grams) congested kidneys and slight subarachnoid oozing of blood.

Sodium Cyanide, the amount unknown, ingested with suicidal intent, caused death in a twenty-five year old chemical engineer, who had

voluntarily come to a State Hospital after his mother committed suicide. He died within ten minutes after taking this poison. Sodium cyanide crystals were found in his clothes. Autopsy, confined to the stomach only, showed the mucous membrane of this organ to be bright red and velvety.

Tri-ortho-cresyl phosphato or so-called Jamaica ginger was presumably partly responsible for the death of a seventy-two year old male who also suffered from chronic alcoholism. He had an advanced polyneuritis on admission to the Mental Hospital, but he did not die until one and one-half years later. At autopsy the spinal cord showed atrophy of the grey matter and anterior horn gliosis.

Of these forty-one deaths caused by poisoning, twelve were accidental and twenty-nine suicidal. The accidental deaths may be listed as follows:

Antisyphilitic treatment	4
Lead Poisoning	3
Luminal	1
Morphine	1
Sodium Fluoride (roach powder)	1
Jamaica-Ginger (Tri-ortho-cresyl phosphate)	1

It is difficult to see how the majority of these can be completely prevented. Those that occurred before admission (lead poisoning morphine and Jamaica ginger) are outside our influence. Of the remainder, the luminal deaths were caused by an error which is unlikely to recur, for the reason that the bottles which contain the magnesium sulphate and luminal have no longer any similarity and cannot be mistaken for each other. The roach powder is tinted so that there is now a distinct difference between it and powdered sugar. Two of the fatalities in giving the treatment for syphilis, those due to the administration of unneutralized arsphenamine, are guarded against recurrence by the fact that it has been replaced by sulpharsphenamine and neoarsphenamine. The other two deaths, which occurred after the injection of sulpharsphenamine, were unavoidable in that there was no obvious contraindication for the use of this therapeutic agent.

The suicides were all caused by poisons which are easily accessible and for the most part may be bought at any drug store. Insecticides, antiseptics or disinfectants being employed by many people require no ingenuity in obtaining them outside of the hospital. Within the hospital many ruses were employed by the depressed patients to obtain these poisons. Occasionally they were smuggled in after the patient returned from visit. Tincture of iodine was stolen from the surgery by a patient polishing the floor at the same time as a nurse was in the room attending to another patient. With regard to the indelible ink, it was not known beforehand that this contained phenol, and the

bottle was not marked poison. In the case of two of the suicides, luminal and sodium cyanide, even after careful investigation it was not possible to determine just how the patients obtained them. The insecticide containing nicotine was taken from the greenhouse, while the florist was absent for a few minutes, by a patient who had been mowing the grass outside. The majority of these patients had shown no suicidal intent previously and several appeared well enough to be allowed parole of the grounds.

When classified according to the mental state, we get the following result:

Undiagnosed	13
Alcoholic	6
Manic Depressive-Depressed	5
Dementia Praecox	4
Toxic Psychosis	4
Psychosis with Psychopathic Personality	2
General Paralysis of the Insane	3
Psychosis with Mental Deficiency	2
Traumatic Psychosis	1
Psychosis with Syphilis	1
Psychosis with Epilepsy	1
Total	41

The thirteen cases that were undiagnosed had taken the poison before admission to the hospital and died before an accurate diagnosis could be made. The alcoholic group is surprisingly high, but may be accounted for by the depressant effects which frequently follow alcoholism. The manic depressive figure, when compared with that of dementia praecox is high, considering that the latter form a much higher percentage of the State Hospital population than the former.

A brief analysis of the age at death shows that twenty-eight of the forty-one were under forty years of age at death. The youngest to commit suicide was twenty-one years of age and the oldest was aged eighty-four years. With regard to sex, seventeen were female and twenty-four male.

CONCLUSIONS

- 1) Massachusetts has cared for 22 000 24 000 mental patients yearly, for twenty years.
- 2) Approximately 2600 cases have come under medical examiners' attention at their death in that time.
- 3) Only forty-one or slightly over 1.5 per cent of this number have come to their death by poisons.
- 4) Twelve of the forty-one, were accidental, twenty-nine suicidal.
- 5) Twenty-two of the forty-one had imbibed the poison before coming to the hospital, nineteen after coming to it.
- 6) The poisons were various: corrosive, non-metallic, metallic, gaseous, alkaloidal and non-alkaloidal organic poisons, metallic poisons were in greatest number.

- 7) The mental diagnoses ranged from "undiagnosed" (13) to psychosis with epilepsy (1)
- 8) The ages were twenty-one to eighty-four
- 9) Males twenty-four, females seventeen in number
- 10) Steps have been taken to minimize these deaths

DISCUSSION

DR WINTRED OVERHOLSER I am sorry that I did not hear the whole of this presentation, I know something of it, naturally. We are very much interested in the office of the Department in the sudden deaths that occur in our hospitals, particularly by suicidal intent.

One thought that occurs to me in looking over the summary on the board is that it is quite obvious, I think, that even under close supervision, such as patients have in mental hospitals, it is not possible to guarantee that there will not be suicidal deaths.

One thing that impresses me, too, in the outside cases, and I am sure it impressed the others here because you are all called in cases of this sort, is the great danger, in cases of depression, that there will be an attempted suicide, which, all too frequently, is successful.

The seriousness, too, of depressions occurring in patients who are in their homes is not sufficiently recognized. We know that. Of course, it is common knowledge from reading the papers, and it is also common knowledge to all of you gentlemen who are called to view the bodies.

The type of poisoning that particularly attracted our attention, recently, is that by sodium fluoride, which I imagine Dr Allen took up in some detail, the ingestion of roach powder. As a result of this affair being called to our attention, we changed the formula by adding a small amount of lampblack, so that the cockroach powder used now, with this formula, is off the white color and is, therefore, sufficiently different in appearance from the powdered sugar so that at least we hope this mistake will not be made again.

Dr Barrett, the Assistant Commissioner, is present, Dr Gay, and it may be that he has something that will be of interest to the group.

DR BARRETT *Dr Gay, and Members*—The thing that is especially interesting to me in discussion of suicide in the State Hospitals reverts to a consideration of administration. It, oftentimes, is an administrative problem that is very difficult to cope with. We do have accidental deaths from poisoning in institutions, and some in which the patients are very strongly implicated. There are others, some of which Dr Allen has reported here, where the patient was not active in the process at all, especially the luminal deaths, in which there was another personality factor involved.

We take very special precautions in the allocation of medicines on the wards, which is absolutely necessary. We must have medications available for immediate use on various types of hospital wards. That is an improvement, I think, over the old hospital system where all medications were disbursed from a pharmacy, by doses. Under those conditions, oftentimes the patient got medications that had been ordered for them, and oftentimes they didn't, and when they did get them, they were maybe

two or three hours late and they didn't get the required dosage.

Under the State Hospital system of Massachusetts, I would like to say that we more or less pride ourselves that we are actually conducting hospitals and not asylums. We are trying to make treatment for patients available at all times so that it is necessary to have medications in certain quantities on the wards. We have taken precautions to see that these storage places are under at least a double lock, and that they are available only to persons who are authorized to administer these medications on order of physician. But, it seems that sometimes there is an error on the part of the administering person. Sometimes there will be that personal factor of becoming somewhat careless and leaving things out. Whether that can ever be entirely corrected, I don't know. I seriously doubt it.

The case of sodium fluoride poisoning, I think, is one of special interest in that the way this was administered is something exceptional and new to me. I had never even suspected that this mixture might be stored in close proximity to powdered sugar. But, that is another personal equation, I imagine, and the Department is especially concerned in seeing that a minimum of those cases occur. I thank you.

PRESIDENT GAY Thank you very much, Dr Barrett. Is there any further discussion?

DR MAGRATH I wish to congratulate Dr Allen on the presenting of such an enlightening and complete analytical study of causes of death from poisoning among institutional workers. It has been very enlightening to know what your experience has been in the State institutions.

My own experience is with people who are, for the most part, in the open, and, as we see, they take matters into their own hands, when this happens, they take almost any of the things listed on the board here.

As I look them over, the substances enumerated include only one, nicotine, with which I have not had experience. I congratulate the chemist on getting nicotine. It is a difficult thing to do.

It is a wonder that more accidental deaths do not occur incident to the compounding of prescriptions. Accidents do occur, of course, but in proportion to the number of prescriptions filled, they are quite rare.

One comes to my mind where a North End drug gist or his clerk, who is not a registered pharmacist, by the way, dispensed on a prescription something which the purchaser of the medicine took home and then ingested, and she very speedily went into convulsions and died. What the physician had written for was stypticin. She suffered from menorrhagia, and the druggist's clerk read it as "strychnine." He reached up on the shelf and took down a bottle of strychnine sulphate from among the poisons, and put up the prescription in terms of a strychnine instead of stypticin.

It isn't to be wondered at that the poor lady died and died promptly.

In another instance of what we might call this pharmacy accidental type came the demise of a woman who bought, or thought she bought, citrate of magnesium, effervescent citrate of magnesium, of which she took an appropriate amount and thereafter became unconscious and vomited, and very speedily died. That was a case of poisoning and it was difficult to trace the source of the error, but probably it was outside of the pharmacy, because the pharmacist showed me the package from which he had taken the materials in order to prepare this

bottle of medicine. It evidently took place in the factory or at any rate on the premises where the cartons were put up. It was a mislabeled package instead of containing citrate of magnesia, it contained tartar emetic so that there was a mistake

not on the part of the pharmacist, but on the part of the wholesaler who manufactured it.

This paper of Dr. Allen's was very enlightening and I am very grateful to have had the opportunity to hear it.

A CLINICAL LECTURE ON MIGRAINE*

BY A. H. GORDON, M.D.†

THE object of my talk this evening is to present the salient features of *Migraine* from the standpoint of the clinician, and to emphasize the width of the many gaps in our knowledge of this mysterious ailment rather than the few small fragments of what we think we know.

Having once about ten years ago been emboldened to write on the subject of migraine I referred to that article when called upon on this occasion, and find I can give wholehearted consent to at least one paragraph which says: "For the purpose of this discussion by migrainous headache we mean a headache protruding in intensity, paroxysmal in onset and periodical in recurrence, which can turn a strong man into a worm and make the affections of a woman dark as Erebus, which may pass a legacy from generation to generation and which attacks a girl as she approaches womanhood and is said to leave her at the menopause but frequently doesn't."

At the outset one must ask the very reasonable question: Is there such a disease as migraine? And immediately I hear twelve good men and true in this room answer, "Yes for I have it." But again I may ask, Is the migraine that afflicts any one of you twelve the same as that which afflicts the other eleven? These two questions cannot be answered with certainty for we are still compelled to identify the disease by the clinical features which it possesses, rather than by the morbid anatomy which it does not possess, and our attitude toward it must for the present be one of rational empiricism.

There is much evidence that this symptom complex of migraine was recognized by the physician of the early days of the Christian era and in particular its tendency to attack one side of the head is remembered in the early name *hemikrania*, which in French became *migraine* and which later in English was corrupted to *megrains* and thus again was applied somewhat disdainfully to any sickness which could be brought on at will to avoid a worse alternative.

Before we touch upon what we are to do for migraine, a word should be said about what migraine does to us, I mean to us as clinicians. For it becomes a mirror into which the doctor may look and see what manner of man he is.

We have heard much these late years of the forgotten man and here we find the forgotten disease, for how often on the eruption of its headache or its vomiting into our peace of mind is the isolated event regarded as an "acute indigestion" (whatever that is) or as a "toxic manifestation" (whatever that is) or as a "neuralgia" (whatever that is) without the effort to integrate the symptoms into a clinical whole by relating them with forgotten or misunderstood episodes in the past.

If we are of the school to which focal infection explains everything, our eyes stray, not unerringly but automatically, to the teeth or the tonsils until Moloch is appeased, or if we are true materialists, a suspicious tenderness is eventually found over the gall bladder or appendix and that's that, and if, perchance we are gifted with an imagination, and no good clinician is without it, the symptom complex of migraine leaps quickly to our minds, and by painting the history here and pruning it there, a good case for the neurological picture of true migraine can be made from a chronic nephritis, a cholecystitis or a pyloric obstruction.

Just here we should pull ourselves together and decide what we mean to include within the limits of the term migraine. In a disease without a morbid anatomy one man has almost as much right to include in the picture any sort of recurring nausea or dizziness or what not, unassociated with a typical attack as another has to exclude recurring headaches which are associated with well defined local paralyses, but until we know more about the classical disease than we do now, it is wiser not to call anything migraine that does not measure up to the orthodox description of a periodical headache chiefly one-sided, which is preceded by certain types of aura and followed by nausea or vomiting the whole attack being succeeded by a return to normal health.

The approach to a nebulous subject like migraine is buttressed somewhat by figures and these figures help to keep us from losing ourselves in speculations. To make these figures less deceiving I have averaged several groups of statistics and it is fair to say from these that three fourths of the cases of migraine commence before twenty-five years of age and that one half show the presence of another case in the same or in the previous generation, and that in addition the cases descend with greater frequency through the maternal side of the family.

Cases occur more frequently in females some

would say two and a half times as frequently as in males, but others feel that this disparity is more apparent than real

City people seem to be more affected than country people

The clinically important features of migraine may be set down as

- 1 Periodicity
- 2 Return to normal between attacks
- 3 Headache which, in its character of one-sidedness, has given the disease its name of hemicrania or migraine. Always severe, the attacks of headache are often prostrating. Some patients will say that if the house burnt down they could not move, so great is the pain.

4 Nausea and vomiting. These unpleasant symptoms occur in three-quarters of the cases and give to the attack its name of sick headache, but vomiting as a rule does not end the attack. To be classed with nausea and vomiting is a group of other symptoms involving the vegetative nervous system, coldness, giddiness, collapse, pallor, sweating, polyuria and diarrhea, which are of a general character, and unilateral sweating and flushing, and fullness and throbbing of one temporal vessel which point toward a sympathetic involvement on one side.

5 Prodromata are not invariable but are frequent. Languor and malaise followed by giddiness and coldness often precede the headache.

6 Ocular manifestations such as zigzags, spectra and scotomata were found by Elliott in 44 per cent of cases and in the form of hemianopia in 18 per cent. This is a proportion far above that which one sees in ordinary medical consultations. I am inclined to think that from their dramatic character, the ocular symptoms are kept in the foreground and that 10 to 15 per cent would cover the number we ordinarily see.

7 Time of onset. It is quite striking in how many instances the attack commences in the morning on rising. Another feature difficult to explain is that if the attack continues into the second day the sufferer's sleep may be undisturbed in the intervening night. Ordinarily however when sleep occurs the storm blows over.

8 Undoubtedly a feature of true migraine but approaching the border line of diagnostic error is the group of unilateral sensory and sometimes motor symptoms that may develop. These may be numbness of the face, arm or leg, slight weakness and slight aphasia and certainly hemianopia. Ryle reports a group of such cases and in addition one with vestibular symptoms.

Their transient character, their appearance in only the more severe attacks and their absolute disappearance between attacks hold these phenomena within the concept of the disease, but keep us on the "qui vive" lest something may be lurking behind the migraine syndrome. One

may take still stronger ground in what is called the ophthalmoplegic type of migraine. In a fairly wide experience with the ailment I have never met with a case. It is described as a migrainous attack in which periodic paralysis of one or more branches of the third nerve may occur and in a few autopsies some organic disease has been found to account for the paralysis.

These features are the ones which commonly make up the clinical picture of migraine but the presence of the ailment in a patient's parent or brother or sister adds as greatly to one's assurance of a correct diagnosis as does its absence inject a feeling of uncertainty.

Having set down what appear to be reasonable clinical criteria for what we shall regard as migraine it is of interest to mention certain cases which for the time may be regarded as inhabiting the border land of this disease. One such is what might be called, whether justly or not time will tell, abdominal migraine. Only one case of this nature has come under my care.

A twelve year old boy had suffered from periodical attacks of abdominal pain with projectile vomiting. These attacks had commenced at four years of age and had continued at intervals of from a few days to one month. They were preceded by lassitude and distaste for food, and came on with severe abdominal pain which continued until a projectile vomiting of large amounts occurred, which gave relief to the pain. The attacks had no relation to food and after they passed off he felt quite well again. He had been operated upon for appendicitis four years before without relief, and when I saw him I suspected a partial obstruction of the small bowel. His x-ray examination and all features of his physical examination were negative and there was no fever, but as he was incapacitated from school and from play an exploratory operation was suggested, which showed absolutely no pathological condition to be present. He recovered rapidly from the operation but was neither better nor worse after it.

The subject of abdominal migraine is a dangerous one to venture upon, dangerous for the physician, but still more so for the surgeon, but I think that there is little doubt that such a condition does exist. An attack of epigastric pain and vomiting without fever, with or without diarrhea, periodical in its appearance, either replacing a cephalic migrainous attack, or appearing in a person who has such attacks, should be carefully weighed and measured before its victim is submitted to abdominal section. I would be the first to admit that a gall bladder or an appendix or a pancreas or a gastric ulcer might be at the bottom of such a symptom complex, but in the light of the case to which I have referred I would be more chary the next time in advising operation.

Another of the borderland types is that associated with psychical symptoms. Nelson reports an instance in a physician of thirty-seven who had periodic attacks of loss of memory and loss of orientation with defects in his visual

field lasting two or three hours and preceded by fortification spectra. One might ask if these attacks were migrainous or epileptiform or whether they were a type of periodic psychosis involving the personality of one who suffered from migraine.

The question has already been raised as to whether the occurrence of definite paralyses of the ocular muscles with attacks of hemianopia could be properly classed as migraine and the same can be said of the facial pareses which have also been reported. The presence in some antopias of local organic lesions in cases of this type further tends to throw doubt upon their truly migrainous character. W. J. Adie of London reports seven cases of migraine which developed permanent hemianopia and in one of which a subarachnoid hemorrhage developed. He puts forward the observation that in migraine in which a recurrent and temporary cerebral circulatory disturbance occurs, this disturbance at times may be severe enough to lead to cerebral infarction or to subarachnoid hemorrhage. As I have already said, we cannot yet readily include within the concept of migraine instances in which permanent structural damage occurs, but such cases are of use in offering explanations upon a very obscure problem.

In this connection I have been struck and I have no doubt many of you have been struck by the frequency with which hypertensive vascular disease appears in those who have been in earlier life the subjects of migraine. The association of migraine with the idiopathic convulsive state has also raised a good deal of discussion. Dr Stanley Cobb has collected a group of 1086 patients with idiopathic convulsive disorders and found in 9139 relatives of these people that forty-three per 10,000 had migraine. In 250 control cases without convulsive attacks their 1896 relatives showed only fifteen per 1000 with migraine. Ely found that in people with convulsive disorders a greater number had ancestors with migraine than had ancestors with the convulsive state. Buchanan's figures give the same result, and he comes to the conclusion that migraine and essential epilepsy are transmitted from generation to generation as the expression of the same underlying factor in the germ plasma. I do not deny the correctness of the figures but no such close affinity between the two diseases has appeared in my own experience.

What are the views at present of the nature of this mysterious malady? Many observers have argued that it is a toxemia but to put the matter shortly no group of cases has yet given evidence of significant alteration in the blood or urinary chemistry though an interesting observation was made by van Leeuwen and Zeider of a substance found in the alcoholic solution of the blood of asthmatic and migrainous patients which stimulated the smooth muscle of the gut of a cat upon which the blood of con-

trols showed no effect. Diamond, in 1927 in a small group of cases found an increase in the van den Bergh reaction and nrobinogen in cases of migraine but no such findings have appeared in cases under my care.

Others have believed that it is an allergic disease. Vaughan and Balyeat upon investigating patients with migraine have found responses to various foods by intracutaneous injection, and on that basis have treated these patients by removing the offending food. Vaughan has found 70 per cent of cases of paroxysmal headaches to be associated with allergy and has reported relief in 51 per cent of thirty-seven cases, and Balyeat reported 52 per cent relieved of symptoms in fifty-five cases. We all have seen occasional instances in which certain foods as wheat bread chocolate etc., would bring on attacks but few have been so fortunate as the authors mentioned in affording relief. To most of us the evidence that allergens are the cause of migraine has still a long way to go to be convincing.

Certain endocrinologists claim that migraine may be due to dysfunction of the pituitary gland. As yet no one can deny this, but the type of evidence put forth to support the argument is somewhat bewildering to the ordinary mind. The ophthalmologists lead us to believe that migraine is often due to eyestrain. I wish it were, and I wish that the type of oculist could be raised up who would correct the offending error of refraction. So far he has eluded me. Or it may be it is associated with disturbance of the genital glands. Its appearance at puberty, its exacerbations about the menstrual period and frequent disappearance at the menopause, and its similarly frequent disappearance during pregnancy are very suggestive. Just what one would do about male patients on this basis raises a difficulty. The statement that migraine is due to some disturbance of the vegetative nervous system is a sort of revelation of the obvious. The almost constant association of sympathetic phenomena with all cases and their predominance in some is well known.

The headache and vomiting remind one of a temporary cerebral tumor and the occasional hemianopia and other visual aberrations suggest a local swelling of the occipital cortex and regions more anterior. All of these symptoms would indicate some process causing temporary swelling of regions of the cortex, but whether of vascular or lymphatic origin no one may yet say. In this connection a verbal communication of Dr Wilder Penfield's is of interest. He would postulate as a cause of migraine a stimulus arising from some so far unknown cause in the substance of the brain, and transmitted along the sympathetic fibres now known to accompany the cerebral vessels to the cerebrospinal nerves supplying the head and neck, in the same manner as the pain due to coronary disease is trans-

Systolic Gallop Sounds There is little agreement in the literature as to the type of patient in whom one is likely to encounter systolic gallop rhythm, doubtless because of the small number of patients upon which each author based his report. Four of the six cases of Cuffer and Barbillion¹ had typhoid fever, one tuberculosis of the lungs, peritoneum and genital organs, and the sixth kyphosis due to Pott's disease. None of their patients had either heart or renal disease such as are frequently exhibited in diastolic gallop rhythm. Potain² found systolic gallop associated with arteriosclerosis of the aorta with atheromata, in typhoid fever and in grippe of the typhoid form. Wiedemann's⁴ case had pulmonary tuberculosis. Giroux⁹ described systolic gallop rhythm in hypertension with left ventricular hypertrophy. The patients of Amblard⁷ had weakened hearts and low blood pressure as part of the general debility of such diseases as typhoid and diphtheria. One of White's⁸ four cases was diagnosed as irritable heart. The other three had enlarged hearts, one with auricular fibrillation and another with auricular fibrillation and intraventricular heart block. Wolferth and Margolies³ found this form of gallop rhythm in two patients, a girl of fourteen years extremely ill with miliary tuberculosis and a fifty-year-old woman with hypertension, coronary arteriosclerosis and heart failure. Thus it appears from the literature that systolic gallop rhythm is encountered in the following three conditions: in the normal heart weakened by a severe general infection, in arterial hypertension and in the presence of atheromatous change in the aorta. No mention was made as to its benignity or its occurrence in otherwise healthy individuals.

Autopsied Cases Autopsies are reported in the literature in but four instances. The heart of one of the cases of Cuffer and Barbillion¹ was contracted and normal, the patient having died of typhoid fever with intestinal hemorrhage. Another presented a dilated and flaccid heart that was otherwise normal, this patient having died of tuberculosis. Both of Obrastzow's⁵ patients had atheromatous change in the ascending portion of the aorta, one with dilatation. The heart itself was not otherwise mentioned. From the meagre autopsy data we know only that systolic gallop rhythm may occur without objective organic disease of the heart. Gallavardin⁶ reported autopsies on three patients with metallic clicking sounds occurring in systole. All three had strands of pleuropericardial adhesions to which Gallavardin attributed the sounds. Lukewise, Lian and Deparis¹⁰ reported fifty cases with clicking sounds during systole and referred to the possible association of this finding with pleuropericardial adhesions, although no postmortem studies were made.

Mechanism of Production As to the mecha-

nism by which systolic gallop rhythm is produced, the literature offers only reasoning by inference. Cuffer and Barbillion¹ thought that the first sound and the gallop sound were produced by the two parts of a double systolic effort made by a ventricular myocardium so weakened that a single effort was incapable of raising intraventricular pressure to a degree sufficient to open the semilunar valves. They felt that one would be likely, then, to encounter the gallop sound in all states in which the heart gives way in consequence of myocardial weakness of any cause, whether such weakness be primary or the result of a general affection of the body. They believed the double systolic elevation of the precordium and the plateau observed in the upstroke of the apex cardiogram to be in keeping with this idea.

Potain² gave origin to the concept of arterial production of the extra sound. According to him, an aorta diseased by atheromatous change or by general weakening of its wall in such diseases as typhoid may produce a sound when stretched to the limit of its distensibility by the inflow of blood from the left ventricle. Under normal conditions, he felt, the aorta is never stretched to its limits and a sound is not produced. Wiedemann⁴ adopted the arterial production theory by the exclusion of other factors and on the basis of evidence of sclerosis of the radial arteries.

Obrastzow⁵ reasoned that there was an increase in the period of isometric contraction of the ventricle, the first sound being produced by the closure of the auriculoventricular valves and the extra sound by the opening of the semilunar valves and the commencement of ejection of blood from the ventricle, these two elements being fused into one sound in the normal heart. Thus the condition of the myocardium and the presence of arterial hypertension must play no unimportant rôle. Bard¹¹ later concurred in this idea. Giroux⁹, whose patients had hypertension and left ventricular hypertrophy, agreed to the theory of a lengthened presphygmie period and to the dissociation of the muscular and valvular elements of the first sound, but thought that the extra sound would not appear unless the valves were sclerosed.

Amblard⁷ studied the blood pressure in his patients with typhoid or diphtheria and systolic gallop rhythm or a tendency to it. He found that on slight exercise the systolic and diastolic blood pressures rose from their previously abnormally low levels to approximately normal levels, at which time the gallop sound appeared. If exercise were carried still farther, the pressure, particularly the systolic, fell markedly, whereupon the sound disappeared. He concluded that after slight exercise his patients were suffering from a relative hypertension which produced the sound in the presence

of a weakened myocardium. White¹² has stated that the cause is unknown, but that it may possibly be deformity of valves, chordae tendineae, pericardium or pleura.

Opinion as to mechanism is, then, roughly divided into two basic ideas, that of a lengthened period of isometric contraction of the ventricle with resultant dissociation of the elements of the normal first sound and that of production by a diseased or weakened aortic wall.

Prognostic Significance of Systolic Gallop Rhythm. There is no intimation in the literature that systolic gallop rhythm bears the ominous prognostic significance so well known in diastolic gallop rhythm. The cases are too few, however, to be of any statistical value. Several of the reported cases died of frankly non-cardiac causes. It is possible that this form of gallop rhythm in the presence of general infection implies a severe general debility but whether such debility is more severe than in those patients who do not exhibit systolic gallop sounds we do not know. Likewise, in those patients with organic heart disease or arterial hypertension we cannot say that the prognosis is worse with than without systolic gallop rhythm. Several cases of recovery from infections with disappearance of the sound, are reported. Some authors, notably White¹², Wolfert¹³ and Margolis¹⁴, and Macleod, Wilson and Barker¹⁵ have regarded it as without significance.

THE PRESENT SERIES

We have observed the gallop sound placed in the systolic phase of the heart cycle in thirty-five patients over a period of eleven years (See table 1.) The relative frequency of this type of gallop rhythm is reflected by the fact that during the same period 186 patients with diastolic gallop rhythm were observed. Approximately 16 per cent, then, of patients showing gallop sounds that have come under our observation have exhibited the systolic variety.

Quality of the Sound. In all of this group the extra sound was separated from the normal first and second sounds by an interval sufficiently long so that we clearly felt we were dealing with an additional rather than a split sound. In general the extra sound resembled in quality the normal first sound. Variations in quality were encountered, at times the accessory sound having somewhat more of a valvular quality resembling the second sound. It is possible that some of these may be similar to the metallic clicking sounds supposedly due to pericardial adhesions.

Intensity of the Sound. The intensity of the extra sound was variable from patient to patient and in the same patient on different examinations. In twelve cases we have made clear notes in this connection. In two it was of slight intensity, that is just loud enough to be positively identified as a distinct extra sound,

in four it was of moderate intensity and in six it was as loud as or louder than the other heart sounds. In the majority of our series it was heard only at the apex of the heart or with maximum intensity at the apex. In but a single case was it heard only at the base.

Effect of Position. The position assumed by the patient during the examination had considerable influence on the intensity or even the presence of the sound. Our notes specifically mention this relationship in twelve instances. In three cases the sound was heard only while the patient was recumbent, disappearing when the sitting posture was assumed. In four cases it was heard in both positions, the intensity being greater in the recumbent in three and in the sitting position in one. In four cases it manifested an equal intensity in both positions. In another it was of marked intensity while the patient was supine and practically absent when he sat up. Three years later this relationship was reversed.

Effect of Rate. In this series of cases gallop rhythm was heard with varying rates of the heart beat. There were ten instances in which it was present while the rate was under 80 and five when it was under 70. In the others the rate was higher, occasionally reaching levels over 120. This is unlike the relationship between heart rate and diastolic gallops for it is very rare to find these gallops present when the heart rate is slow, especially under 70.

Constancy of the Sound. The constancy with which the sound was observed in a patient who had once exhibited it was also variable. In three cases it was noted after its absence on a previous examination. One of these had a mild rheumatic infection and a systolic murmur, thirteen months later the murmur had disappeared and systolic gallop rhythm was present. In one case the sound had practically disappeared when the patient was examined one year later. In one the sound was observed on twelve of thirteen examinations over a period of seven years, while another exhibited it on four of seven examinations over eight years. One had the sound when seen one week after an acute coronary closure. He made a good recovery and it was not heard again on the five examinations during the next two years. Adequate follow up data on this group over a long period are not available since the patients were largely seen in consultation and remained under the immediate care of their own physicians.

Clinical Features of the Group. By and large the patients in this series made up a rather miscellaneous group. There were some with mild and others with severe cardiovascular disease. There were still others who had organic disease not involving the cardiovascular system and finally a group which had no organic disease whatever, merely manifesting

minor functional disturbances. There were no patients in the group who had severe acute infections such as typhoid fever or diphtheria similar to those reported in the literature. This is perhaps due to the fact that such acute infections are rarely encountered in the practice from which these cases are drawn. Only two patients in the group had known infections of any sort, both having mild rheumatic fever. Eighteen patients or half the group had no demonstrable organic disease whatsoever and twenty-three or two-thirds had no detectable cardiovascular disease.

The presenting complaints of most of these patients were strikingly either mild or bizarre. Seven were sent by their own physicians because something queer had been heard on auscultation. Two came voluntarily because they wanted their hearts examined. Only one of these nine patients had a notable symptom, a woman whose palpitation and pain about the heart had been annoying since she was told that she had a heart murmur. Eleven complained of being tired or lacking vitality. One man stated that he was nervous since witnessing a death. Sixteen patients complained of pain about the apex of the heart, but only five were regarded as having coronary artery disease. In the others the pain was mild, vague and precipitated by nervousness and not by exertion. Belching of gas, nervousness, palpitation and peculiar sensations in various parts of the body were common complaints. Actual physical incapacitation was entirely absent except to a slight degree in the five patients who had coronary artery disease. The striking thing about the group was that the majority were "nervous" people who were concerned about the possible existence of heart disease.

Of the twelve patients who did have cardiovascular disease, five had disease of the coronary arteries, in three of whom occlusion had occurred. Two of these five and six others had arterial hypertension. The degree of hypertension was not marked, however, as only three had systolic tensions of over 160 mm and only two had diastolic tensions of over 100 mm. The other patient in the group with cardiovascular disease was a man of sixty years who had left bundle branch block without other evidence of heart disease. There were none with valve defects. It is notable that in the entire series there were only two patients whose hearts were clinically enlarged. Equally notable is the fact that in not a single instance was there subjective or objective evidence of congestive heart failure.

Electrocardiograms were obtained in thirty of the group. Significant abnormalities, without consideration of left axis deviation or occasional premature contractions, occurred in only five patients. Four of these had coronary

disease and one had bundle branch block. Atrioventricular nodal rhythm occurred in one of the group without heart disease, but this we have not considered a significant abnormality.

Age There is a fairly sharp division of the groups with and without cardiovascular disease according to age. Among those with cardiovascular disease there was but one less than forty-four years old, a man of twenty-one with slight arterial hypertension, while in the group without cardiovascular disease there was but one who was more than forty-four years of age. Thus almost without exception the older patients in our series had cardiovascular disease while the younger ones did not. The extremes of age in the entire series were eleven and seventy-one years.

Sex The sexes were represented by nineteen males and sixteen females. Among those with cardiovascular disease, however, there were twice as many males as females while the sexes were equally represented in the group without cardiovascular disease.

Prognosis The prognostic significance of systolic gallop rhythm is suggested by the fact that none of the group are dead, and most are in a good or excellent state of health. This is in striking contrast to the fact that 46 per cent of the cases with diastolic gallop observed during the same period of time are known to be dead, the remainder being unheard from or known to be in poor condition. The dead who showed a diastolic gallop rhythm lived an average of ten months and twenty days after the detection of the gallop, the living have so far survived an average of about fifteen months. The patients with systolic gallop rhythm have already lived an average of more than five years and for the most part are well.

The absence of symptoms of myocardial insufficiency of any appreciable extent in those with heart disease, the slight degree of arterial hypertension in those who exhibited it, the rarity of cardiac enlargement and the complete absence of all signs of congestive failure make it appear that this variety of gallop rhythm has no unfavorable influence upon the subsequent course of the patient's life.

The importance of systolic gallop rhythm lies in the fact that it may be confused with diastolic gallop and an incorrect prognosis given as a result of this error. In a few cases we have experienced difficulty in timing the extra sound. The following procedure, however, has been useful in deciding that the abnormal sound occurred between the first and second sounds rather than between the second and first. During auscultation the stethoscope is first placed at the apex and then rhythmically moved with each heart beat to points nearer and nearer to the aortic area. It will generally be found that the sound that gradually disappears is the

middle one of the three and the examiner is therefore left with the normal two heart sounds on reaching the base of the heart. We are fully aware that indisputable evidence that the gallop sound was truly systolic could only have been obtained with sound tracings photographed simultaneously with other events of the cardiac cycle such as those recorded in the electrocardiogram. The sharp clinical distinction and subsequent course of the cases included in this study as contrasted to those with diastolic gallops are fairly satisfactory proof that the bedside findings and terminology were valid.

Mechanism of Production As to the mechanism by which systolic gallop rhythm is produced we have nothing to offer from our series except in so far as the previously mentioned theories may be applied here. We cannot speak of atheromatous plaques in the ascending portion of the aorta without autopsy material. It does not appear, however, that such degenerative changes could be an important factor in our cases with such a preponderance in the younger age group. It is true that many of our patients were asthenic individuals. This would be consistent with Potain's theory of production of the sound by distention of an aortic wall the tone of which is diminished. Certainly the physical state of our patients, however, is not comparable to that which obtains in typhoid fever. This can scarcely explain all instances. The other theories also seem inadequate, although pericardial or pleuropericardial adhesions may possibly account for some of these cases.

SUMMARY

Thirty-five patients with systolic gallop rhythm observed over a period of eleven years are reported. This number represents 16 per cent of all patients with gallop rhythm encountered during this period.

The extra sound in systolic gallop rhythm is placed in systole between the normal first and second sounds. In most cases it has a quality resembling the normal first sound. Its maximum intensity is usually in the region of the apex of the heart. Its intensity is variable in different patients and occasionally in the same patient from time to time. It may alter its intensity or even disappear with change in the position assumed by the patient, although generally it is loudest in the recumbent position. It may also appear or disappear without apparent cause.

Two-thirds of the group had no cardiovascular disease. Most of them had no complaints having been seen in consultation because of suspected heart disease or they presented bizarre complaints of a minor or functional nature. Most of them were "nervous" people. The remainder of the group, twelve in number, had demonstrable cardiovascular disease. Five of

them had coronary artery disease, two of these and six others had arterial hypertension, usually mild in degree, and one had bundle branch block without other evidence of cardiovascular disease. Valve defects, congestive failure or congestive signs of any sort were not found. Only two patients had cardiac enlargement. Significant electrocardiographic abnormalities were absent except in four of those with coronary disease and the one with bundle branch block. No real incapacitation was present except in those with coronary artery disease.

Extremes of age were eleven and seventy-one years. With one exception in each group, those below forty-four years of age had no cardiovascular disease, those above forty-four had such disease. Males were predominant in the group with cardiovascular disease while there was no difference in the number of males and females in those without it.

None of the group are dead at the time of this report, while 46 per cent of the group with diastolic gallop observed over the same period are dead. The rarity of cardiac enlargement and physical incapacitation, the slight degree of arterial hypertension in those who had it and the complete absence of congestive signs all point to the benignity of systolic gallop rhythm.

It appears that none of the proposed theories as to causation of the extra sound can satisfactorily account for all cases.

CONCLUSIONS

1 Systolic gallop rhythm is more frequent than is commonly supposed.

2 It occurred in this series predominantly in "nervous" people. Heart disease is more often absent than present in patients with systolic gallop rhythm although serious heart disease may be present.

3 It has no unfavorable influence on prognosis.

THEELIN THERAPY IN VULVOVAGINITIS

BY RICHARD BETTS PHILLIPS, M D †

SINCE the introduction by Lewis¹ of theelin, the estrogenic hormone, in the treatment of vulvovaginitis in 1933, there have been a number of papers published on this particular aspect of hormone therapy. J. Brown², Huberman and Israeloff³, Miller⁴, and in England, Nabarro and Signy⁵. Other very interesting work has been published recently on the chemistry of this hormone, its apparent relationship to carcinogenic tar derivatives, and its effect on the male and female organism, Leo Loeb⁶, Cook, Dodds, and Hewett⁷, Burrows and Kennaway⁸, and A. Lacassagne⁹ (Vide infra).

Theelin* is the name given to the estrogenic substance by Parke Davis. Schering prepares it as Progynon. G. W. Carnrick has named its preparation Thelestrin, Squibb calls it Amniotin, and still other names by which this hormone is known are Menformon, Estrin, and Folliculin. Theelin has been found to have the formula $C_{18}H_{22}O_2$. It is lipoidal in type, with absence of nitrogen, and possesses a structural picture very similar to the male sex hormone, the corpus luteum hormone, and cholesterol, all of which are phenolic compounds.

The hormone theelin may be administered either intramuscularly or orally. The oral preparation is called Theelol by Parke Davis, and the oral dosage is approximately five times greater than the intramuscular. Dosage is estimated in rat units or in international units. The rat unit is approximately 3.3 times stronger than the international unit. The international unit is defined as the activity of one ten-thousandth of a milligram of a standard international crystalline powder identical with the theelin first described by Dr. Doisy. There are about 3,000 rat units per milligram of theelin. One Doisy or rat unit is equivalent to 3.3 international units. A Doisy rat unit is the smallest amount of estrogenic hormone which will induce estrus in mature but ovariectomized rats, as judged by cornification of epithelial cells in vaginal smears. The hormone must be the smallest amount which will cause this effect when administered in three divided doses, four hours apart. Twenty rats must be used in each test, and 75 per cent of these animals must show a typical response. One rat unit is equivalent to five mouse units. Wide variations in dosage have been described, from 25 rat units as administered by Raglan Miller⁴ intramuscularly in patients in whom a theelin reaction has been established, to 50,000 international units administered orally and intramuscularly in one dose by Nabarro and Signy⁵ of London.

*One-half of the Theelin used was kindly presented to us by Parke Davis & Company.

†Phillips, Richard Betts—Junior Assistant Surgeon, Department of Gynecology, Boston Dispensary. For record and address of author see This Week's Issue, page 1040.

Edgar Allen¹⁰ in 1928 showed that in the *Macaca rhesus* monkey a proliferation and thickening of the vaginal epithelium follow shortly after the administration of the ovarian hormone. Herein lies the rationale of this treatment as applied to vulvovaginitis. That is to say, one hopes that, by creating a temporary transformation of the immature vaginal epithelium as seen in young girls into one which is thickened and adult in type, a cure may be established. The upper layers of the vaginal epithelium become cornified, and increase in thickness from five to thirty layers or more. There is pronounced sloughing of this outer or functionalis layer (see figures 1 and 2). Fur-

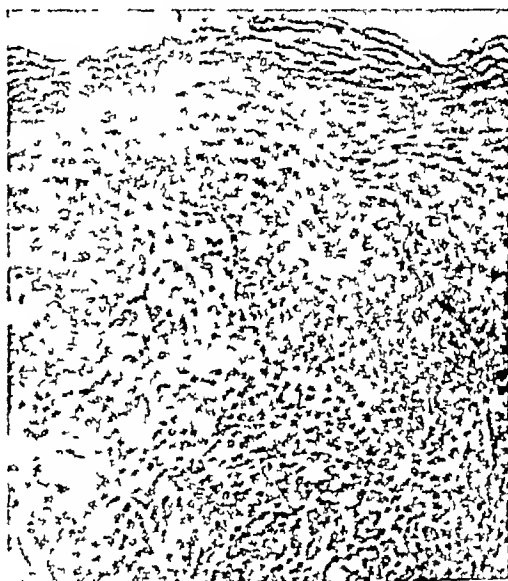

FIG 1 S. B. aged 8
Vaginal epithelium removed November 15, 1934. Treatment begun October 12. Total number of rat units of Theelin to November 15, 1934. The epithelium shows cornification, desquamation and marked hypertrophy. It is of a thickness of approximately thirty layers. The basal cells are undergoing active proliferation. The uppermost layer of the functionalis or outer layer can be seen to be desquamating.

thermore, there is a tremendous activity demonstrable in the basal cell layer, with mitotic figures in the cell nuclei and a heaping up of what might be called swollen cells in the intra-epithelial layer or the zone midway between the functionalis and basalis layers (see figure 2). It is thought that the sloughing of the epithelial cells (see figure 3) takes with them gonococci which are embedded in the uppermost layers of the epithelium. Furthermore, by keeping up the reaction over a moderate length of time (several months), one hopes to create a more resistant vaginal wall and thereby to prevent reinfection or relapse.

In our series of thirteen cases, treated in the Out-Patient Gynecological Department of the Boston City Hospital, we found eleven of the

children to have positive smears at the beginning of treatment. The other two had squamous smears, and all had from +++ to ++++ discharges. The smears were loaded with pus

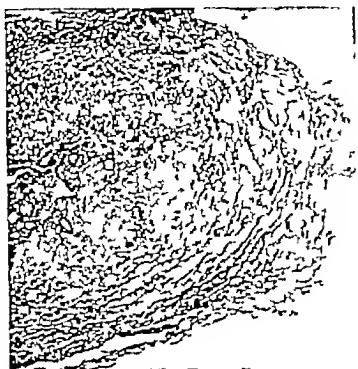

FIG. 2. M. J. aged 6.

Biopsy November 15 1931 four weeks after treatment had been instituted with Theelin. The patient had received 2100 rat units of Theelin at this time. The smears were still positive although a number had been positive in the preceding month. Note the cornification, desquamation and thickening of the epithelium. The basal cell membrane is hypertrophied. The arterioles are distended and the intra-epithelial layer is what might be called swollen or bulbous cells, while the functional layer is seen to be shedding flattened squamous epithelium.

FIG. 3. M. P. aged 6.

Smear taken with platinum loop on November 15 1931 same day as biopsy (see figure 2) and with large numbers of desquamated epithelial cells which are cornified. There are still a few pus cells present, but there were no gonococci evident. Both this patient and her sister aged three and a half, had positive smears in October.

cells and gram negative diplococci, both intracellular and extracellular in large numbers. Six patients had marked inflammatory reddening of the vulva, one with excoriation. Urethritis was present in two. Two children had marked

lower abdominal pain with slight temperature. In one of these patients (M. J.), a little colored girl, aged six, typical gram negative intracellular diplococci were found on performing direct paritoneal aspiration (Dr. J. Tartakoff). This latter case was our only patient who was hospitalized. She had been admitted with a diagnosis of acute appendicitis.

Our plan of treatment was as follows. Each patient received approximately from 700 to 900 rat units administered in three divided doses weekly. The smallest amount of theelin received by any patient was 2100 rat units, and the largest was 4460 rat units. Figures 1 and 2 show the effect of the estrogenic hormone on the vaginal epithelium following the administration of 1450 rat units in the one case, and 3300 in the other. It would appear that the theelin reaction is established when the patient has received in the neighborhood of 2,000 units. We used the theelin in oil preparation exclusively, not the aqueous solution. The former preparation is supposed to permit of slower and more uniform absorption of the hormone.

Weekly smears were taken throughout the entire period of treatment. The smears were taken by means of introducing a platinum loop into the vagina under reflected light, and scrapings of the vaginal walls obtained. After the first one or two examinations, we found that practically all the patients stood the examination with the greatest of ease. We performed vaginal biopsies once on each patient (see figures 1 and 2). On our charts we recorded the character of the theelin reaction as evidenced by the comparative number of cornified epithelial cells in the microscopic field, a diminishing amount of pus cells, and, of course the presence of the gonococcus. It was remarkable to note the rapidity with which the smears became loaded with epithelial cells in a short space of time, where previously there had been practically none of these cells. In every case one can notice a marked grayish tumescence of the hymen, visible to the naked eye. This is especially noticeable in colored girls. Raglan Miller¹ describes what he calls the "glassy" appearance of the vaginal smear when it consists almost entirely of epithelial cells, as contrasted with the "opaque" appearance when the smear is taken at the beginning of treatment and consists mostly of pus. We found the knee-chest position to be the best for securing vaginal wall scrapings. Figure 3 shows the large number of epithelial cells of adult type which nearly fill the microscopic field after the reaction is well established. Notice the contrast in these cells and the thin oval immature cell found before treatment.

The average age in our group was six and one half, the youngest three, and the oldest ten.

The average number of rat units of theelin administered was 3,160

At the end of ten weeks' treatment, when all patients were regarded as evidencing negative smears and no discharge in ten, and very slight discharge in three, all treatment was discontinued for six weeks. At the end of this time,

FIG 4
Vaginal epithelium of infant two and three-quarter months old. Autopsy specimen. In general but little change in thickness of layers is noted up to about ten years of age. Courtesy of Robert M. Lewis, M.D., Yale University School of Medicine, New Haven, Connecticut.

all were examined again and it was found that 70 per cent (nine out of thirteen) had relapsed. We do not believe that reinfection from extraneous source occurred in any of them. All mothers and fathers had been carefully checked up. Of the nine who were thought to have relapsed, three had positive smears, and six had suspicious smears. All nine had a return of their discharge, but not of such severity as before treatment with theelin. The four who were presumably cured were all subacute cases, and they have remained apparently cured to this date, April 1, 1935.

The economic and social features of vulvovaginitis are serious and far reaching. Oppenheimer and Everett¹¹ have published an interesting article on this aspect of the disease, and describe forty-three children who were kept out of schools in Washington, D. C., for from one to four years. We ourselves had one patient (A. de C.), aged eight, who was kept out of school for a year and a half and whom we finally were able to have taken back to school only after repeated effort. Oppenheimer and Everett¹¹ further emphasize the great loss, both economic and sociologic, which this disease may be responsible for.

Theelin is a most potent hormone, and its use is still attended with a certain unknown danger as to what the end result on the patient may be. By its exhibition menstruation can be caused experimentally in ovariectomized women and monkeys, and endometrium which has been atrophic can be proved to show hyperplasia (Werner and Collier¹²). Lacassagne⁹ has demonstrated the fact that the male may be influenced by theelin. He showed that following injection of estrogenic substance into male mice, the posterior lobe showed marked hypertrophy. He also showed that it was pos-

sible to increase the mammary cancer rate in mice by increasing the estrogenic substance. Burrows and Kennaway⁸ have produced estrus with enlargement of the horns of the uterus in mice and complicated with pyometra and peritonitis merely by applying this hormone to the non-epilated skin of the back. C. Clauberg¹³ showed that it is possible to stimulate even the smallest adult human uterus by means of large doses of follicular hormone and proved this by salpingography. Leo Loeb⁶ and Lathrop and Loeb¹⁴ demonstrated that with mice in whom early oophorectomy had been performed, there occurred a very marked diminution in the cancer ratio both in mice possessing a cancer susceptibility and in those that did not. Leo Loeb⁶ has further emphasized the apparent close relationship between estrogenic hormones and certain carcinogenic derivatives of tar. Cook, Dodds, and Hewett⁷ in 1933 have produced estrus successfully in mice by the use of a synthetic compound which is chemically closely allied to tar. Doisy, Veler, and Thayer¹⁵ showed that one milligram of the crystalline estrogenic hormone is equivalent to 3,000 rat units in potency. On the other hand, Robert T. Frank¹⁶ demonstrated that no estrogenic hormone could be detected one-half hour after injecting 2000 mouse units into a rabbit and that none could be found in the urine or tissues in the succeeding twenty-four hours. However, since it is well known that estrogenic substance will produce active epithelial cell proliferation (see figures 1 and 2), the question which naturally arises is, Will there be any harmful change in these young girls in either the near or the remote future? From a review of the results obtained to date in several clinics, and the experimental work on animals, one can feel moderately certain that the possible damage to any individual is minimal. J. Raglan Miller⁴ reported one case recently in which he had the opportunity of performing a biopsy on an ovary of a child who had received 1100 rat units of theelin, and the organ proved to be quite normal. Novak¹⁷ states in a very recent article that estrogenic substance is not a stimulant to ovarian activity, and adds "The fear that pelvic hyperemia produced by estrogenic substance may predispose to uterine and tubal extension of the vaginal infection is probably more apparent than real." This is in conformity with the progress of one of our cases, M. J. (Vide supra). Nabarro and Signy⁵ in London reported breast hypertrophy in one case which regressed upon cessation of treatment. They report no untoward results in any of their twenty cases, although they gave as much as 10,000 to 50,000 units intramuscularly in one dose, sometimes repeated, and in several cases 1,000 units per day for approximately three months. In three children receiving 3,000 rat units daily, the average length of treatment was cut down to twenty-eight days, and the last

positive smear was found sixteen days after beginning of treatment. Relapse occurred in four teen out of twenty after having been home an average of two months. These writers advocate large dosage treatment, 4,000 units by mouth at a time. Raglan Miller⁴ believes that in new cases treatment should be continued from four to six weeks with smaller doses in the neighborhood of 100 rat units daily and once the theelin response has been established then vigorous squamous cell reaction should be maintained for several months. This can be accomplished with a greatly decreased number of rat units, administered weekly. Miller further believes that estrogenic hormone is of value, no matter what organism may be responsible for the vulvovaginitis.

In June 1935 J. Thornwell Witherspoon¹⁰ of Tulane has reported an unsuccessful series of vulvovaginitis cases¹⁰ treated with estrogenic hormone, none of whom were cured. They all showed temporary improvement, however during the middle of his two to three months period of treatment. His results therefore have been slightly worse than mine. His dosages were somewhat similar.

CONCLUSIONS

1. Thirteen girls were treated in the Out Patient Department of the Boston City Hospital with theelin only for a period of four to six months.

2. The patients received approximately the same amount of theelin the average number of rat units being 3,160. The average age was six and one-half.

3. The discharges cleared up rapidly in all cases to a greater or less degree, and smears became negative in every case within four to six weeks of treatment. Six weeks after cessation of all treatment 70 per cent of the patients (nine out of thirteen) "relapsed." Two of the remaining four patients continued to have slight discharge which was negative and which cleared up after several more weeks of treatment. Two of the nine were cured after more treatment with theelin. Thus, seven appeared to be in statu quo in the final analysis.

4. No harmful results were noticed in any of our patients. Larger doses than we gave should not be administered since the epithelial response may be obtained with the doses outlined above. Larger doses may cause scar tissue formation in the ovaries, and it is possible that the menarche in these girls may be delayed or otherwise interfered with. These possibilities will be questioned until a report is published later, dealing with the onset of the catamenia in girls who have been treated with theelin.

5. Theelin (or other estrogenic hormone) may be used in the treatment of vulvovaginitis in conjunction with our other and standard methods of treatment. The cost has recently decreased considerably.

6. The criteria in following the treatment are

- 1 The presence of Gonococci
 - (a) Intracellular,
 - (b) Extracellular,
 - (c) Absent,
- 2 Presence of Pus
 - 1 plus
 - 2 plus
 - 3 plus
 - 4 plus
- 3 Epithelial Cells
 - (a) Amount
 - (b) Type, immature oval, adult cornified,
 - (c) Appearance of slide, "glassy", or "opaque",
 - (d) Biopsy of vaginal epithelium
- 4 Hymen

Grayish and edematous when the estrogenic hormone reaction is established

The Vaginal Epithelium Blocks were made by the Tufts Pathology Laboratory

CASE RECORDS of the MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

FOUNDED BY RICHARD C CABOT, M.D

TRACY B MALLORY, M.D., *Editor*

CASE 21471

PRESENTATION OF CASE

First Admission A thirty-five year old white American janitor was admitted complaining of swelling of the legs

Two weeks prior to entry the patient developed a sore throat associated with nasal discharge and mild headache. These symptoms continued for about three days and then subsided. At this time he noticed swelling of his ankles and, in the absence of other symptoms, continued with his work. The swelling gradually extended up his legs and he began to fatigue readily. A slight non-productive cough developed. He had a nocturia of one or two times since the onset of his edema but there were no other symptoms noted. Because of the increasing fatigue, after ten days he consulted a physician and was immediately hospitalized.

He had never had any previous illness of significance.

His family history is irrelevant.

Physical examination showed a well-developed and nourished young man appearing quite comfortable. There was marked pitting edema of the lower extremities, penis, scrotum, sacrum and lumbar region, and puffiness of the eyelids and to a less degree of the face. The tonsils appeared to be normal. The lower teeth were quite carious and discolored, the upper teeth had been removed. The fundi were negative except for slight tortuosity of the arterioles and a physiological cupping. The heart was not enlarged and no murmurs were audible. Gallop rhythm was heard. The blood pressure was 150/110. There were scattered rare medium coarse râles over the posterior chest bilaterally. The abdomen was slightly distended and tympanic and there was slight edema of the abdominal wall. Intraperitoneal fluid was not demonstrated clinically.

The temperature was 100.3°, the pulse 100. The respirations were 20.

The urine showed a large trace of albumin and a specific gravity of 1.032. The sediment contained 8 red blood cells, an occasional white blood cell and a few hyaline casts. Examination

of the blood showed a red cell count of 4,900,000, with a hemoglobin of 80 per cent. The white cell count was 4,900, 75 per cent polymorphonuclears. A stool examination was negative. The nonprotein nitrogen of the blood was 28 milligrams per 100 cubic centimeters. The serum protein was 2.8 grams per cent. A Hinton test was negative.

He was given a diet containing a low salt content with a protein component of 80 to 100 grams per day. Although the charted intake and output exhibited moderate fluid retention the patient's edema gradually subsided. His temperature dropped to normal twenty-four hours after examination and except for transient rises to 101° to 103° following intravenous injections of typhoid vaccine (25,000,000 to 100,000,000) at scattered intervals it remained at the normal level. At the end of the first week he became nauseated and vomited each morning. This subsided after six days. During this time his white blood cell count rose to 14,000, with 84 per cent polymorphonuclears. The serum protein was now 3.97 grams per cent, the chlorides 631 milligrams per cent and the nonprotein nitrogen 38 milligrams per cent. The urine continued to show a large trace of albumin and had a specific gravity varying from 1.002 to 1.032. The sediment remained similar to that of the admission specimen. During the third week a booming quality of the second aortic sound became evident. By this time the edema had almost entirely disappeared and the patient felt much improved. At the end of one month he again began to vomit and the edema returned. The blood pressure was 135/95 and a systolic murmur was now audible over the precordium. He was given a transfusion of 500 cubic centimeters of blood with no evident change in his condition. His hair was observed to be graying quite rapidly. Ascites appeared. He was given 3 grains of thyroid daily for five days without any clinical change. His vomiting ceased within a week. During the sixth week the edema diminished slightly but examination of the fundi revealed some haziness of the discs and fullness of the veins. Diuresis was not established, nor had his edema subsided completely, but he was sent home at this time for convalescent care.

Second Admission, five weeks later.

He felt quite well for two weeks and then there was a rapid return of edema and repeated vomiting of food directly after ingestion. Two weeks before entry he began to have slight blurring of vision and twelve days later developed diarrhea.

Physical examination showed generalized anasarca. The skin was dry and coarse. The fundi showed choked discs, small patches of exudate and rare hemorrhages. There was a slight systolic murmur audible over the precordium and a moderately accentuated aortic second sound. The blood pressure was 200/145. A few me-

drum coarse râles were audible at the angles of the scapula. The abdomen was tense and distended. The serotum was swollen to the size of a large grapefruit. There was marked clubbing of the fingers and toes, a finding which had not been recorded at his previous admission.

The temperature was 98°, the pulse 100. The respirations were 20.

The urine showed a specific gravity varying from 1.008 to 1.023. There was a slight to large trace of albumin. The sediment was similar to that reported upon his initial admission. The blood showed a red cell count of 4,500,000, with a hemoglobin of 75 per cent. The non-protein nitrogen of the blood was 24 milligrams, the chlorides equivalent to 106 cubic centimeters N/10 chloride per 100 cubic centimeters. The serum protein was 3.5 per cent, the cholesterol 555 milligrams per cent.

The urinary output continued slightly below the fluid intake except for a slight spontaneous diuresis directly following admission and a brief induced diuresis two weeks later following the injection of salyrgan. Vomiting ceased promptly after admission. On the third day intravenous injection of typhoid vaccine (100,000,000) produced a febrile rise to 102°. During the third and fourth weeks he received three grains of thyroid daily with a subsequent gradual rise of pulse to 120. The temperature remained normal. On the twenty-eighth day he complained of diminution of hearing and left earache. A reddened drum was noted and was treated expectantly. The temperature rose to 99° but subsided promptly. Three days later he developed right earache. The right drum likewise became injected. The temperature rose to 100°. The pain and fever subsided gradually but the patient remained partially deaf. During the fifth week he again began to vomit small amounts at irregular intervals after meals. This continued for the remainder of his hospital stay. On the thirty-fourth day the blood pressure was 160/120. The eye grounds were unchanged. The edema was still marked. He was drowsy at times but for the most part was quite cheerful. The white blood cell count was 20,000. The specific gravity of the urine now remained between 1.007 and 1.015 with a single specimen showing a specific gravity of 1.020. The non-protein nitrogen was 31. He was discharged on the forty-ninth day with little evident improvement.

Final Admission, a month and a half later. There had been no change in his condition until two weeks before entry. At this time his physician did an abdominal paracentesis. A few days later he developed a sharp pain in the right loin which radiated to the kidney region. This usually occurred after meals and was relieved by a sedative.

The patient had a pasty yellow face. The

abdomen was huge and there was massive generalized edema. Examination of the fundi showed slight haziness of the discs medially. There were some small hemorrhages and many whitish yellow exudates. The vessels were not remarkable. The tongue was dry. There was flatness over the lower half of both lungs posteriorly with absent tactile fremitus. Some bronchial breathing was audible in the area of dullness and was more marked on the left where egophony was also present. The heart was not enlarged and there was a rough to and fro friction sound heard best over the mitral area. The heart sounds were distant. The blood pressure was 125/105. A fluid wave was demonstrated in the abdomen.

Examination of the urine showed no change from the specimen previously examined. The blood showed a red cell count of 3,290,000, with a hemoglobin of 60 per cent. The white cell count was 12,300, 74 per cent polymorphous cells. A second abdominal paracentesis was done in which 7,500 cubic centimeters of fluid was removed. The specific gravity was 1.006, the total cell count 57 per cubic millimeter, red blood cells 29 per cent, lymphocytes 47 per cent.

Because of nausea and a capricious appetite the patient was permitted to eat and drink whatever he chose. There was no change in his general condition. During the third week another abdominal tap was done. The specific gravity was 1.002. Chlorides were equivalent to 90 cubic centimeters of N/10 sodium chloride per 100 cubic centimeters. The total protein was 8 per cent, the cholesterol was 86 milligrams per 100 cubic centimeters. There was little change in the cell content. During the fourth week the plasma proteins were 4.2 grams per cent. The non-protein nitrogen was 49 milligrams. The chlorides were equivalent to 84 cubic centimeters N/10 chloride. Because of restlessness he was given morphin. During the fifth week his respirations were between 6 and 10 per minute. He became progressively more drowsy and at the end of the sixth week, eight months after the onset of his symptoms, went into coma and died.

DIFFERENTIAL DIAGNOSIS

DR. MYLES P. BAKER. To single out a few of the more significant findings here, if we are dealing as I suspect, with a case of Bright's disease,—chronic glomerulonephritis—the appearance of the edema three days after the patient had had sore throat with nasal discharge is interesting and important, although the exact nature of the association remains decidedly in doubt. As a rule the appearance of edema as early as two or three days after the upper respiratory tract infection is more indicative of an exacerbation of glomerulonephritis than an

initial attack, in which the period between onset of tonsillitis or sinusitis, and the like, and the appearance of symptoms of nephritis is more often as long as a week or two weeks, ten days perhaps is the average

The statement of slight non-productive cough is interesting. It may be only an impression on my part but it seems to me that most of the few such cases that I have seen beginning with stubborn edema, presenting edema as the main complaint, have this irritative cough, perhaps definite moist râles at the bases, evidences of an ill-resisted bronchial infection

The nocturia of one or two times since the onset of the edema I hesitate to comment on, as no further mention is made of it. It seems hardly likely that this is the beginning of a compensatory polyuria with renal insufficiency because we have no other proof of that at the moment

Slight tortuosity of the arterioles in the fundi is an equivocal finding, but does bear out our impression that this man has had an insidiously developing renal lesion, for some time antedating the appearance of his symptoms. I think that, too, is borne out by the finding of the low level of serum protein, 2.8 grams per cent. It seems hardly likely that this level would be reached in such a short period of time as his symptoms would indicate. Presumably he had a marked proteinuria for some time largely albumin, and that had led to this depletion of serum protein

The urinary findings mentioned at this point are important here because they are the only specific mention we have of examination of the urine sediment. He has microscopic hematuria, a few white cells, which one would expect in this type of Bright's disease, and only a few hyaline casts. One generally finds in association with such marked proteinuria as this man has fatty granular casts with, frequently, doubly refractile lipid bodies in the urine sediment. The white blood cell count is such as you would see particularly after an upper respiratory tract infection, 75 per cent polymorphonuclears are consistent with secondary infection,—bronchitis, tracheitis and so on

This episode lasting a week, of nausea and vomiting, with leucocytosis, is unexplained. One wonders if there has been a recrudescence of upper respiratory infection, but we do not know. One wonders in such a case whether there is active poorly resisted pneumococcus infection in an ethmoid sinus, for instance

We have evidence of retained ability to concentrate the urine, and a suggestion that such gallop rhythm as was observed on admission was the result of some cardiac dilatation such as occurs with an acute phase of glomerular nephritis, and the booming quality of the aortic second sound indicates a more satisfactory cardiac function

No attempt was made to treat his tonsils by

radiation or surgery, nor have we any evidence that throat cultures were done. As a rule figures bear out the clinical impression that this type of nephritic does not respond well to tonsillectomy. One would hesitate not to treat pus under pressure in the sinuses, or tonsils around which there had been a peritonsillar abscess on their own merit. But a hunt for some focus of infection and eradication on vague indications does not help this type of unemittingly edematous individual. There appears to be a mediocre immune reaction, unimproved by, let us say, tonsillectomy

One wonders on the second admission how close this patient came to some cerebral episode such as has been described under the general heading of hypertensive encephalopathy with this marked rise in blood pressure and evidence of hypertensive neuroretinopathy

"He was given three grains of thyroid daily for five days without any clinical change." The pulse rate later increased. That is rather unusual. Usually most of these patients tolerate large doses of thyroid without any apparent tachycardia

DR WYMAN RICHARDSON: I do not think that was right. He got up to twelve or fourteen grains a day

DR BAKER: This second admission was punctuated after he had been in the hospital for four weeks by mild otitis media. He continues to have high blood pressure and the leucocytosis often seen in these cases. He is beginning to show difficulty in concentrating his urine, indicating fewer and fewer functioning glomerulotubular units

The physical findings on the third admission are interesting. They are consistent with fluid at both bases. The signs on the left make one wonder whether the man has a pericardial effusion, to which in some degree he is entitled with his general anasarca. To-and-fro friction sounds heard over the mitral area may be the first evidence of a fibrinous pericarditis with fluid in both pleural cavities. It may be a pleuropericardial rub. The distant heart sounds, the lowered pulse pressure and the lowered systolic pressure speak for fluid in the pericardial sac, or cardiac dilatation

Examination of the urine showed no change from the specimens previously examined

There is a high chloride content in the ascitic fluid, I believe a rather characteristic finding in these cases. The total protein is a little high for such a so-called "nephrotic" fluid

This man has been through most of the trials and tribulations of the essentially edematous nephritic, as Dr O'Hare chooses to call such a case. As far as differential diagnosis is concerned it seems to me highly unlikely that we are dealing with any other disease than progressive glomerulonephritis. One wonders about the possibility of amyloid disease but

amyloid disease in the presence of such definite hypertension and hypertensive neuroretinopathy as this man has must be a very rare finding. Amyloid disease does occur without any obvious focus for sepsis, but I think we can exclude it here as a most unlikely possibility. This man has had on physical examination definite signs of arterial damage and I take it that it is probable that his kidneys will show not only marked evidence of glomerulitis and tubular degeneration but also arteriosclerosis which may have contributed to the rather rapid tempo of his disease. I think it is quite likely that his kidneys will be fairly normal in size, perhaps the slightly swollen, large, pale kidney of essential ly edematous nephritis.

DR. TRAUB B. MALLORY Dr Richardson you saw this patient on the ward. Have you anything to add?

DR. RICHARDSON In the first place I am not sure he had clubbed fingers. I think they were very likely the hereditary type. When I first saw him he had fingernails that curved in both directions.

From the point of view of treatment one of the most difficult symptoms were the attacks of severe pain in the right epigastrium not in the right loin, coming on after eating at the time when he had marked ascites. It was very severe pain requiring a large dose of morphia for relief. I do not know now what the cause of this pain was, unless, associated with edema in the gastrointestinal tract, it was possibly some temporary obstruction.

In regard to the treatment, there is probably some question why typhoid vaccine was used in this patient. It was, I thought a brilliant idea of mine on the basis of previous patients I had seen, one in particular who developed an acute appendix when he was edematous with this disease. The appendix ruptured, operation being impossible, and he developed an appendix abscess and had a high swinging temperature when he had the most tremendous diuresis I have ever seen. When the nephrosis cleared temporarily, the surgeons went in and drained the abscess and he was well for a number of years. So when we discovered that this patient could not take a high protein diet—I did not feel very brave about the acacia intravenously that we hear about—it does not seem to me that the reports are very encouraging—and since we could not transfuse him frequently we did try the typhoid and if you look at the chart with hopeful eyes you will see an increase in output of 50 to 100 per cent, temporary improvement that was not lasting.

I did not see him during the last month of his illness, but up to the time I left I did not think he had any pericarditis or pericardial fluid. I agree with the diagnosis that Dr. Baker has made, although in the beginning I was inclined to think it was subacute. I agree that it

was long standing glomerulonephritis with acute exacerbation at the end.

About the tonsils, I again could not get very enthusiastic about fooling around in the throat although the tonsils did look infected.

DR. J. H. MEANS I was interested in the last note, the statement that the tongue was dry when he was water logged. I think that is an interesting relationship and one we see not infrequently. He was dehydrated and water logged at the same time. I remember a patient a year ago with a somewhat similar picture of dropsy and cerebral symptoms that could have been uremic or something else but the tongue was very dry indeed. He was given intravenous fluid in spite of his edema with marked improvement and marked diuresis.

I think the therapeutics are more interesting than the diagnosis, which does not interest me very much. The therapeutics are extremely complicated and we are very much in the dark about what to do with people of this sort. There is nothing in this history to tell what was done about fluid. It speaks of fluid balance but it does not say whether fluids were given freely or withheld except in the last paragraph where it says he was permitted to drink what he chose. I often think that letting the patient drink what he chooses is the best thing to do because nature knows more about what the body needs in the way of fluids than the doctor.

DR. RICHARDSON In regard to fluids by mouth, we could not get much into him. For long periods we gave large amounts of glucose by vein with a low salt diet. At the time of the first entry he had a high blood chloride.

DR. MEANS When you gave him intravenous fluids what happened to the fluid output? Did it give him a diuresis?

DR. RICHARDSON I do not think it did. It improved his general condition but the charted output did not show much change.

DR. MEANS What did the thyroid do in the way of producing diuresis?

DR. RICHARDSON Nothing. I think he got up to fourteen grams a day.

DR. MEANS That is a colossal dose if it is USP thyroid.

CLINICAL DIAGNOSIS

Chronic nephritis with edema

DR. MYLES P. BAKER'S DIAGNOSIS

Early chronic glomerulonephritis, with edema

ANATOMIO DIAGNOSES

Subacute glomerulonephritis.

Multiple septic infarcts of the lungs

Hydrothorax bilateral

Ascites

Sterile peritonitis

PATHOLOGIC DISCUSSION

DR MALLORY The kidneys here were essentially normal in size, weighing 270 grams, perhaps small for a man, but he was a small individual and all the other organs were proportionate. Grossly they were smooth and pale, consistent with a subacute nephritis or nephrosis. Microscopically there is a quite typical intercapillary glomerulonephritis. The tubules show comparatively little degeneration. The average case of Bright's disease with marked edema will show generally a pretty marked fatty degeneration of the tubules, but one can see the entire syndrome of nephrosis with absolutely negative tubules and changes apparently limited to the glomeruli.

The other point which Dr Baker raised in the differential diagnosis, as to how long this process had been going on, is not possible to settle exactly. It is a very common experience that the first symptom noted by a patient with Bright's disease comes at the very terminal stage, a few weeks or months before death, in an illness that later pathologic examination assures has been in existence for years, and it is almost always safe to bet that a case of nephritis is considerably more chronic than the clinical history might indicate. However, in this case I do not think that was true. The kidneys had not shrunk to a significant degree. There were very few completely sclerosed glomeruli and few changes in the blood vessels.

The heart was somewhat small in size, certainly no hypertrophy at all. There was no evidence of pericarditis.

The terminal pulmonic signs turned out to be emboli rather than bronchopneumonia. There was one rather large area of infarction and there were two quite small septic foci in the upper lobes with beginning abscess formation which I feel were septic infarcts.

A PHYSICIAN Was there anything in the gastrointestinal tract?

DR MALLORY Absolutely nothing.

DR BAKER Was the intestine edematous?

DR MALLORY Not noticeably so.

DR BAKER Do you think that diarrhea could be caused by edematous intestine?

DR MALLORY Diarrhea in the terminal stage of nephritis is usually associated with typical uremic colitis, but he did not have it.

A PHYSICIAN Did you find a focus for the emboli?

DR MALLORY No.

I neglected to mention that the peritoneal fluid at the time of autopsy was slightly hemorrhagic and somewhat turbid. It impressed us as a sterile peritonitis following hemorrhage at the last tap rather than an acute infectious peritonitis.

DR BAKER I would like to report that the patient whose history Dr Richardson cited has

been coming back to the Outpatient Department from time to time and now, four years after his serious illness, has no signs of even a latent glomerulonephritis. The sediment is entirely normal as far as we know, without doing Addis counts. There is no active renal lesion. After he left the surgical wards the first time he had to return two months later for treatment of a subdiaphragmatic abscess, and he was very sick for two or three months, but he has never had any return of edema.

A PHYSICIAN I should like to ask about the sediment of the urine in today's case.

DR BAKER It tallied with Dr Mallory's findings,—less evidence of tubular damage than one would expect in such an individual.

CASE 21472

PRESENTATION OF CASE

A sixty-four year old white native farmer was admitted complaining of abdominal pain, loss of weight and malaise.

One year before entry the patient had an attack of frequent loose watery bowel movements which continued for ten days. At this time he observed that his weight, which had been 200 pounds four years previously, had decreased to 174. This had followed no dietary restrictions or other known etiological factor. Following the cessation of the attack of diarrhea the patient continued to feel run-down and after three months consulted his physician who prescribed a diet and a tonic. He was told to avoid fatty foods. There was no improvement in his condition and he developed "chafing" pains in his right upper quadrant which caused him to lift his clothes from the involved area for relief. This recurred irregularly, often seven to eight times daily and then not at all for several days. These pains continued with little change up to his admission. For a year he had also suffered from cramplike pains in the lower abdomen which usually began one and a half hours after his noonday meal and often aroused him from his afternoon nap. The distress was promptly relieved by a teaspoonful of milk of magnesia but recurred at almost daily intervals. Two months before admission the patient made several visits to a clinic where x-ray studies of the gall bladder and gastrointestinal tract were negative except for the presence of diverticula along the sigmoid. He was also told that he had high blood pressure. At no time was there nausea, anorexia, vomiting or noticeable melena. His bowels moved regularly daily after his initial attack of diarrhea. He had developed a nocturia of three times during his illness. His weight had decreased to 151 pounds.

His father died at the age of sixty-eight of pneumonia, his mother at eighty-four of shock.

Several members of his father's family had had tuberculosis.

He had had typhoid fever but no other illnesses of significance.

Physical examination showed a well-developed and nourished elderly man who appeared to be comfortable. His thyroid was enlarged and firm. The heart was enlarged to the left and a systolic murmur was audible. A was greater than P₂. The blood pressure was 220/110. The remainder of the physical examination was reported as being negative.

The temperature was 99.6°, the pulse 70. The respirations were 20.

Examination of the urine was negative. The blood showed a red cell count of 3,300,000 with a hemoglobin of 55 per cent. The white cell count was 18,500, 72 per cent polymorphonuclears, 13 lymphocytes, 13 monocytes, 2 eosinophils. The platelets were reported as being normal. The stools repeatedly gave a strongly positive reaction to the guaiac test but were otherwise negative. A Hinton test was negative. The nonprotein nitrogen of the blood was 30 milligrams. The basal metabolic rate was +18 per cent. Analysis of the gastric content showed a free hydrochloric acid of 0 to 9 and a total acid of 3 to 15. The reaction to the guaiac test was negative. An electrocardiogram showed left bundle branch block.

A barium enema passed through the ileocecal valve without delay. There were a few small diverticula in the sigmoid. There was no evidence of spasm and the bowel emptied moderately well with defecation. A gastrointestinal series showed a small hernia of the stomach through the esophageal hiatus. The first part of the duodenum was long and the second part short. Some of the loops of the small intestine appeared to be slightly dilated but there was no evidence of any intraluminal disease.

Proctoscopy was done shortly after admission but no pathologic process was found up to a point 14 centimeters from the anus. The stools continued to react positively for microscopic blood and occasionally showed fairly large amounts of macroscopic blood. He remained in the hospital for one week and then returned to his home. Four days later he was readmitted stating that although his bowels had moved once daily they had been tarry in appearance and on that day they had been quite copious and fluid in character. He became weak and had frequent dizzy spells. Transfusion was given on the following day and two days later a laparotomy was done.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK. This man of sixty-four had apparently been sick for about one year and his initial symptom as near as one can tell, was an attack of frequent, loose, watery bowel movements lasting ten days. As-

sociated with this he first noticed loss of weight of twenty-six pounds, but he had not been weighed for the previous four years. There is nothing about the first attack of loose watery bowel movements which gives me any lead as to just why he had it. Presumably there was no gross blood. He did not have a complete recovery following cessation of diarrhea and that, presumably, can be taken as the beginning of this present illness. He had with that this "chafing pain" in the right upper quadrant. He has had cramp like pain in the lower abdomen and the striking thing about this pain is that it comes pretty regularly an hour and a half after the noonday meal and is relieved by milk of magnesia. It is my impression that not infrequently a patient, particularly beyond middle age, may refer the pain of a posterior wall ulcer to the lower abdomen or elsewhere. That is, he may not be definite about the location. The constant regularity with which it recurs and the fact that it is relieved by milk of magnesia may be of some significance. Later the x-rays were negative. That makes duodenal ulcer unlikely but does not exclude it particularly if it were a posterior wall one.

He had no more vomiting or diarrhea but he continued to lose weight, having lost a total of forty-nine pounds. There is nothing in the history up to this time that makes it possible for me to draw any definite conclusions as to what is the matter with him. His family history is negative. I do not believe the past history of typhoid means a great deal. He has an enlarged firm thyroid which I think is not significant. He does have, apparently cardiovascular disease. He has an enlarged heart, a hypertension of 220/110. He is essentially afebrile. He has a perfectly good pulse. On the laboratory side he has a pretty marked secondary anemia, also a leucocytosis, both actual and relative that is a polymorphonuclear increase. His blood is apparently normal from the point of view of platelets and there is nothing to enable them to say he was bleeding because of any blood disease. He has a persistently positive guaiac in the stools and at times he has gross macroscopic blood. In his vomitus where the hydrochloric acid is low he has a persistently negative guaiac. Therefore, it would seem to me that we can discount his stomach as having anything to do with the hemorrhage. More than that, it would seem at present that large quantities of macroscopic blood point pretty definitely to the fact that the blood must be lower down than the small bowel. I think it is possible for active hemorrhage from the upper bowel to come out of the rectum as macroscopic blood but it does not occur very often and I never had seen it. Therefore it seems to me that it must be coming from the large bowel.

A barium enema was negative except for a few diverticula of the sigmoid. We cannot accept these as having anything to do with the hemorrhage.

The diaphragmatic hernia I think can be passed by. There are occasional cases of secondary anemia associated with diaphragmatic hernia but I think in this instance that that cannot be a factor because of the negative guaiac in the stomach contents and positive guaiac and the gross blood by rectum.

The proctoscopy was negative for a distance of fourteen centimeters. It does not say why it was not passed higher or whether there was any blood in the rectum at that time. I do not think the statement of a negative proctoscopy is particularly helpful to a person who is trying to interpret it, but I might assume from the negative proctoscopy that they saw nothing in the mucous membrane or any evidence of blood, either localized or coming down from above.

DR RICHARD H SWEET That is correct.

DR MCKITTRICK The association of bloody diarrhea and abdominal cramps of course brings several things to mind immediately. At least one of them is ulcerative colitis. I believe a negative x-ray and negative proctoscopy exclude ulcerative colitis. Carcinoma of the large bowel has not been excluded. It is perfectly possible and surely not at all unlikely to have a carcinoma of the large bowel in the absence of a positive x-ray. Carcinoma of the hepatic flexure particularly may not show by x-ray. On the other hand, about eighty per cent of lesions in this location have a palpable mass and a negative x-ray plus absence of a palpable mass make this unlikely. The proctoscope did not get high enough to exclude another blind area 18 centimeters up, which is the common site for polyp and cancer and difficult to visualize by x-ray. In other words, I am not able at this time to make what to myself is a satisfactory diagnosis in this instance, but I cannot exclude a lesion of the rectosigmoid.

He has cardiovascular disease. I do not believe that a mesenteric thrombosis can very satisfactorily give this picture.

Therefore, I am forced to leave this today without a definite diagnosis except to say that I believe his bleeding is from the large bowel. I do not think he has a carcinoma. I do not believe he has a diffuse polyposis and I feel very sure that he does not have an ulcerative colitis.

X-RAY INTERPRETATION

DR AUBREY O HAMPTON This is the chest film. It is practically normal except for enlargement of the heart and calcification in the midlung field. There is no enlargement of the glands and nothing to suggest malignancy. I did not fluoroscope this patient but these films

of the stomach show nothing abnormal except for this small hiatus hernia through the diaphragm. I think the variation in the length of the duodenum was probably due to pressure from the colon upon the stomach displacing it upward. This hernia of the stomach is the commonest type of hernia and is surprisingly common in old people. It is probably normal. The barium enema filled the colon perfectly satisfactorily. It is a little bit dilated in the proximal portion. The evacuation is not quite so complete as usual but certainly the dilatation did not persist. You cannot say he had an obstruction. In this film you get the impression that the spleen is enlarged. Here is the mucosal relief of the sigmoid just proximal to the rectosigmoid and it is perfectly normal except for this diverticulum-like pouch.

CLINICAL DISCUSSION

DR TRACY B MALLORY Dr McKittrick has left the case wide open.

A PHYSICIAN How about bleeding from Meckel's diverticulum. Would that be possible?

DR ARTHUR W ALLEN Would he not have had that earlier in life?

DR DANIEL F JONES Several things might clarify it a little. In the first place he had pain one and a half hours after meals which is about the time for pain in large intestine obstruction. He had blood in the stools constantly. He had irregular bowel movements, mostly diarrhea. The textbooks talk about constipation in carcinoma of the rectum. The surgeon rarely sees patients with constipation in cases of carcinoma of the rectum. It is much more often with frequent loose movements. I think that if many physicians could get that into their minds they would not go astray on so many cases. By the time patients get to the surgeon they have diarrhea, which is a very improper term to use. The patients themselves rarely admit that they have diarrhea. They do have anywhere from five to twenty-five episodes a day when they have to go to stool to get rid of a little gas, mucus or blood and frequently very little stool, so that the word diarrhea is a very improper term to use to the patient. You have to talk the language of the patient in order to find out what he means. Now that puts it very definitely, it seems to me, in the large intestine. That might be a polyp or malignancy. Polyps would frequently cause diarrhea or frequent movements without any great amount of obstruction but you must account for some obstruction here by the frequency with which he has pain. It is true that you occasionally get pain in the lower abdomen from an ulcer but that is much more frequently due to a gastroduodenal ulcer than an ordinary gastric ulcer or ordinary duodenal ulcer.

As to proctoscopy, I should like to say that

in a man with a loss of weight and diarrhea and pain I do not think it is fair to say that the proctoscopic examination is negative when you go only 14 centimeters, because 18 centimeters as Dr McKittrick said, is the most frequent site for a polyp and if you are going to use a proctoscope you should at least go up to the rectosigmoid junction because that is the difficult place to see a growth by x ray and it is a little difficult to get by also with a proctoscope. If he cannot get by this region the surgeon should know why.

As to diverticulitis and bleeding I think that it is a very important question. I think you should not consider that diverticulitis causes bleeding. It does have a little blood occasionally. I am not sure of the figures but the only records that I have seen state that there is a little blood in five or six per cent, so that you cannot go much on that and you ought not to in this man because he has lost so much weight, from two hundred pounds down to one hundred and seventy four.

I do not know about arterial disease but I think that it very rarely gives pain regularly after each meal. Therefore, I do not think it can be due to arterial disease. Occasionally these people lose weight. It would not be likely that a patient would lose as much as this man so that I think that it is much more likely that this is a carcinoma or malignant disease of the colon or a polyp.

DR. SWEET: There are two or three facts in the history that Dr McKittrick should have had. As it is he certainly made an admirable job of his discussion. The man was sent in with the diagnosis of probable undulant fever because the outstanding symptom was recurrent attacks of chills and fever. He had been to several other doctors. One had treated him with emetin. Every few weeks he had a spell of fever with chills, the last persisting attack of fever and chills was about three weeks before he came in here. We could not make a diagnosis. Incidentally, he had had no bleeding from the rectum until after he came into the hospital and then he had a massive hemorrhage on the day following proctoscopic examination. It is not fair to say that the proctoscopy was negative. The reason I could not get beyond fourteen centimeters was that there was something which seemed to be outside of the bowel which made it impossible to turn the corner of the sigmoid. The x ray had shown us that he had diverticula and I thought he might have an inflammatory mass resulting from that which made it impossible to get around it. There was no sign of polyp or tumor and no blood was seen.

One other interesting point which Dr Schatzkin brought out was that he had several dilated coils of intestine in the x ray. Another point in the history was that he had had two definite attacks suggesting bowel obstruction during the preceding year with vomiting and acute illness, one attack lasting four days.

At operation we found a tumor of the sigmoid which I thought of course was carcinoma. This had perforated and caused a local abscess in the pelvis, not a large abscess, however. It also perforated into the ileum and he had a fistula between his ileum, about eight or ten inches above the ileocecal valve, and the sigmoid. I wonder if the fact that he passed tarry stools was not due to bleeding from the ileal side of the fistula so that the blood went around the colon and thus to the rectum rather than directly down the rectum, in which case the blood should have been bright red.

PREOPERATIVE DIAGNOSIS

Intestinal hemorrhage.

DR. LELAND S. MCKITTRICK'S DIAGNOSIS

Hemorrhage from colon—cause undetermined

PATHOLOGIC DIAGNOSIS

Lymphoblastoma, sarcomatous type

PATHOLOGIC DISCUSSION

DR. MALLORY: The examination of this tumor showed that it was not carcinoma but a lymphosarcoma. The great majority of the tumor lies in the outer layers of the wall of both the sigmoid and the ileum, the mucosa being relatively free in each instance. I do not find it possible to say with certainty from the specimens in which of the two structures it originated, although there was more tumor present in the sigmoid than the small intestine. The patient recovered from the operation and is still under observation.

DR. SWEET: He now has a palpable spleen and a very abnormal blood picture which Dr Hunter thinks is rather suggestive of early lymphatic leukemia. His polymorphonuclear count is down to twenty and he has a lot of abnormal lymphocytic series cells in his blood.

DR. JONES: May I say that it is not fair to say that the proctoscopic examination was negative. I want to call it to your attention that errors are made with a proctoscope very often because the examiner does not feel with the end of the proctoscope. It is a perfectly legitimate thing to do.

CLINICAL APPLICATIONS OF HETEROPHILE ANTIGENS AND ANTIBODIES

UNTIL quite recently, the terms, heterophile antigen and antibody, were used by only the most erudite of immunologists. The latter term was applied to the nonspecific antibody produced by the injection of certain bloods or organ and tissue extracts into certain animals, a phenomenon originally described by Forssman in 1911, who demonstrated the presence of anti-sheep hemolysins in the sera of rabbits that had been injected with guinea pig organ extracts. The antigens capable of producing such antibodies are contained in the organ and tissue extracts of guinea pigs, horses, mice and pigeons and in the bloods of sheep and goats. They are absent in another group of animals, including rabbits, cattle, pigs and rats, and in these animals heterophile antibodies can be produced by the injection of the antigen. Man is peculiar, as the antibodies are present or can be developed even though the antigen has been demonstrated in red blood cells of groups A and AB. More recent work has shown that the antigen is present in cer-

tain bacteria, such as members of the typhoid-paratyphoid-dysentery group and pneumococci.

Heterophile antibodies can usually be demonstrated in the sera of normal human beings, but, when present, are in very low concentrations. In certain diseases, notably infectious mononucleosis and certain blood dyscrasias, it has recently been shown that such antibodies are markedly increased. So much so, in fact, that the demonstration of anti-sheep hemolysins in high dilutions of freshly obtained serum from a suspected case of infectious mononucleosis practically confirms the diagnosis.

The practicing physician is now confronted with a prophylactic and a therapeutic procedure, both of which have been developed on the assumption that the presence of such antibodies, either produced actively by the administration of the antigen or injected passively, is of the utmost significance.

The first is an oral vaccine which has been recommended^{1, 2} as a prophylactic agent against the common cold. The active constituents of this vaccine consist of the dried bodies of an avirulent, non type specific pneumococcus, containing heterophile antigen, and a hemolytic mouse virulent streptococcus. In the clinical report, 462 vaccinated individuals showed a decrease of 57 per cent in the number of colds for the school year as compared with the average number per year for the preceding three years, whereas the 527 controls showed a decrease of only 12 per cent. Among 30 carefully studied cases, the development of appreciable heterophile antibody titer was associated with almost complete immunity. In spite of such excellent results, one must be extremely cautious in adopting such a procedure until more confirmatory evidence has been presented. One should not forget that the probable etiologic agent of the common cold is a virus, that parenteral injection of most vaccines is more efficient than oral administration and that even the parenteral injection of vaccines for the common cold is of distinctly questionable benefit.

The second is the addition of heterophile antibody to antipneumococcal serum³. On the basis of the stated, but not necessarily proved, facts that horse serum and pneumococci contain heterophile antigen, that union of these antigens with the protective heterophile antibodies in the patient diminishes the efficacy of such antibodies and may produce untoward reactions and that such sera have been proved to be more effective (in rabbits), it is claimed that the preliminary treatment of antipneumococcal horse sera with heterophile antibodies and their addition to such treated sera result in a product which gives fewer reactions and may be used against all infecting types. Finland, Rueggsegger and Felton⁴ have justly criticized these theoretical claims, after having failed to show that heterophile antibody has any relationship to

the course or outcome in human cases of pneumococcal pneumonia? They question the contention that this serum is less toxic. They call attention to the fact that advances in the serum therapy of pneumococcal pneumonia can be attributed to the results obtained in cases treated with adequate amounts of homologous serum. If the claims made for the serum containing heterophilic antibody are accepted, they believe that a certain number of patients will fail to receive sufficient amounts of homologous antibody, because of the absence of "typing" and others will be exposed, unnecessarily, to the hazards of administration and the expense of a serum of questionable potency. They acknowledge that their opinions are not based on direct observation of the use of fortified sera and rightly conclude that such observations, in the last analysis, furnish the final criteria on which the use or discard of this product should depend.

THE SOCIALIZATION OF MEDICINE

WHAT is this socialization of medicine of which so much is said, and of which so little is actually thought through? One does not get a very clear idea from the views expressed. Something is going on in medicine, some important change is taking place, and we are on our way, although we do not know whether the path will lead us. It is said also that physicians are backward, even blind, in failing to recognize this inevitable progress and adapt to it themselves and their practice.

Socialization of medicine means to make medicine conform to the principles of socialism. Since the socialists perhaps most of all, fail to agree as to the principles of socialism, how can others be expected to know what it is all about?

Socialism and individualism are permanent tendencies in human nature, as an ultimate philosophy either is inadequate and so misleading. In the division of labor it has been found expedient to have certain functions ultimately controlled by society at large, directly controlled by society organized politically, that is to say by the government. These functions are performed for the whole by the parts. Under com-

plete and perfect socialism, if such there be the government controls and directs every part. The question as to whether a function is or is not performed socialistically is settled by the answer to the questions: Who directly pays the bill? Who directly controls the group? Of course, in the long run society pays the bill in any case. It is to be remembered that a given socialistic scheme is not intrinsically better because it is socialistic, neither is it intrinsically worse. The outcome can be determined only by experiment. The method of science includes controlled experiment. It is true that history repeats itself, but never quite exactly.

Education is one of the socialistic enterprises to which we are committed. There are students of education however, who think that our very commitment to this socialistic enterprise has made more imperative than ever the need of our continuing to develop our private educational system.

The question at issue in medicine does not concern primarily the quality of medical service. That is to say, it is not that the science and art of medicine are so far behind what one has a right to expect. It is a fact that the science of medicine has progressed so far, and that the art of medicine has become so complicated and thus so expensive that the average citizen can not pay the cost for all medical services out of his own resources. The socialization of medicine means that the cost of medical care should be met by the government and not by the individual. Control goes to the person or organization responsible for the payment of the bill.

Again and again we have found that the governmental hand has had a paralyzing influence. Indeed so often has this been true that many persons look askance at the injection of the government into any undertaking. If mere quality of service, dollar for dollar is considered, is there anything the government does that would not be done better by private competitive enterprise?

Yet many times it has seemed wise, even necessary, to have the government interpose—to protect the weak against the strong, the poor against the rich, the ignorant against the knowing. Is there any justification besides protection?

What justification is there for the socialization of medicine? Against whom do the sick need to be protected? Is it against the medical profession?

If it has been expedient perhaps necessary, to socialize medicine in some fields, to protect the well against the sick, and the poor and the ignorant against themselves, is not this the best of reasons why medicine should not be wholly socialized, why more vigorous efforts than ever should be made to preserve part of it, at least, from the dry rot of governmental influence?

BOSTON MEDICAL LIBRARY

ROBERT HOOKE, 1635-1703

THE subject of this biographical sketch was one of the remarkable geniuses of the 17th Century, in a general way comparable in its diversity and imaginative foundation to the genius of Leonardo da Vinci. He lacked, however, that very essential quality of mind which enables a versatile individual to "follow through" in his strokes of genius. This may perhaps have been due to the multiplicity of ideas that were always crowding each other in his mind and demanding attention. To have originated, as he claims to have done, a hundred new inventions within an average lifetime, he might well be excused if some details were left incomplete. Besides the discoveries that may unquestionably be credited to him, he provided a clue to many another that was later recorded by some other observer. The intense mental activity that characterized his entire career should have had a more robust physical background than he seems to have possessed. In early youth, on account of his lack of physical stamina and the persistent headaches from which he suffered, he was regarded as poor material for the life of study that his quickness of wit seemed to entitle him to pursue. In view of the turn his mind took when left to itself, it would seem that science might have suffered more than the church would have benefited, had he been made to follow the course originally blocked out for him by his father, the Reverend John Hooke, who was minister to the parish of Freshwater on the Isle of Wight.

It was here that Robert Hooke was born on the 18th of July 1635. Interest in him from a medical viewpoint rests upon his activities in the Royal Society, that distinguished body of scientists whose approbation all research workers in whatever field of science sought. After his father's death in 1648, he took the 100£ left him by will and went up to London at the age of thirteen where for a short time he was a pupil of Sir Peter Lely. Later he entered Westminster School and lived in the house of Dr Busby. Here he manifested some of that intellectual precocity so frequently an accompaniment of genius. He acquired Latin, Greek and some Hebrew and other oriental languages, mastered six books of Euclid in one week, and of his own volition learned to play twenty lessons on the organ and "invented thirty several ways of flying."

In 1653, at the age of eighteen, he was enrolled at Christ Church, Oxford, as a chorister. He secured his M.A. Degree upon the recommendation of the Chancellor of the University in 1663. Because of his aptitude for mechanics he made the acquaintance of many prominent

men at Oxford and was enabled to pursue his studies in Astronomy and Chemistry. Proficiency in the latter resulted in his becoming, as associated with Robert Boyle whom he assisted to perfect his air pump. He worked with him until released to become the curator of experiments for the Royal Society as a recognition of a commendation of his upon capillary attraction. He was elected a Fellow of the Royal Society in 1663 and later in the year became custodian of its collections an office that later he was chosen to fill permanently, on a salary with quarters which he occupied during the remainder of his life. His income was supplemented by appointment to a lectureship in the Society, the subjects upon which he was to lecture to be determined by the Society. In 1665 he was appointed Professor of Geometry in Gresham College and as locum tenens for Dr. Pope he gave the lectures in Astronomy for two seasons.

He became greatly interested in respiration, combustion, the laws of falling bodies, specific weights, diving bells, land transportation, telegraphy and the relationship of barometrical readings to changes in the weather. In reference to many of these matters, his results were inconclusive but his interest in them indicates the activity of his mental processes.

He contributed to the methods of measuring time by inventing a machine to fashion the teeth of watch wheels and by measuring the variations of swinging pendulums. He published his *Micrographia* in 1665 in which were recorded numerous curious and interesting observations many of which were anticipatory of knowledge later to be more definitely established. Among them was a theory of light which he regarded as a "short vibrative motion." Heat, also, he conceived of as being a property of matter dependent upon the vibration of its composite particles. He anticipated Mayow's conception of the nature of combustion by eleven years.

In a paper on gravity, the force of which he showed could be measured by the oscillations of a pendulum and in a subsequent communication on curvilinear motion, offered a demonstration of the fact that the center of gravity of the earth and the moon is a point that describes an ellipse about the sun. He declared that the movements of planetary bodies are problems in mechanics.

He invented the first screw-divided quadrant and an anemometer of a form that, up to quite recently at least, was regarded as adapted for universal use. At about this same time, he devised a "weatherclock" and applied the principle of the circular pendulum to watches. He submitted himself to experimental study in an exhausted receiver and found time to give lectures on the nature of earthquakes. In 1667, he prepared a model to illustrate the rebuild-

ing of the city of London after the great fire but his plan was not accepted though it procured for him a lucrative position as city surveyor. Several thousand pounds, accumulated through his activities as a surveyor, were found in a chest after his death. He designed a number of public buildings. By some, he is regarded as the originator of the biological concept of the cell. At any rate, his *Micrographia* served to stimulate other observers in the Royal Society, notably Nehemiah Grew, to prosecute his important studies upon vegetable histology and physiology. In the field of Astronomy, Hooke made a number of original observations pertaining to the orbits and behavior of several of the planets but for the most part he lacked the mathematical knowledge that would have enabled him to follow the clues through to their conclusion. Particularly was this true in connection with his views upon gravitation about which he had a rather acrimonious controversy with Sir Isaac Newton, in which he claimed priority of discovery.

His jealous and peevish temper frequently brought him into conflict with workers in the fields of science. Some of these controversies only embittered his opponents, others either halted the announcement of valuable discoveries or postponed them for so long a time that others obtained the credit for their discovery. In the case of the application of the spiral spring to watches, there was no question of Hooke's priority of discovery but owing to a disagreement about the terms of a patent which Boyle volunteered to procure for him, credit for the invention passed on to Huyghens in 1675, seventeen years after its discovery by Hooke. For certain of his venomous criticisms of Oldenham, the secretary of the Royal Society, he was taken to task and forced to recant. After Oldenham's death, however, he was chosen his successor which position he filled from 1677-1682, editing seven numbers of the philosophical transactions of the Society. In his later years, he continued his investigations and there was scarcely a single invention of his period that he did not make or claim as his own. He did actually make about one-half of the discoveries of his age. He designed an anticonstiction, suggested a practical method of telegraphy, a universal joint, a sounding machine, the anchor escapement for clocks and many other mechanical devices. He also extended his interest into the fields of science, for he had ideas on the nature of fossil formation and the succession of living things upon the earth, which have been shown to be sound in the light of present day knowledge. His last invention a marine barometer, was described for him, before the Royal Society by Halley. This was in 1700. He was created a Doctor of Physic at Doctors Commons in 1691.

Always of insignificant stature, stooped in his carriage, even in youth, this attitude became a deformity in later years. Intensely active, quick-moving and restless, he burned himself out at about sixty-four years of age and his remaining three years were for the most part unproductive. The last year he became wholly blind. Death claimed him on the third of March, 1703. He lived an essentially monastic life, lacking in all the social virtues that human associations cultivate, an unlovable character. Even his genius suffered because of his estrangements from his fellows and much that he might have had the credit for, ultimately went elsewhere. Appraisal of the significance of the life of such a man is difficult. If the "capacity for taking infinite pains" is essential to the make-up of a genius, then Robert Hooke was not in that class. Probably mere versatility falls short of true genius. Some, however, of the mechanical devices he either invented or paved the way to the discovery of, were the first steps in Watt's and Stephenson's steam engines in the mechanical field, and the perfection of the microscope, the telescope and various meteorological instruments of precision, in the purely scientific fields. For these it is fitting that the part he played in advancing civilization should not be forgotten on this his Tercentenary.

GONORRHEAL INFECTION COMPLICATING PREGNANCY

Gonorrhea complicating pregnancy is not uncommon. Rapid invasion of the infection, before a developing pregnancy has blocked the uterine cavity, not infrequently results in termination of that pregnancy. Early miscarriage, therefore, in these cases is common. It very frequently happens that the etiological background is obscured by those symptoms referable to the miscarriage. Especially is this true of miscarriage followed by febrile reactions and acute pelvic symptoms. This latter represents, in a certain number of cases, the invasion of the pelvis by the gonococcus infection which

follows rapidly the emptying of the uterus. In all miscarriage cases, and especially those occurring with the first pregnancy shortly after marriage, one should make a careful inspection of the meatus for clinical evidences of gonorrheal infection, and if there is any question, repeated smears from the urethra and cervix.

In pregnancy complicated by a gonococcus infection, treatment of the latter should be vigorously carried out, using the same technique, as would be used if the patient were not pregnant. One should employ the douches, suppositories, and local treatment, customarily used in these cases. A warm sitz bath, a cleansing douche, followed by a vaginal suppository containing two per cent mercurochrome, or one-half grain of methylene blue, with, if necessary, local applications to cervix and urethra of mercurochrome, is a dependable treatment. The knee-chest position after insertion of the suppository is an important detail.

A mercurochrome tablet against the cervix, retained by a dry wool tampon, with a small piece of mercurochrome tablet in the urethra, retained by a cotton pledget, is excellent office treatment in these cases.

At the end of the eighth month of pregnancy, treatment should cease, this because of the assumed theory that vaginal procedures prior to delivery increase the danger of puerperal sepsis. It has been repeatedly demonstrated that this active treatment during the first eight months of pregnancy will not cause miscarriage or premature delivery. Repeated smears should be taken throughout this period as a check on the progress of the treatment, and intercourse, naturally, is absolutely interdicted.

The management of the delivery of the patient with an active gonococcus infection raises two important points. First, special prophylactic measures for the baby's eyes, and secondly, the possibility of the infection of the obstetrician's eyes by a spatter of vaginal discharge during delivery. For the latter, glasses are a valuable protection and if any question of contamination arises, the immediate adoption of prophylactic treatment is most important.

In regard to the baby's eyes the wise procedure in these cases is to institute active treatment, as if infection of the baby's eyes had actually occurred. It is wisest from all points of view, to delegate this care to an ophthalmologist. In the absence of the latter, the baby's eyes at birth should receive the usual prophylactic treatment and then at least twice daily for ten days, have the eyes washed out with boracic solution with the instillation of twenty-five per cent argyrol. The eyes should be carefully inspected twice daily and at the slightest suggestion of redness or discharge the ophthalmologist must be consulted. This active treatment in it-

*A series of short selected articles by members of the Section is being published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the Section.

self not infrequently produces a mild inflammatory reaction. With a beginning gonorrheal ophthalmia, the first smears are very apt to be negative, and no obstetrician is justified in assuming responsibility for what a given case may or may not be.

Symptoms resembling puerperal sepsis follow usually late, delivery of the woman infected with gonorrhea are frequently encountered representing pelvic invasion following the removal of the obstructing pregnancy. The terminal manifestations of such an invasion are often abscess formation, primarily in a tube or tubes, but easily becoming the characteristic type of pelvic abscess. The ultimate pathology differs in this respect from the pus type in the non-puerperal state which very uncommonly develops into a typical pelvic abscess.

A not uncommon complication of gonorrheal infection is abscess in Bartholin's gland. The usual management of these should be followed. Those which are allowed to rupture spontaneously have a very much higher percentage of permanent cures than those that are excised. Warm borax sitz baths, repeated several times daily seem to hasten spontaneous rupture and to lessen the discomfort. Such an abscess may rupture during delivery. In cases observed there has been no noticeably increased post-delivery morbidity and lacerations have healed by first intention. The liberal use of antiseptics during the delivery of such a case is indicated.

Subsequent to the lying in period the patient should be carefully investigated to determine if there is a persisting gonococcus infection which, if discovered, necessitates a continuation of active treatment.

It should also be remembered that a very considerable number of infections in women are acquired shortly after their recovery from child birth. In these cases the irregular and excessively protracted flow is frequently attributed to delayed involution rather than to its real cause. Cases which describe too frequent "menstrual" periods within a few months post partum should be viewed with definite suspicion until the possibility of a recently acquired infection is ruled out. The characteristic symptom of the invasion period of the disease, discharge, under these circumstances is of course very easily assumed to result from the usual child birth injuries the excessive flow to delayed involution displacements, etc. The appearance of the urethra in these cases, is the most important single guide to a correct appraisal of the situation. A case with the above symptoms in the postpuerperal period, which has an inflammatory reaction in and about the meatus should be assumed to have a gonorrheal infection until the contrary is proved by innumerable smears.

THIRD ANNUAL POSTGRADUATE MEDICAL EXTENSION COURSE

The following sessions have been arranged by the Committee for the week beginning November 24

Barnstable

Sunday November 24 at 4 00 P.M., at the Cape Cod Hospital, Hyannis Subject Kidney and Bladder Diseases A (Surgical) Hematuria Its Significance in Surgical Diseases of Kidney and Bladder Instructor S B Kelley J I B Vail, Chairman

Bristol South (Fall River Section)

Monday November 25 at 4 00 P.M. at the Stevens Clinic of the Union Hospital Fall River Subject Lung Collapse Therapy Instructor G L Stivers Eugene A. McCarthy Chairman.

Essex North

Friday November 29 at 4 00 P.M., at the Hotel Bartlett, 95 Main Street Haverhill Subject Accident Work in Cases Covered by Insurance Practical and Professional Considerations Instructors Mr Charles Horan and H. C Marble. Francis W Anthony Chairman

Essex South

Tuesday November 26 at 4 00 P.M., in the Nurses Home of the Salem Hospital Salem Subject Kidney and Bladder Diseases, A (Medical) Acute Nephritis—Etymology Diagnosis and Treatment. Nephrosis and Its Treatment. Instructor L H Hoyt. Walter G Philpen, Chairman.

Hampshire

Wednesday November 27 at 4 15 P.M. in the Nurses Home of the Cooley Dickinson Hospital, Northampton. Subject Pediatrics The Neonatal State and Its Diseases Medical and Surgical Aspects Instructors L W Hill and H. W Hudson Jr Robert B Brigham Chairman.

Middlesex South

Tuesday November 26 at 4 15 P.M., at the Cambridge Hospital Cambridge Subject Cancer of Stomach, Bowel and Genito-Urinary Tract. Modern Care of Inoperable and the Incurable The Development of Improved Methods of Caring for These Cases with Less Pain and Discomfort with Minimum of Drug Therapy Instructors R. C Graves and Horatio Rogers Edmund H. Robbins Chairman.

Norfolk South

Monday November 25 at 8 30 P.M. at the Quincy City Hospital, Quincy Subject Arthritis (a) Medical Care of Patient in the Home. (b) Orthopedic Treatment in Hospital and Aids in Home Treatment. Instructors F R Ober and C S Keefer David L Belding Chairman.

Plymouth

Tuesday, November 26, at 4 00 P M, at the Brockton Hospital, Brockton Subject Kidney and Bladder Diseases, A (Medical) Acute Nephritis—Etiology, Diagnosis and Treatment Nephrosis and Its Treatment Instructor J M Flynn W H Pulsifer, Chairman

Worcester North

Friday, November 29, at 4 30 P M, at the Burbank Hospital, Fitchburg Subject Neurological Aids in the Diagnosis and Treatment of Disease from the Medical Viewpoint Problems of History and Examination with Special Reference to (a) Neurosyphilis, Multiple Sclerosis and Other Degenerative Conditions (b) Diseases with Acute Onset, such as Meningitis and Cerebral Accidents Instructor T J Putnam Edward A Adams, Chairman

PHYSICAL THERAPY

The Committee on Physical Therapy of the Massachusetts Medical Society is prepared to assist any city or county medical society with advice and, in so far as is possible, to provide speakers for programs of medical meetings during the coming winter.

Talks, demonstrations, and motion pictures may be arranged in order to bring, to the general practitioner, practical suggestions as to the value and possibilities of physical therapy in the treatment of his patients. Many simple procedures of physical therapy which have proved of value should be more generally employed. These, as well as other methods, will be discussed. It seems to the Committee that the place which such measures may occupy in the treatment of many disorders might well be emphasized.

The following subjects are offered

The Present Status of Physical Therapy

Physical Therapy in General Practice

Body Mechanics, Posture Training, and Therapeutic Exercise

Massage—Indications and Effects

Pathological Conditions Helped by Physical Therapy

Phototherapy (Radiant Light and Heat)

Hydrotherapy

Diathermy, Medical and Surgical, including Short Wave

The Committee is glad to welcome inquiries or requests

FRANKLIN P LOWRY, M D

GEORGE R MINOT, M D

ROBERT B OSGOOD, M D

MISCELLANY**AIR CONDITIONED AMBULANCES**

Air conditioned ambulances, embodying the world's first commercial application of the new principle of controlled atmosphere for automobiles

which is expected ultimately to become standard equipment on all passenger motor vehicles, are shortly to bring greater safety and comfort to New York's ill and injured.

Following an announcement before the Motor Bus Operators' convention in New Orleans that custom made weather for motorists has reached the stage of engineering reality, Willis G Gray made known recently that installation of the first of these motor car air conditioning units would be in one of the ten ultramodern "hospital rooms on wheels" which his concern operates in Manhattan, Brooklyn, the Bronx and London, England.

"Invalid transportation offers the most advantageous of fields for application of automotive air conditioning," said Mr Gray. "Invaluable medical advantages and practical comforts will accrue to the sick from controlled atmosphere in ambulances.

"They can be moved in a moderate temperature in summer and kept comfortable and uniformly warm in winter. They will breathe only the purest of purified air, filtered and humidified or dehumidified. By keeping the windows closed at all times, the air will be kept constantly and completely clean within, even when it is dirtiest without, and all draft will be entirely eliminated.

THE USE OF PUBLIC FUNDS

A scathing denunciation of the proposed use of public funds by the PWA for a futile public health project was published in the November 1 issue of the *New York State Journal of Medicine*, the official organ of the Medical Society of the State of New York, which comprises among its membership 13,074 of the practitioners of the state.*

"The project," states the *Journal*, "calls for a survey of deaf children in Monroe County, New York, at a cost of \$10,440. The prospectus states that Monroe County contains sixty of these children. Other evidence from the head of the Bureau for Handicapped Children in the New York State Education Department at Albany accounts for only fourteen such, exclusive of those already in the Averill Avenue Nursery. Hence, it is intended to spend \$10,440 to survey these fourteen children."

The Medical Society of the County of Monroe, according to the *Journal*, has remonstrated against this step through its Public Health Committee, which reports that the plan has been studied by a subcommittee on Deafness and Hard of Hearing.

"Such a project," states the *Journal*, "has no health value whatever. It presupposes subsequent training of the deaf child for which no provision is made, and its value is emphatically questioned by educators. Since it is impossible to detect deaf children before the age of three years and, since the public and special schools take them over at five years of age, the whole project is limited to children between three and five years.

"The project is an unwarranted intrusion into a medical and educational problem by sponsors who

are not certified as competent by either medical or educational authorities. In times of great depression such as we are living through it would hardly seem possible that funds could be wasted on so futile a project. —*Bulletin, Public Relations Bureau N Y State Medical Society*

MASSACHUSETTS BOVINE TUBERCULOSIS

The Department of Agriculture has designated Massachusetts as a modified accredited area practically free from bovine tuberculosis. The total number of accredited states is thirty-one.

A CRISIS CONFRONTS NEW YORK CITY

Mr S W Reyburn chairman of the commerce and industry committee of the United Hospital Campaign Committee, affirms that a real crisis confronts New York City's 107 voluntary hospitals which are running into debt \$4,500,000 annually. Several have already closed their doors and some have completely exhausted their funds. To meet the situation a public appeal will be made for \$2,500,000.

AIDS TO MASSACHUSETTS STUDENTS

More than \$50,000 is being paid out to Massachusetts students each month by the National Youth Administration according to statements by Mr Arthur G Rotch. The money distributed is for work and wages in a school.

Students in Middlesex College Massachusetts College of Osteopathy and the Boston College of Physicians and Surgeons have received small grants.

The three Class A Medical Schools were not included in the recently published list.

THE HEALTH SURVEY

On Friday November 1 an important conference was held at the headquarters of the Massachusetts Medical Society at which Mrs Miriam Steep regional supervisor of the survey representing the Surgeon General of the Public Health Service outlined the plan of procedure and informed the group that Miss Rose Flynn would be in charge of the project in Massachusetts and would have headquarters at 41 Pearl Street in Boston. Those attending the conference were Dr Henry D Chndwick, State Commissioner of Public Health Dr Charles E. Monahan President of the Massachusetts Medical Society Dr A. S. Begg Secretary and Drs Walter A. Lano Ernest L. Hunt Michael A. Tighe Francis H. Dunbar of the Public Relations Committee and Dr Dwight O'Hara of the Committee on Public Health.

It was decided that the State Society would cooperate in every possible manner and that the officers of the District Societies, in which the studies are to be made, would be instructed to render all possible assistance. The nature of the investigation is such as to make it mandatory for the physicians of Massachusetts to give it their support if the results are to have any value. Mrs Steep and Miss Flynn ex-

plained the method by which the enumerators would be trained and discussed in detail the schedule which is to be completed for each family study. They pointed out that these schedules are confidential and would not be made available for any purpose other than that of tabulation. Each schedule as completed by the investigator is to be cross-checked in the local office and immediately sent to the headquarters in Detroit for tabulation. Matters which concern diagnosis are to be referred to the physicians who were in charge at the time the diagnosis was made. No diagnosis made by a nurse or lay person will be accepted. The entire program is to be carried out as a project under the Works Progress Administration and will provide work for a considerable number of the so-called white collar class.

GENERAL PLAN OF THE HEALTH SURVEY

A. Purpose — The United States Public Health Service cooperating with the state and city health departments is making a Health Survey and Study of Chronic Illness and Physical Impairments in the general population.

Information regarding the extent and severity of chronic diseases and physical impairments is meager and health authorities cannot prevent disease unless they know when, where and under what conditions it is occurring. The relative prevalence of various types of disease, the geographic location, the age, sex, occupation and in particular the relation between disability and employment of persons affected will be studied. All this information is necessary before chronic diseases and disabilities can be prevented and controlled with the same degree of effectiveness as has been achieved during the past 50 years in the control of communicable diseases such as typhoid fever, smallpox, diphtheria, scarlet fever, etc.

Modern preventive medicine has increased the expectancy of life from about 40 years in 1870 to 60 years in 1935. But nearly all this good record has been due to the prevention and control of infectious diseases of childhood. It is now proposed to study the causes of chronic illnesses and disabilities which usually appear after middle age and which are so intimately associated with occupation and with the economic and social status and habits of the people. A careful analysis and study of the collected data will provide the Federal and State health authorities with information which it is hoped will serve as a basis for specific recommendations for the prevention and control of the chronic diseases.

B. Scope — The survey is to be carried on in 19 states, divided into 5 areas. Large cities, smaller cities and towns and selected rural communities will be included*. A list of the states and cities which have been selected as bases of operations is included in Section 4. In the large cities sample areas will be selected for enumeration. In smaller cities and towns the survey will include all families.

*The centers of the five areas in Massachusetts are Boston, Fall River, Greenfield, Ipswich and Pittsfield.

Rural communities will be selected in areas where supervision and enumeration can be most satisfactorily arranged and where a representative sample of rural families can be interviewed

The survey will include interviews with 750,000 families in about 95 cities and towns. An average personnel of 3500 will be engaged on the project with a peak employment of five to six thousand persons

C Duration—The survey will begin on October 15 and will require from four to five months for enumeration and editing in the field, and a somewhat longer period for coding, tabulation, and analysis. The field work will consist of the house-to-house canvass of a predetermined number of families in each city or community, careful editing of the schedules for completeness and consistency, a verification of diagnoses by doctors who attended the cases, and in some places transcription of records of hospitals, sick benefit associations, a survey of medical facilities, and probably, a survey of communicable diseases. The last four will be covered by special instructions later if they are included in the survey and become the responsibility of the present organization

The field work for the Health Survey has been planned to end not later than March 15, 1936. It is hoped that in many cities, towns and rural areas it may be completed before that date

The purpose of the Emergency Relief Appropriation is to provide the means for useful employment of persons who have been receiving relief. Therefore, the rules promulgated by the President and the Federal Works Progress Administrator require that nearly all of the persons employed on this project shall be taken from relief rolls. In order that the work may be conducted in an efficient manner provision is made for employment, in essential positions, of a few nonrelief persons, whenever it is found that no competent persons are available from relief

DRINKER RESPIRATOR PATENTS HELD INVALID

The District Court of Massachusetts has recently held invalid three patents numbered 1,834,580, 1,906,453 and 1,906,844, granted to Philip Drinker and Louis A. Shaw in an infringement suit brought against John H. Emerson by Warren E. Collins, Inc., manufacturers of hospital equipment in Boston, who were sole licensees under the patents. The defendant, John H. Emerson, maintains a machine shop in Cambridge for the manufacture of hospital and research equipment, and began the manufacture of respirators in 1931

The patents covered the construction of apparatus for producing prolonged artificial respiration, especially for human beings suffering from infantile paralysis as well as in cases of gas poisoning, electric shock and drowning. These respirators worked

admirably and have been in great demand for use in hospitals since 1929

The court found that the defendant began to make his respirators after having seen the Drinker respirator. The defendant, however, excused his infringement on the ground that the patents were invalid because all the alleged novel features covered by the patents were old and disclosed in the prior literature

After considering all the evidence and prior publications produced by the defendant the court agreed with the defendant that the Drinker patents were invalid. The important features of the patent claims of all three patents were found to be anticipated by prior publications, some as far back as 1876, or by prior-issued patents

The patent statutes permit the defendant in an infringement suit to excuse his acts if he can definitely prove that the patent or patents on which the suit is brought are invalid on account of prior knowledge, use or publication more than two years before the filing date of the patent application on which the patent was granted — *Abstract from "Drinker respirator patents held invalid," by Joseph Rossman Science 82 221 (Sept 6) 1935*

THE WARREN TRIENNIAL PRIZE

The Warren Triennial Prize, of five hundred dollars, which was founded by the late J. Mason Warren, in memory of his father, and which is awarded every three years to the author of the dissertation considered most worthy of a premium, has been given by the General Executive Committee of the Massachusetts General Hospital to Dr. Norman E. Freeman, for his essay entitled "The Physiology of Gaugrene." Honorable mention was given to Carl C. Speidel, Professor of Anatomy of the University of Virginia Medical School for his essay entitled "The Phenomena of Nerve Irritation and Recovery, Degeneration and Repair, as Revealed by Prolonged Observation of Individual Fibres in Living Frog Tadpoles." Previous to 1934 there have been sixteen awards of this prize, thirteen going to men in this country and three to foreigners

SEDGWICK MEMORIAL MEDAL PRESENTED TO DR. HAVEN EMERSON

The American Public Health Association at its sixty-fourth annual meeting in Milwaukee awarded the Sedgwick Memorial Medal to Dr. Haven Emerson of the College of Physicians and Surgeons of Columbia University. The presentation was made by Dr. William H. Park, of the Department of Health of New York City. The medal was established in honor of the late William Thompson Sedgwick, of the Massachusetts Institute of Technology, and is awarded for distinguished service in public health — *Science, October 18, 1935*

DR. AND MRS WOJTASINSKI ARE FOUND
GUILTY

Dr Walter Wojtasinski and his wife, Katherine of Ashmont street Dorchester trading as W Wojtasinski Drug Company of Boston manufacturers of 'Katro-Lek', a patent medicine were found guilty November 14 1935 by a federal district court jury of mislabeling the product in violation of the Pure Food and Drugs Act.

The verdict was reached after the jurors had deliberated five hours On recommendation of Charles A. Rome assistant U S attorney who prosecuted, the case was continued for sentence by Judge George C. Sweeney

The government claimed that the circulars and packages had misrepresented falsely the curative and therapeutic remedies of "Katro-Lek."—*Boston Herald November 15 1935*

FOOD AND DRUG FAKERS

The November 13 1935 *Bulletin of the Department of Agriculture* gives details of more than twenty-five prosecutions with convictions for illicit trades in medicines and foods.

Manufacturers and sellers of medicines with fraudulent claims for the cure or relief of a great variety of diseases, have been fined in large amounts of over a thousand dollars in several instances.

These reports show remarkable success in controlling the distribution of alleged remedies and adulterated foods, for which the public is paying large sums of money

Such expenditures are wasted and in most cases of drugs more than wasted, for in many cases the resort to such preparations leads to neglect of effective treatments.

CORRESPONDENCE

SUPRARENAL CORTEX EXTRACT IN THE
TREATMENT OF VOMITING IN PREGNANCY

Worcester State Hospital
Worcester, Mass

November 6, 1935

Editor, *New England Journal of Medicine*,

In the issue of the *Journal* of Volume 213, p 885 of the week of October 31, the article under the Section of Obstetrics and Gynecology outlining treatment in the cases of vomiting in pregnancy has not taken into account one of the latest methods of therapy which seems to be very beneficial. This treatment consists of intramuscular injections of suprarenal cortex extract.

The articles of Kemp in *Endocrinology* (16 434, 1932), and in the *Canadian Medical Association Journal* (28 389, 1933), also Freeman and Melick in the *American Journal of Obstetrics and Gynecology* (29 602, 1935) would indicate that this treatment has proved effective when other methods have failed. The rationale behind the treatment would appear to be the substitution of an active principle of the suprarenal gland which shows a relative deficiency during pregnancy. It could be postulated that in these cases the hypertrophy of the adrenal gland, which is prone to occur in normal pregnancy, has not been sufficient to take care of the extra load on the mother and for this reason relative deficiency in cortical hormone occurs. This leads to nausea and vomiting of the same type as is found occurring in Addison's disease. The giving of small amounts of suprarenal cortical extract appears to be specific therapy for this condition.

Very sincerely yours,

JOSEPH M LOONEY, M.D.,
Director of Laboratories

IODINE AS AN ANTISEPTIC

Mallory Institute of Pathology
Boston City Hospital
Boston, Mass

Editor, *New England Journal of Medicine*,

The letter from Dr Elliott C Cutler in the November 7th issue of the *Journal*, relative to the recent editorial on "Iodine as an Antiseptic," is deserving of comment. Dr Cutler admits the *in vitro* germicidal efficiency of iodine, but questions its value as an antiseptic, particularly in relation to skin disinfection. It should be noted that no reference to skin disinfection was made in the editorial. Furthermore, the solutions referred to were all aqueous and one would not expect such to be used on the skin, unless the latter had been prepared in some way so that these aqueous solutions could penetrate the hair follicles and sweat glands. Be that as it may, the writer feels that little, if any, experimental evidence has been submitted which has proved iodine to be less effective than any other anti-

septic, regardless of how or where it is used. Even those authors referred to in Dr Cutler's letter, who might be considered the most impartial, came to the conclusions which are at variance with what he maintains. Simmons (U S Army Medical School) concluded, in part, in his 1928 article that "from the standpoint of bactericidal action, tincture of iodine (U S P) was found to be far superior to any of the solutions when used on the unbroken skin" and in his 1933 article that "mercurochrome should not be considered as a substitute for iodine", and Smith (Medical Corps, U S Army) concluded, in part, that iodine is "an excellent skin disinfectant".

The majority of recent articles on antiseptics reveal the marvelous bactericidal and bacteriostatic properties of certain mercurial compounds and it is the latter—the bacteriostatic or growth inhibiting property—which has led to many conclusions which, to the writer, are false. Shippen was the first to draw attention to the fact that in the standard *in vitro* bactericidal tests sufficient amounts of mercurial compounds may be contained in the single loopful of the antiseptic-culture test mixture to inhibit growth in the culture tube. For this reason, he recommended that a second transfer be made from the first culture tube to a second. A specific example may be taken from experiments conducted in this laboratory. In tests using the "F.D.A. method (special) *S aureus*, 37°C," certain mercurial compounds did not show growth in the first culture, but did in the second, of transfers from test mixtures ranging in concentration of the antiseptic from that recommended for use to a dilution of 1:32. As the test mixture contained 50 cc of antiseptic plus 0.5 cc culture, the transfer (1 loopful) 0.02 cc. and the culture 100 cc, this means that a usable solution

1	5	1	1	1	
concentration of	$\frac{1}{32}$	$\frac{1}{55}$	$\frac{1}{50}$	$\frac{1}{10}$	$\frac{1}{17600}$
	is suf				

ficient to inhibit the growth of the staphylococci, even though the undiluted antiseptic is unable to kill the bacteria under the conditions of the experiment. In skin scraping and biopsy tests, such as those cited by Dr Cutler, mercurial compounds have shown up exceptionally well, but no suitable controls, comparable to the Shippen modification, can be made for bacteriostatic concentrations. The antiseptic and bacteria are intimately connected with the material and, unless cultures have been applied to the skin, effective bacteriostatic dilutions are undoubtedly much higher, due to the relative scarcity of bacteria.

It is acknowledged that the bactericidal effect of iodine is diminished by the presence of serum, but the writer has failed to find any mercurial antiseptic which, in the recommended usable concentration combined with an equal amount of horse serum, will kill *Staphylococcus aureus* in five minutes. On the other hand, a 1:32 dilution of Lugol's Solution, U.S.P., will kill under identical conditions. Some mercurial compounds, mercury oxycyanide (1:4000), mercurochrome (1:50), merthiolate (1:1000) and

merphenyl nitrate (1:5000) will not kill in these usable concentrations even in the absence of serum.

As Dr. Cutler has stated "the true appraisal of an antiseptic is a difficult measure. Numerous properties have to be taken into consideration and many claims have to be disproved. So much trash has appeared in the advertisements of commercial antiseptics within recent years that an attempt at an impartial evaluation has been undertaken in this laboratory. Although the work has not been completed everything to date points to iodine as the most efficient ~~second~~ antiseptic. If equitable and comparable tests can be devised for testing skin disinfectants the writer feels that iodine will again emerge on top.

Very truly yours,

ROBERT N. NYE, M.D.

PNEUMONIA DEATH RATE

The Commonwealth of Massachusetts
Department of Public Health
State House, Boston

November 6, 1935

Editor *New England Journal of Medicine*

On October 26, 1935, *The Boston Herald* printed a dispatch from New York to the effect that the death rate in pneumonia can be reduced by 50 per cent by the use of newly developed serums. In part this is true, but the statement needs qualifying. About three-quarters of all pneumonias appear due to pneumococci. These organisms, however, are not all alike and by immunological methods can be separated into distinct types at least thirty-two of which have been recognized in this and other countries. There are serums available to combat pneumonias due to some but not all of these types. Satisfactory serums have not been produced for the treatment of cases caused by other organisms.

The early use of potent serum has been shown to reduce the death rate of pneumonias caused by Type I pneumococcus by over 60 per cent and in Type II cases by nearly 50 per cent. Pneumococci of these two types are of the greatest importance and are responsible for about one-quarter of all cases of pneumonia. Serums used to treat such cases can scarcely be called "newly developed" as they have been in use since 1910. Within the past six to eight years serums have been prepared against several of the other types of pneumococci. They have been somewhat extensively used in New York City and good results are claimed from the treatment of pneumonias caused by these types—such as Types VII and VIII and a few others. Sufficient cases treated with and without such serums have not yet been obtained to establish their value clearly. Nevertheless the results appear very encouraging.

The usual death rate of Type I cases not given serum is about 25 per cent. This can be reduced to 10 per cent if serum treatment is begun within the first four days of illness, and to 7 per cent when such treatment is begun within three days of the

onset. Similarly in Type II cases the usual death rate of 40 per cent can be reduced to 25 per cent or less by early treatment.

A study of pneumonia death rates brings to light the interesting fact that nearly two-thirds of pneumonia deaths occur in males. Excess death rates for males from birth to puberty and from twenty to sixty years of age have been found. This is especially true in the latter age group in the most highly industrialized communities and tends to disappear in rural areas. Further, in the United States pneumonia appears far more prevalent along the Atlantic seaboard from Maine to Georgia (inclusive) and in a group of Southwestern states encompassing the Colorado Plateau than elsewhere.

A study of the ten original registration states and of Massachusetts death rates from pneumonia indicates that only a slight downward trend has occurred during the past thirty-five years. Thus pneumonia as a cause of death is but little less common than formerly.

Very truly yours,

RODMOR HEBBORN, M.D.

In Charge of the State Department
of Health Pneumonia Study

DR. CHARLES H. MAYO EXPLAINS CERTAIN QUOTED STATEMENTS IN NEWSPAPERS

Editor *New England Journal of Medicine*

The following is an account of what happened at the meeting of the Inter-State Post Graduate Medical Association of North America in Detroit and a digest of my words and thoughts.

I had my manuscript with me but spoke without it. My main subject was Goiter and the Changes in Its Treatment. I recalled the cretins whom I saw several years ago in Switzerland when visiting Dr. de Quervain. Cretins are seldom seen now because of recognition of the disease and administration of thyroid, either to the patient or to the expectant mother, also by administration of thyroid to myxedematous persons; they can be rendered mentally active. When the thyroid is oversensitive as it is in exophthalmic goiter there is a markedly increased metabolism. These varied states are due to deficiency or increase of thyroid secretion with secondary effect on the capillary circulation of the body including one would expect, that of the brain.

Reduction in the circulation not always continuous might conceivably bring on mental changes in conditions in which the thyroid was not involved. These changes may go on for varying periods in the early stages, but eventually become permanent and close in part, the function of the brain. Vascular constriction when it occurs in other parts of the body than the head, as it does in Raynaud's disease, is not necessarily permanent in the early stages. Emotional disturbances are known to be potent in the crises both of Raynaud's disease and psychical disorders. This similarity in the course of the vascular condition and of certain psychic conditions

tends to suggest that the vascular constriction may be a factor in the psychic abnormality

There is experimental evidence that control of the circulation of the brain can be exerted through the carotid bulb, but it cannot be denied that to prove an effect on the circulation of the brain is difficult, because the vessels of the brain are relatively inaccessible. Nevertheless, the head is an extremity of the body, just as are the hands, and it is well known that when the blood vessels of the hands are not obliterated but are constricted, as they are in Raynaud's disease, they can be made to dilate by local anesthesia, general anesthesia, or induced fever, and that permanent dilation can be brought about by the operation known as cervicothoracic sympathectomy. Also, a temporary good effect has been produced in certain forms of insanity by applying, to the head, methods similar to those that have been applied to the other extremities. There seems nothing unreasonable in the assumption that the cause of the observable effect on the mental condition in early cases might be the same as the cause of the observable effect on the hand or the foot, if the arterial condition of the brain in certain types of insanity is analogous to the arterial condition of the hands and feet in Raynaud's disease. At all events, the treatment has been tried, notably in the catatonic form of dementia praecox.

I do not think that the physicians before whom I spoke were for the most part startled by what I said for they heard the context and my inflections and thus were in a position to sketch in a background which I thought I implied but knew that I had not time to delineate. I said that the effects of the treatment had worn off in three weeks, but I voiced the hope that methods of injection or operation would be found to make them permanent in treatment of patients who had not been mentally affected for too long a time. I spoke to stimulate others to seek methods of controlling the circulation of the brain, such as have been found to control the circulation of other extremities. I estimated that at least five years would pass before such methods would be found.

If my expression of a hope inadvertently took the form of a prophecy it would not be strange, for, in more than fifty years of the practice of medicine, I have seen very many times when the general opinion was that all that would ever be known or done in a certain field already was known or had been done. I never believed this in any instance and I have not been disappointed in my hope that in any field concerning which science has a hint, ultimately more would be known.

However, the effects in the forms of insanity which I referred to have been only temporary, and not I, my colleagues, nor any others of whom I know, are yet prepared to effect a cure.

Sincerely yours,

CHARLES H. MAYO,
Rochester, Minn.

November 9, 1935

RECENT DEATHS

BLANCHETTE—ALEXANDER BLANCHETTE, M.D., of Haverhill, Massachusetts, died in that city, November 13, 1935, by suffocation due to a fire.

Dr. Blanchette was born in 1869 and graduated from the University of Bishop College Faculty of Medicine, Montreal, Canada, in 1892.

GOODWIN—EDWARD EVERETT GOODWIN, M.D., of 436 Elm Street, Brockton, Massachusetts, died in the Emerson Hospital, Boston, November 6, 1935.

He was born in North Mariaville, Maine, October 28, 1864, the son of Mr. and Mrs. George P. Goodwin.

After his early education in Maine public schools he studied in Dedham and Brockton schools, later attending Boston University School of Medicine, graduating therefrom in 1899.

He was a Fellow of the Massachusetts Medical Society and the American Medical Association. In addition to his professional activities he was prominent in religious and civic organizations including the Massachusetts Homeopathic Society, the American Institute of Homeopathy, the Boston Surgical Society, the Brockton Medical Society, Paul Revere Lodge, Free and Accepted Masons, Satucket Chapter, Royal Arch Masons, Brockton Council, Royal and Select Masters, Bay State Commandery, Knights Templars, Massachusetts Consistory and Aleppo Temple, Ancient Arabic Order of Nobles of the Mystic Shrine.

He is survived by his widow, Mrs. Myrtle E. (Hollis) Goodwin, two daughters, a brother, and two sisters.

OBITUARY

DR. LEONARD WHEELER*

Leonard Wheeler, M.D., for sixty-five years a member of the Massachusetts Medical Society and from 1872 to 1912 a practicing physician in Worcester, died at his home there October 2, 1935, aged ninety years and thirty-two days.

Born in Lincoln, where his emigrant ancestor settled in 1642, he prepared for college at Phillips Exeter Academy, joined the sophomore class at Harvard in 1863, graduated in 1866 and in 1870 received his M.D. degree, after three years at the Harvard Medical School and one as medical interne at the Massachusetts General Hospital. The next two years he spent in medical studies in Breslau, Leipzig and Vienna, coming in close contact in the latter city with such men as Rokitsansky, Freund and Schroeder. In 1872 he came to Worcester as Superintendent of the Worcester City Hospital, organized the previous year. This hospital, at that time the only one in the city, had but eight beds and the Superintendent was allowed, in addition to his duties there, to attend to private patients at their homes.

*Presented to the Worcester District Medical Society by the committee duly appointed.

As a general practitioner giving special attention to obstetrics and operative gynecology Dr Wheeler ranked for forty years among the leaders of the profession in the city and county. In 1874 he resigned his superintendency but retained his connection with the hospital until his death sixty-three years later serving as visiting physician until 1888 as obstetrician from that time until 1896 and for the remainder of his life as consulting obstetrician and a member of the general consulting staff.

Soon after he came to Worcester the Washburn Free Dispensary was opened and from 1876 to the time of his death he was connected with that institution with the Memorial Hospital of which the Dispensary became the Out-Patient Department when the hospital opened its doors in 1888. He served on the hospital staff as physician and surgeon until 1900 when he became a Trustee was President of the Board from 1904 to 1917 and Vice-President from 1917-1925.

He was a member of the Consulting Staff of St. Vincent Hospital for twenty-five years was a Trustee of the Foxboro Hospital 1905-07 Secretary of the Worcester District Medical Society 1872-76 Vice-President 1893-95 President 1895-97 and Vice-President of the Massachusetts Medical Society 1906-07.

A charter member of the St. Whistan Society of the Worcester Club and of the Tatnack Country Club he was also a member of the American Anti-Quarian Society, the Worcester Fire Society the Worcester Art Museum, of various other civic organizations and of the Harvard Club of Worcester and the Union Club of Boston.

In 1881 he became a Corporation of the Worcester County Institution for Savings a Trustee in 1889 and for the last thirteen years of his life served as one of its three Vice-Presidents.

A discriminating student of history a writer of numerous medical articles the Librarian for many years of the local Medical Society's library it was always a pleasure and a privilege to listen to his opinions on medical social and historical matters.

Handicapped for many years by various physical disabilities he retained to the very end of his life a keenness of mind that was a delight to everyone that knew him. There was no observable failure of his mentality and no one who came in contact with him could have suspected that not one member of the Massachusetts Medical Society Dr Stevens of Cambridge had been a member longer than he.

Dr Wheeler married Elizabeth Bancroft Cheever daughter of the Rev Henry Cheever November 29 1897.

He is survived by his widow four children and three grandchildren. His son Bancroft C. Wheeler is at present an Assistant Surgeon at the Memorial Hospital.

SAMUEL WOODWARD,
HOMER GAGE,
DAVID HAREWELL.

NOTICES

THE APPOINTMENT OF DR. R. H. GUTHRIE

RILEY H. GUTHRIE, M.D. has been appointed Chief Executive Officer of the Boston Psychopathic Hospital.

A COURSE BY PROFESSOR GEORGES PORTMANN

Professor Georges Portmann will conduct an intensive five weeks' course in Oto Rhino Laryngology in the University of Bordeaux, France beginning July 30 1936. English language, didactic laboratory clinical and operative instruction.

For particulars address Dr James A. Flynn, 1511 Rhode Island Avenue N W Washington, D C.

BOSTON UNIVERSITY SCHOOL OF MEDICINE SURGICAL CLINIC AT THE BOSTON CITY HOSPITAL

Friday November 22 12-1 Cheever amphitheatre Dr Frederic J. Cotton will speak on "Fractures of the Wrist and Ankle."

Physicians and medical students are invited.

REPORTS AND NOTICES OF MEETINGS

TESTIMONIAL EXERCISES FOR DR. EDSALL

Dr David L. Edsall recently retired dean of the Harvard Medical School and School of Public Health, was honored with a testimonial meeting and dinner held by the Harvard Alumni Association Wednesday October 23. The afternoon meeting was held at the medical school with Dr Walter B. Cannon presiding. Dr Cannon in reviewing Dr Edsall's contributions to the medical world in the past twenty-five years emphasized his investigations in occupational disease and the impetus which he early gave to the study of this relatively new branch of medicine. His efforts in the advancement of the Harvard School have been unequalled except by those of Dr Elliot.

Three addresses were delivered on the subject, "The Development of Medical Education in the United States Since the World War." Dr Walter A. Jessup President of the Carnegie Foundation for the Advancement of Teaching was the first speaker in this group. In tracing the evolution of medical teaching from ancient times he told of man's constant struggle against disease, and his steady search for aid in scientific and pseudoscientific fields. Many forces have hindered the study of medicine. Ignorance and superstition long prohibited dissection and the study of gross anatomy. Absolute acceptance of the authority of Hippocrates and Galen hindered advance for centuries. The academic teaching of medicine with law and theology provided little stimulus for experimentation and advancement of medical knowledge. Then for many years the study of medicine became an apprenticeship with medical schools serving only as centers for academic lec-

tures Little or no coordination existed with other branches of the university, if indeed the medical school was connected with a university at all

Early in this century the American Medical Association sought the aid of the Carnegie Institute for the Advancement of Teaching in an attempt to improve the quality of medical instruction. This committee, headed by Dr Flexner, emphasized the necessity of thorough scientific instruction of medical students before clinical exercises were undertaken. As a result of this report many inadequate medical schools have been closed since 1910, and the character of those remaining has been greatly strengthened with the development of strong preclinical departments. An indirect result of this development has been the domination of medical thought by great scientific institutes for research. The application of scientific methods to the solution of public health problems has brought about the practical elimination of certain diseases such for example as typhoid fever, and yellow fever. Large corporations have realized the value of, and have aided in the application of public health measures to industry, with the resultant elimination of many occupational diseases.

Dr Edsall emphasized the importance of personality and human kindness to the physician. He advocated a thorough knowledge of literature, believing that such knowledge was essential for an understanding of human nature and a correct evaluation of laboratory data. Within recent years great strides have been made in the cultural education of students before they enter on a purely medical course.

Under Dean Edsall, Harvard was anxious to meet the demands for education in public health. He established the requirements of a scientific background to such an education, as well as a thorough knowledge of adjoining fields such as sociology and psychology.

Harvard Medical School, one of the most richly endowed schools in the world, has well met her obligation to society. No small part of her success is due to the efforts of Dr Edsall.

Dr Eugene DuBois, Professor of Medicine at Cornell Medical College, talked of the influence of the preclinical sciences on clinical medicine. A generation ago the aim of medical schools was to prepare their students to secure internships. No effort was made to stimulate reading of original articles, and teaching was done entirely from textbooks. Dr Edsall changed the whole atmosphere of medical education. He favored the elimination of the "spoon feeding" system, and advocated the wider use of source material instead of textbooks. He introduced the tutorial system which allowed more leniency to exceptional students, with the opportunity for special work in selected fields.

The division between preclinical and clinical subjects has been overemphasized. The teaching of the preclinical courses in conjunction with other college courses, as is done in some schools, is not desirable.

They should be more closely welded to the clinical departments of the school, at the expense of some separation from the rest of the college courses if necessary.

In recent years the additions made by clinical investigators to scientific knowledge have increased tremendously. The narrow concept that "work on animals is more scientific than work on man" is no longer tenable. Many of the modern reviews on physiology and biochemistry are largely referable to clinical work.

The organization of the present day clinic is open to many criticisms. Some need complete reorganization. Financial depression has limited the funds available for research, which forms an important part of every modern clinic. Young men interested mainly in caring for patients or teaching feel that they must do a certain minimum of research if they are to gain academic advancement. Those interested mainly in research see a future only as assistants if they remain in laboratory work alone. With academic advancement and increase in administrative duties, there is a steady decrease in the extent of researches performed by men formerly very active, and often the appointment to a professorship entirely curtails further investigative work.

A new type of organization is suggested which will take advantage of clinical material, but with appropriations separate from those of the hospital housing it. Its board of directors and connections should be such as to allow the staff to move from one hospital to another to obtain the clinical material needed for the problems under consideration at any one time. Administrative duties should leave the staff adequate time for investigative work. Such a system would improve the character of medical instruction, and while decreasing the quantity of research published would definitely improve its quality.

Dr Lawrence J Henderson, Professor of Chemistry at Harvard, in delivering the closing address of the afternoon spoke of the various interactions between medical and other sciences. In early times the path to other fields lay through medicine, and many of the concepts of other branches of knowledge were made by men who began their careers as physicians. Then came the period in which contributions to medical knowledge were largely made by workers in other scientific fields. This period is exemplified by the contributions made by Lavoisier, a chemist, to the study of metabolism, and the fundamental concepts given by the chemist Pasteur to the field of bacteriology.

A generation ago chemistry, physics and other "pure sciences" were still quite independent of medicine. The frontiers of science were then several and real. Now these several frontiers have become false and unreal. Medicine and the various sciences can no longer be clearly demarcated, and segregated. Advancement in one field usually influences all the rest.

At the time Dr Edsall began his deanship, the

"Guild Economy" was in full swing. The medical school was isolated from the rest of the university and the laboratories were segregated from the clinics. These isolations were intellectual as well as physical. Dr. Edsall had experienced the detrimental influence of this system in his early experimental clinical studies and in the application of clinical methods to industrial hygiene. He undertook to eliminate this "pigeon hole" method of investigation and teaching. In the founding of the School of Public Health intimate relationships were established with the Medical School. The close relationships now existent between the school and the Children's Hospital, the Fatigue Laboratory and the Engineering School are examples of the success of his efforts to abolish the Guild System. He had a large part to do with the founding of the Committee on Industrial Hygiene which administers large grants from the Rockefeller Foundation. This committee has given funds to such apparently diverse enterprises as the Harvard Expedition to Chile, the Fatigue Laboratory and the department of anthropology. An example of the interrelationships of the various sciences which have been promoted is afforded by the presence of a physician on the Cancer Commission and a mathematical statistician on the faculty of the School of Public Health.

The institution of the tutorial system at Harvard has greatly aided undergraduates in shaping their studies. The presence of young medical men among the college tutors has promoted and inspired a better relationship between the medical and college faculties.

In all these advances toward closer collaboration Dr. Edsall has taken a leading part, and it is chiefly through his efforts that many of the results have been achieved.

The testimonial dinner was held at the Harvard Club with Dr. Conant presiding. Dr. Conant expressed his appreciation of the encouragement, cooperation and assistance which Dr. Edsall had so freely given him since his appointment as president of the university. Dr. C. Sidney Borwell, new dean of the medical school, spoke briefly of Dr. Edsall's contributions to pediatrics, occupational disease, public health, and the advancement of Harvard Medical School. The change from academic to bedside teaching, the development of a well functioning tutorial system and the encouragement given to research contributed much toward keeping the Harvard Medical School among the leaders of present day medical education.

Dr. A. Lawrence Lowell, President Emeritus of Harvard University, emphasized Dr. Edsall's advancement of the Medical School by the union promoted between the preclinical and clinical sciences and the harmonious relationships developed between the various departments. The value of a general examination over the whole of the four-year medical course was recognized by Dr. Edsall and he succeeded in establishing it a year after assuming his office as dean. His introduction of the system of

"self education" instead of the academic teaching of "pre-digested" information has been one of the greatest contributions to modern medical instruction.

The address of Dr. Edsall will be printed in its entirety in a future issue of this Journal.

HARVARD MEDICAL SOCIETY

The Harvard Medical Society held its first meeting of the current year at the Peter Bent Brigham Hospital, October 22. Dr. Henry A. Christian presided.

Two cases were presented. The first, a medical case by Dr. Sullivan.

A thirty-seven year old Canadian male entered the hospital five days previously with the history of persistent vomiting for the past three weeks. He had been under medical treatment for peptic ulcer fourteen and ten years previously but since that time had been well until the onset of the vomiting.

Physical examination revealed him to be markedly dehydrated and cynotic. There were rales of both lungs and tenderness in the right upper and lower quadrants.

Laboratory studies: urine very slight trace of albumin; specific gravity varying from 1.010 to 1.014. P. S. P. test of renal function showed excretion of 10 per cent of the dye in three hours. Blood: red cells 5,400,000; hemoglobin 123 per cent; white count 15,000.

He was placed under routine ulcer management with frequent feedings and alkali powders but vomiting persisted for the four days. On the fourth day there was marked increase in the cyanosis and the patient complained of headache. Chvostek's and Trousseau's signs were present. The blood carbon dioxide combining power was found to be 108 volumes per cent. He was given ten grams of ammonium chloride in one hundred cc. of normal sodium chloride solution by rectum. He became lethargic and semicomatose on the morning of the fifth day when his blood urea nitrogen was 159 mg. per cent. Forty-five hundred cc. of normal saline solution was then administered subcutaneously and intravenously with subjective improvement, disappearance of lethargy and disappearance of Trousseau's and Chvostek's signs. The carbon dioxide combining power of the blood fell to 88 volumes per cent and the blood sodium chloride rose from 235 milligrams per cent, the next morning to 300 at three P.M. and the serum calcium was 7.4 mg. per cent, the serum phosphorus 11 mg. per cent. Dr. Ambrose, in discussing the case, emphasized the great constancy of the blood base and the fact that other substances were retained or excreted to maintain it as constant as possible. In this case salt was lost in the vomitus and there had been inadequate elimination of bicarbonate in the urine. There was a decrease in the available calcium ions and tetany developed. High values of blood base result in damage to the kidney with rise of the blood urea nitrogen due to retention.

Dr Emery commented on the frequent upsets experienced by patients on the Sippy diet with high alkali intake. Ill effects are more apt to occur in patients with previously damaged kidneys, although they may occur in those with normal kidneys. Change from calcium to bismuth compounds will relieve the toxic symptoms in many cases, even though the proportion of soda administered remains the same.

Dr Christian stated that either alkalis or acids in large excess above normal will produce a toxic nephritis, experimentally. The development of evidence of alkalosis in ulcer patients should always lead one to expect renal impairment, since the normal kidney is capable of excreting excessively large amounts of bases or acids. Headache is a very early symptom of renal dysfunction in patients on ulcer treatment.

The second case was presented by Dr Ryder. A seventy three year old white male entered with a history of typical angina pectoris for the past ten years. For the past two years he had suffered attacks of upper abdominal pain distinct from his anginal attacks, and characteristic of gall bladder disease. Four months ago he had severe right upper quadrant pain radiating to the angle of the right scapula, associated with nausea, vomiting, and jaundice (icteric index 40). X-ray studies revealed a pathological gall bladder. He was sent home because he was considered a poor operative risk. Thirty-six hours before his present entry he suffered abrupt onset of diffuse upper abdominal pain, worst in the epigastrium, and not relieved by nitrites.

On entry his white count was 14,000, temperature 101°, and his urine showed a 1 plus test for bile. The icteric index was 12.

Dr Cutler expressed the opinion that cholecystectomy was not justified in this case because of his poor condition.

Dr Cheever stated that in his experience, patients suffering from both angina pectoris and gall bladder disease often receive considerable relief of their angina after cholecystectomy. A possible explanation of this phenomenon might be the abolition of reflex nervous or infectious stimulus to the heart. The evidence of gall bladder infection with the last attack points to the likelihood of more trouble in the future. He advised operation.

Dr Christian concurred with Dr Cheever. In his experience patients with combined angina and gall bladder disease stood cholecystectomy well and were often relieved of symptoms of both diseases post-operatively.

Dr Walter B Cannon, George Higginson Professor of Physiology, at Harvard Medical School, then recounted in delightful fashion some of the interesting features and impressions of his recent trip to the Orient, Russia, and Scandinavia.

He was very favorably impressed with the efforts for advancement of public health in China, which are under the able direction of Dr J Heng Liu, a graduate of Harvard Medical School. Recently a

new medical school has been founded in Nanking with the specific purpose of developing men for service in the Public Health Department.

In Russia, Dr Cannon was impressed by the regard paid to the human factor in labor, and by the facilities provided by the Government for the recreation of the working class. An earnest attempt is apparently being made to utilize, profitably, the leisure afforded by the thirty hour working week. Large, beautifully landscaped "parks of culture and rest", provided with reading rooms, outdoor theaters, children's nurseries, game rooms, etc., are to be found in the large cities. An effort to popularize education and appreciation of art is also quite noticeable, although such effort is always colored by propaganda. Young men of promise are now being encouraged to enter the field of medicine by the expedient of doubling the salary paid to physicians by the state, huge institutes for research have been built, and great activity in scientific fields is in progress.

The increase in patients suffering from neuroses has been quite marked in Russia during the last decade. A quite probable explanation of this increase lies in the demands of time and machinery on a previously leisurely, rather primitive agricultural people, and also in the operation of fear.

In marked contrast to Russia were the Scandinavian countries with their fine educational systems, and great coöperative programs. To Dr Cannon these seemed the most civilized countries in the world.

WILLIAM HARVEY SOCIETY

The first meeting of the year of the William Harvey Society was held on October 25 in the Beth Israel Hospital. Dr Walter C Alvarez spoke on "Functional Digestive Disorders." He was introduced briefly by Dr Louis F Curran.

In Doctor Alvarez's practice he finds that fully one-third of his patients show no evidence of organic disease and he believes that medical schools do not, as a rule, give adequate training to their students who will later have to meet functional problems almost as often as organic. A detailed history, taken with great care, should reveal the diagnosis of functional trouble even before the physical examination and laboratory work are done. It frequently requires several visits with the patient before the real truth becomes evident, since the idea of a functional disorder is most distasteful to the average person, who wants an operation and a rapid cure. Extreme care is needed in creating the proper frame of mind in such patients if one is to bring about restoration to health. It must be pointed out that many under the strain of certain unfortunate circumstances become neurotic.

Of course it is always necessary to make a most careful examination of all patients regardless of whether the disease is organic, because frequent

mistakes will otherwise be made and because there is nothing so convincing to a patient as a thorough physical examination.

A patient with organic disease is always straight forward and direct in his answers to the doctor's questions while the neurotic individual dodges and refuses to "stick to the point." Dr. Alvarez spoke particularly of what he chose to call the constitutionally inadequate patient. Such people are often intellectually alert but seem unable to meet the strain of everyday life. The doctor cannot cure this type of individual but he can often guide him into some occupation where he will be able to meet the requirements adequately pointing out that there are limitations to every man's ability.

Doctor Alvarez's lecture was replete with excellent examples through which he drove his points home. He particularly stressed the necessity of a careful history and said that frequently when one doctor fails to get at the underlying cause of a functional disorder it is wise to let another physician try to discover an etiology. It is important to find out the precise circumstances under which the difficulty began. It is rare to have functional attacks at night. Note the type of pain and have the patient point out exactly where it is, for a neurotic often complains of burning pains and is indefinite when asked to put his finger on the exact site. Functional pain is usually unrelated to any of the functions of the body and is unrelieved by certain measures that usually help organic digestive disturbances as for instance the Sippy régime in gastric or duodenal ulcer. Pain due to migraine always follows a head ache. The general sensitivity of the patient should be noted. Those patients that cry out repeatedly during a barium enema and have much pain at the dentist are probably abnormally sensitive to all pain.

The family history often makes a diagnosis, for many of the constitutionally inadequate may be mildly insane and give a family history of insanity. In treating these patients, sympathy is most important and a brutal heartless approach will only drive them elsewhere. Insomnia is a frequent complaint and must be combated. Barbiturates may be used, because rest, often in the daytime but certainly at night is essential. Doctor Alvarez often uses some active treatment because it gains the patient's confidence and gets him to return frequently so that the doctor can also treat him actively for his neurosis.

THE NORFOLK DISTRICT MEDICAL SOCIETY

A regular meeting of the Society will be held in the Norwood Hospital, Norwood, Massachusetts Tuesday evening November 20 1935 at 8 15 P.M. Tel. Norwood 1620

ARTHRITIS CLINICS AT THE ROBERT BRECK BRIGHAM HOSPITAL

A bi-monthly series of clinical meetings on the general subject of arthritis will be conducted during the winter months at the Robert B. Brigham Hospital 125 Parker Hill Avenue, Boston. Physicians and medical students are cordially invited to attend. The next meeting will be held Wednesday December 4 at 5 00 P.M.

The third clinic this fall was held November 13 when two patients were presented one a fifteen year old boy with rheumatic fever and rheumatoid arthritis, the other a thirteen year old girl with Still's disease. In addition there was a demonstration of acetyl beta methylcholine chloride iontophoresis a therapeutic measure which has lately attracted some attention in the treatment of chronic arthritis and peripheral vascular disease.

BOOK REVIEWS

The Woman Asks the Doctor Emil Novak 189 pp
Baltimore The Williams & Wilkins Company
\$1 50

In this book Dr Novak has attempted to put into print his answers to the questions which the average woman patient asks her doctor about herself. He has succeeded admirably in accomplishing this purpose Your reviewer does not know of any book which is at all comparable to it. The style is simple and readable Every doctor will recognize the questions which have inevitably come up many times in his own practice Dr Novak has had this skill and the knowledge to answer them in an authoritative manner We can recommend this book in every way, and the price brings it within the reach of any patient.

Section of Primate Physiology, Laboratory of Physiology, Yale University School of Medicine
Collected Papers, July 1, 1934-June 30, 1935 Vol II New Haven, Connecticut

This second volume of collected reprints from this very active physiological laboratory of the Yale Medical School is a fitting tribute to the work of Professor John F Fulton, the head of the department The work of this laboratory indicates that under his direction productive research is being carried forward along many lines of neurophysiology Thirty new papers published in the course of a year are conveniently bound for easy reference, with an adequate table of contents

SOME OBSTETRICAL ASPECTS OF CARDIAC DISEASE COMPLICATED BY PREGNANCY*

BY H. B. NELSON, M.D.† AND M. F. EADES, M.D.†

It has been frequently said that women with heart disease have easier and shorter labors than when no cardiac disease is present. In order to verify this statement, it was decided to analyze the histories of a large series of pregnant patients with known organic heart disease where sufficient data were present regarding their labors to make satisfactory observations. Such material was available through the cardiac clinic of the Boston Lying In Hospital. The patients had been individually studied and their condition diagnosed as organic heart disease by our cardiologist, Dr. B. E. Hamilton and his staff. All were women with compensated or decompensated organic heart disease who entered the Boston Lying In Hospital either through the cardiac clinic or as emergency cases during the years 1922-1932 inclusive. During this period, 530 pregnant women with organic heart disease were treated. Because of various omissions in the records, for our purpose only 495 records were available for this study.

FAILURE DURING PREGNANCY

Management of the cardiac patient aims to anticipate failure, recognize it early, and if it occurs, to treat it in the most appropriate manner.

Hamilton found an incidence of cardiac disease at the Boston Lying In Hospital of 500 cases in 45,069 deliveries or 1.1 per cent. Watson reported from Sloane Hospital for Women 240 cases in 18,000 deliveries, or 1.3 per cent. One finds in the textbooks of obstetrics very vague statements regarding the occurrence of failure during pregnancy. In the literature, conclusions are frequently based on relatively few cases. Certain aspects of vascular physiology would seem to have a definite and direct bearing on these problems. Nehenauer, and Rowntree and Brown have demonstrated an increased blood volume in normal human gestation. The

latter workers show this change to result from an increased plasma volume. Stander, Duncan and Sisson have reported an increased minute volume output of the heart in animals and in human beings during pregnancy. In normal women they demonstrated that the cardiac output begins to rise at the fourth month of pregnancy and progressively increases until full term is reached. At that time it assumes a value of fifty per cent above normal. In other words, pregnancy imposes a progressive load on the heart from the fourth month until term. We should expect, therefore, to encounter cardiac failure during pregnancy in proportion as this burden on the cardiovascular system is increased.

Of this group of 495 patients with organic heart disease, seventy-six or 15.3 per cent developed frank decompensation during pregnancy or labor. Primary postpartum decompensation did not occur in any of this group although six patients decompensated during labor. Seventy patients, or 92.1 per cent of decompensated cardiacs had their heart failure during pregnancy. In this group 47.8 per cent of the failures occurred during the seventh and eighth months of pregnancy. The incidence of cardiac decompensation during the various months of pregnancy and during labor is shown in Chart I.

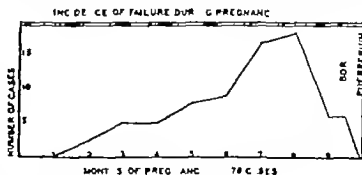

CHART I. Note the marked increase in failure during the seventh and eighth months of pregnancy.

LENGTH OF LABOR

It has been commonly taught, and we have heard it repeatedly stated that patients with heart disease have easier and shorter labors than comparable normal patients. In explanation it was stated that the increased congestion of the cervix as a result of poor peripheral circulation produced abnormal softening, thus facilitating

*From the Department of Obstetrics, Harvard Medical School, and the Boston Lying In Hospital.

†We are greatly indebted to Drs. F. C. Irving and B. E. Hamilton for their permission to make this study and for their valuable assistance.

†Eades, M. F.—Physician to Out Patients Boston Lying In Hospital. For records and addresses of authors see "This Week's Issue," page 1161.

ing easy dilatation In the recent literature, little is said regarding this matter Daly states that the labor is "usually shorter and less strenuous in cardiacs" He says further that "spontaneous labor and delivery is usually safe The labors are short and easy as a rule unless there is an obstetric complication "

Corwin, Herrick, Valentine, and Wilson in 196 cases of pregnancy and heart disease give an average first stage of labor as eleven and a half hours They state that these patients were delivered in order to shorten the second stage of labor, so the statistics for the short second stage show only the average duration of second stage labor before artificial termination MacLennan, in a series of thirty-eight cases of definite heart disease and pregnancy, noted an average duration of eight hours in primiparous and six hours in multiparous labors In our series 333 patients were delivered by the pelvic route Ninety-two were primiparae and 241 were multiparae The duration of labor was considered to extend from the first painful contraction until the birth of the placenta The duration of labor in this group is shown in Chart II According to Williams and to

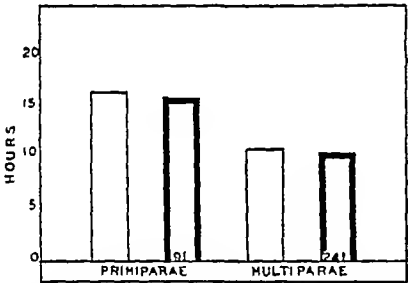

CHART II. Duration of labor in normal cases and in patients with organic heart disease The heavy columns represent the latter group

De Lee, the average duration of labor in normal primiparae is eighteen hours, and in multiparae twelve hours This series, as shown by the chart, shows no comparative shortening of labor in the cardiac group On the contrary since one half of this group had artificial termination of the second stage the average length of labor would, in this group, have been higher than the average normal

DELIVERY

Following the teaching of our cardiologist, the policy of this clinic has been to deliver cardiac patients by the easiest possible method from the standpoint of the mother Generally the plan has been to deliver all patients with compensated heart disease by the pelvic route if no obstetrical contraindication was present These patients were theoretically to be delivered at the end of the first stage of labor by low forceps in order to obviate the straining associated with the second stage of labor How unsuccessful we were in accomplishing this will be shown in a later chart Further, in this clinic, it is the rule that pregnant cardiac patients who had previously failed, were in failure, or had an indicative obstetrical complication, should be delivered by cesarean section This was based on the assumption that this method of delivery best conserved the interests of mother and baby We are aware that differences of opinion exist relative to this policy During the period this group of cases was observed, these policies have been carried out as stated, and we have no comparable series of previously decompensated or actual decompensated cardiac patients where pelvic delivery has been the method of choice

In this group of 495 cardiac patients, 333 or 67.3 per cent were delivered by the pelvic and 162 or 32.7 per cent by the abdominal route

Of the group delivered through the pelvis, it will be noted that 241 were multiparae, almost three times the number of primiparae so delivered It will also be noted that a very small fraction of patients in decompensation were delivered from below 1.8 per cent of the primiparae and 6.9 of the multiparae In those cardiac patients who were delivered by the pelvic route, it was the aim to eliminate the "bearing down" efforts of the patient by effecting delivery under full anesthesia at full dilatation of the cervical os This was thoroughly impressed both upon the house and visiting staff To our knowledge, constant, conscientious effort has been made to accomplish this How successful these efforts were is demonstrated by the fact that spontaneous deliveries occurred in 33.3 per cent of all cases (table 1) It is surprising to

TABLE 1
PELVIC DELIVERIES WITH RELATION TO SECOND STAGE OF LABOR

	Multiparae		Primiparae		Total	
	Num-ber	Per Cent	Num-ber	Per Cent	Num-ber	Per Cent
Without Second Stage	69	28.2	52	56.52	121	36.33
With Second Stage Shortened	19	7.8	27	29.31	46	13.81
With Complete Second Stage	153	63.4	13	14.1	166	49.84
Total	241		92		333	

note that 63.4 per cent of the multiparae and 14.1 per cent of the primiparae were delivered with complete second stage of labor in spite of constant effort to eliminate it. Watson has reported an incidence of 45.5 per cent normal deliveries in 240 cardiac labors. It is easy to appreciate that in many multiparae the complete dilatation of the cervix is practically synchronous with the appearance of the head on the perineum. With the larger percentage of non-viable and premature infants following spontaneous premature labor in these serious cases of heart disease it is not surprising that there should be an increase of rapid second stage and of precipitate labors. In the primiparae this is somewhat more difficult to explain. Unfortunately in these groups we do not have the data on what percentage was nonviable or premature. These factors we feel go far in explanation of these apparent discrepancies in treatment.

It is probable that in certain instances the attendant may not have kept sufficiently close observations of the patient to anticipate full dilatation of the cervix. Parenthetically, we know of no way to conduct these labors, especially in multiparae, so as to insure delivery at full dilatation, except to be with the patient constantly once dilatation of the cervix begins. Depending on progress one should make preparations for delivery before full dilatation has been reached and not wait until this has occurred. Frequent rectal examinations should keep the observer informed as to progress. This elementary procedure is of utmost importance in conducting cardiac labors with a view to avoiding second stage labor.

METHODS OF DELIVERY

The methods of delivery in the 333 patients delivered through the pelvis are shown in Chart

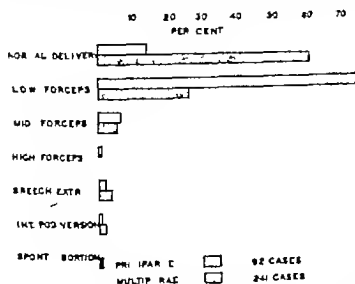

CHART III. Types of pelvic delivery. Note the low incidence of difficult operative procedures.

III The small number of difficult operative deliveries is to be noted. High forceps were used in only one instance. The total of mid forceps deliveries, twelve per cent, and relative

ly large percentage of low forceps deliveries represent an effort to deliver the patients at full dilatation in order to eliminate the second stage of labor. Drop other was the anesthetic used almost entirely.

In the group of 162 cases, which was 32.7 per cent of the total number, thirty-five cases, or 21.5 per cent, of abdominal deliveries represent early termination of pregnancy by either hysterotomy or hysterectomy. The remainder were delivered by classical cesarean section under some form of local anesthesia or under drop ether when a general anesthetic was used. The classical type of cesarean section has been used because its technique is simple, rapid, and involves little disturbance of the viscera. Since the operation in this cardiac group is usually one of election, or when the patient has had little labor, the use of the classical operation has presented certain advantages, and in our opinion no increased risk over the lower segment type of operation.

STERILIZATION

Since definite organic heart disease does not improve but becomes worse with increasing age, and because it is common clinical knowledge that each pregnancy takes its toll of the already damaged heart, it is obvious that repeated pregnancies in such patients sooner or later lead to a medical impasse. We are not concerned here with the proper advice to the nulliparous patient with organic heart disease. In this clinic we advise sterilization to any patient whose heart has decompensated previously or decompensates during pregnancy or labor. This leaves a large group who must be conducted on their individual merits. In general, if the patient has a cesarean section as the easiest method of delivery because of a serious cardiac condition we feel that sterilization is also indicated. In those patients who are well compensated during their first pregnancies but who show increasing heart strain during subsequent ones, we are inclined to advise sterilization after two or three pregnancies when this is evident. In short, the cardiac patient after childbearing has occurred becomes of increasing social value to her family, and sterilization is advised to protect her life and health from the strain of possible future pregnancies.

Of the entire group of patients here studied, 117 or 23.6 per cent of the total group were sterilized. Thirty-six or 7.25 per cent aborted or were terminated early in pregnancy. As is shown in table 2, the majority were sterilized at the time of cesarean section. Sixty-nine women or 54.3 per cent of 127 deliveries by cesarean section were sterilized. It must be clearly understood that cesarean section was performed because of the heart disease primarily in the great majority of cases and sterilization was only an incidental operation performed at that time. We do not believe that

medical desire for sterilization is an indication for cesarean section. Those cases who were delivered through the pelvis and who consented to sterilization had this operation performed at a subsequent period varying from the second week of the puerperium to several months later. Vaginal sterilization was performed in a small series. The methods used consisted of hysterectomy of the early pregnant uterus, excision of the cornua, Pomeroy's method, and the operation devised by Irving. Complete data on the

MATERNAL MORTALITY

During the period of this study twenty-nine out of 530 cases died—a total gross mortality of 5.4 per cent. Six deaths occurred in undelivered patients and were not considered in this group. In the 495 *delivered* cases analyzed, twenty-three died, a mortality of 4.6 per cent. This mortality figure was applied to these delivered patients during their routine twenty-four day postpartum stay in the hospital. These mortality rates compare favorably with published statistics of recent years. Reid, in an analysis of 830 pregnant cardiac patients, found a mortality of 5.1 per cent. In the particular group of 500 cases studied by Hamilton and Carr, the mortality rate was 6.4 per cent. This is an average mortality rate which has diminished from a rate of twelve per cent twelve years ago to a rate of three per cent the last few years. As these authors point out, one must take into account that approximately one-half of the cases were referred into the hospital as emergencies and had not previously been under the care of the institution. In most cases there had been little prenatal care, and usually no medical supervision of the cardiac condition. This same situation obtained in the group which we have studied. In this clinic, we feel that even under these circumstances the major credit for the decrease in the mortality rate should go to the cardiologist. He has taught us that the great need of these patients is a restricted régime of living and rest. Of probably less importance is the knowledge gained by the ob-

stetrician in handling these patients. Careful individualization of delivery of methods and of anesthetics is necessary. We are not convinced that anyone can state arbitrarily which is the easiest method of delivery. Sterilization of all serious cardiac patients has undoubtedly diminished the percentage of cases in failure and indirectly the mortality rate. It has diminished the number of severe cardiac patients who would have repeated pregnancies until failure and death occurred. We feel that this matter is one of some importance.

The relative incidence of death with or without failure in patients delivered by pelvic and by abdominal methods is shown below (Table 3). In those patients who had cardiac fail-

TABLE 3

Maternal Deaths	Num- ber	Per Cent

Abdominal Delivery with Failure	8	34.7
Total	23	

ure, eight deaths, 34.7 per cent of the mortality group, occurred in abdominal deliveries, and five, 21.7 per cent, in the pelvic deliveries. This does not mean that abdominal delivery per se carries this increased mortality rate, as the most serious cases were electively delivered by this method. This group would have carried a higher mortality rate by any method of delivery. The factor of failure at the time of delivery did not seem to have increased the mortality risk to a great extent. Of the twenty-three deaths, it will be noted ten patients, 43.3 per cent, who died were not in failure at the time of delivery.

Of those patients not in failure, six patients, twenty-six per cent, delivered through the pelvis, died, as opposed to four, 17.3 per cent, in which abdominal delivery was used.

SUMMARY

1. A series of 495 patients with rheumatic heart disease complicated by pregnancy has been analyzed.
2. Ninety-two per cent of the cardiac failures occurred during pregnancy.
3. Forty-seven per cent of the failures occurred in the seventh and eighth months of pregnancy. If a pregnant cardiac patient is able to go through the eighth month of pregnancy without failure, her chance of decompensation with proper care during the ninth month or during delivery should be relatively small.
4. We were unable to demonstrate in this series of cases that the cardiac patient has any *shorter* or *easier* labor than the normal woman.

5 Sixty seven and three-tenths per cent of these patients were delivered by the pelvic and 32.7 per cent by abdominal route. The majority of patients in actual decompensation had abdominal deliveries. In spite of our attempts to obviate the second stage of labor 63.4 per cent of the multiparae and 14.1 per cent of the primiparae were delivered normally an incidence of 49.8 per cent of normal deliveries for the entire group.

6 The low incidence of difficult pelvic deliveries is to be noted, also the increased incidence of easy artificial termination in an effort to obviate the second stage of labor.

7 Sterilization was performed in 23.6 per cent of the cardiac cases.

8 In the 495 cases here studied, the mortality rate was 4.6 per cent.

9 The incidence of mortality was little higher in patients delivered in failure than in those without.

10 The importance of treating the pregnant

cardiac patient primarily as a medical problem and secondarily as an obstetrical problem is emphasized.

WHOOPIING COUGH AND ITS PREVENTION*

BY LOUIS SAUER, M.D.†

THE Cutter Lecture in Preventive Medicine by Madsen¹ a decade ago, inspired American students of the pertussis problem. The first paper on the Danish cough plate method of early diagnosis to appear in this country was that of Lawson and Mueller² who wrote "During the winter and spring of 1925-6 the Commission for the Study of Whooping Cough studied the disease at the On Shore Department of the Boston Floating Hospital." They concluded "The method has a wider range of usefulness than was at first expected. Carriers, second cases, and suspected cases in which the patient never whoops, all of which would otherwise remain undetected, may be diagnosed by bacteriologic studies. During the catarrhal stage positive cultures may be obtained with considerable regularity. As the disease progresses, there is a coincident decline in the percent age of positive cultures." This aid in early diagnosis, discovered by Chuvitz and Meyer has been in use at the Evanston Hospital since 1925, plates have been exposed to about 600 private pertussis patients. Late in 1932 the Michigan State Department of Health chiefly through the efforts of Doctor Kendrick and Miss Eldering³, made the cough plate method of early diagnosis available to the physicians of Grand Rapids and Lansing. In less than two

years over a hundred Michigan physicians have had local health department technicians expose plates to more than a thousand children with suspicious coughs. Table 1, A, gives the per

TABLE 1

centage of positive cough plates in 4,432 collected cases. The earlier that plates are exposed, the more likely will they be found positive. Negative plates do not exclude the disease. The surface of the medium should be cherry red smooth and moist the technician entrusted with the exposure and subsequent examination of incubated plates, should be familiar with the vagaries of *B. pertussis* colonies and stained

smears Erroneous laboratory reports bring this valuable laboratory aid into unwarranted disrepute Over a score of original papers on the Danish cough plate method of early diagnosis have appeared in this country since Madsen acquainted us with it

The Danish State Serum Institute pertussis vaccine contains, since 1916, approximately 10,000 million bacilli per cubic centimeter To this day they recommend 0.5, 0.7, and 1 cc at three to five-day intervals, a total of 2.2 cc In all, 2700 Danish and Faroe Islands patients had been injected up to 1924 Madsen said "No absolutely sure prophylactic effect was obtained three hundred and sixty-four children were vaccinated, one to three months before being exposed, in spite of this, they all, without exception, caught whooping cough" He concluded "Shall we do away with whooping cough entirely? Of course that is our future ideal."

Von Sholly, Blum and Smith⁴ of the Bureau of Laboratories of the New York City Health Department, in a critique on pertussis vaccine, warn against drawing conclusions about pertussis vaccine, without making a critical comparison with control cases They point out that members of the same family, ill with whooping cough at the same time, have the disease in varying severity, some escape entirely The personal equation of the examiner must also be reckoned with Many mothers are anxious to please the physician, others exaggerate, hoping for better treatment, or, they lessen symptoms so that the quarantine will be shortened Control cases were injected with B influenzae vaccine or with diluted milk In recording results, the investigators did not know with which preparation the child had been injected In summary they state "Of the children exposed to whooping cough in their immediate family, 19 received injections of influenzae vaccine, and 30, injections of pertussis vaccine, none developed characteristic pertussis Of 700 exposed children in 243 families, 174 (24.8 per cent) escaped" The shortest course was in unvaccinated controls, or in children injected with diluted milk They conclude "More critical observations with controls for comparison must be made before the case can be made out for the curative and prophylactic value of a specific pertussis vaccine" The ages of the children who escaped are not mentioned, nor do they give the basis on which a diagnosis of whooping cough was made

Convinced of the inefficacy of commercial pertussis vaccine, it had been discontinued several years before Madsen's paper appeared Although the Danish results, with a total of 2.2 cc of their potent vaccine, were not very striking, we began to make pertussis vaccine at the Evanston Hospital in 1925 Because Miss Hambrecht had noted that the hemolytic zone was usually

more pronounced in colonies recently isolated by the aid of the cough plate, five to seven such fresh strains were used each time that vaccine was made Our culture medium has always been made with human blood, as we planned to give larger doses, and wanted a vaccine free from unnecessary hazards To carry over as little of the culture medium as possible, the growth was scraped off Made without alien blood, it was not necessary to "wash" this vaccine, whereby soluble antigen might be discarded The vaccine contains no alien protein, formaldehyde or other denaturizing agent It is refrigerated until used Neither in the Cutter Lecture, nor in the writings of Chievitz and Meyer⁵ is the age of the strains used in vaccine production, mentioned*

Between 1925-8, a hundred private pertussis patients (and definitely exposed nonimmunes) were given a total of 2 cc to 5 cc, divided into three doses, and injected at three or four-day intervals Such data as stage of the disease, age, season, hygienic care, duration, severity and complications were recorded At the same time, similar data were kept on a hundred untreated pertussis patients The percentage of mild (30 per cent), average (50 per cent), and severe (20 per cent) cases, in the injected and noninjected groups, were about alike We concluded "Such variation in the severity of the disease in the vaccinated and the unvaccinated makes it difficult to evaluate vaccine therapy The simultaneous occurrence of mild and severe whooping cough in families who received the vaccine, and in the institutions in which no vaccine was given, indicates that the course is more dependent on the immunity response of the individual and his ability to resist secondary infections than on the virulence of the strain or the influence of vaccine The high mortality during infancy, when the morbidity rate is relatively low, because of lack of exposure, is primarily due to the infant's inability to ward off secondary infections Aside from the age, other subjective factors, such as the previous health, nutritional state, appetite and stability of the central nervous system, seem to influence this immunity response External factors, such as the season of the year, the food, exposure to secondary infections (colds, influenza, enteritis), and nursing care, are equally important Infants and young children should have aseptic nursing, to prevent secondary infections"

From what was known about the prevention

*Madsen⁶ recently wrote that the Danish vaccine is being made from fresh strains and Miller⁷ stated last year that the State Serum Institute vaccine is made from strains isolated within the three previous weeks (obviously such a polyvalent vaccine can only be prepared at a Cough Plate Diagnostic Station) Their strains are kept on B-G medium until inoculated on vaccine medium (3 parts nutrient calf agar 2 parts potato glycerin agar and 2 parts defibrinated horse blood) The three day growth is washed into 1 per cent formalin (0.4 per cent formaldehyde solution in physiological sodium chloride) after a week it is centrifuged and resuspended in 0.5 per cent phenol in physiologic sodium chloride and standardized to 10,000 million bacteria per cubic centimeter

of typhoid fever by the injection of potent typhoid vaccine, it seemed logical that our antigen might actively immunize infants and young children, if injected in sufficient amount sufficiently long before actual exposure occurred. Since 1928, a total of 8 cc. has been given as an immunizing agent. Nonexposed, nonimmune older infants and young children were chosen. The first 394 were selected private patients whose past medical histories were accurately known since infancy. Families with, also older or younger nonimmune children (controls) were given preference. To produce minimal local and systemic reactions, the first 109 children were given 1 cc. weekly (in alternate arms) for eight successive weeks. Then, for about a year 1 cc. was injected, simultaneously in each arm for four successive weeks. Since 1931, the vaccine has been injected as follows: one cubic centimeter is injected just under the skin in the deltoid region of each arm, one week later 15 cc. is injected in theiceps region of each arm, one week thereafter 15 cc. is injected in the triceps region of each arm. Syringes and needle are sterilized by heat (oven at 250°F for 1 hour), the rubber cap of the vaccine vial, and the skin at the site of the injection are briskly rubbed with sterile gauze or cotton saturated with alcohol. More than 11,000 individual injections have been given by me without a vesicle, pustule, infection or scar at the site of injection. Each mother is told just before or after each injection that nothing should be applied locally. Reactions are chiefly local although a transient rise in temperature may occur within four to thirty-six hours after an injection. No local or systemic reaction has been sufficiently severe to postpone a subsequent injection. The local tenderness, redness and in duration do not always occur, they are usually absent in young infants. The peak is usually reached within twenty-four hours in some instances a small, circumscribed, residual induration of the skin or a subcutaneous nodule may be palpable for a few weeks. The latter is rarely as large or persistent as that following alum toxoid injections. Reassurance by the physician when an injection is given allays unnecessary apprehension for the same reason the mother is requested not to take the child's temperature. Should the child feel feverish or indisposed, it is advisable to keep him quiet and to reduce or omit the next meal. As a rule, the younger the child the more likely will there be no local or systemic reaction. We have not encountered any reaction as severe as the mildest smallpox vaccination. When the vaccine is properly administered no untoward effect should occur. This vaccine, devoid of alien protein, will not sensitize, nor will it cause anaphylactic reactions, serum sickness or the Arthus phenomenon. As the reactions have not been severe, attempts to

detoxify the antigen seem superfluous, and might lessen its immunizing qualities. Should a severe reaction follow an injection, the subsequent injection might be postponed a few days, or, it might be better to give only 1 cc. in each arm the next week, with an extra, in lateral injection a week after the third, until a total of 8 cc. has been given.

During the first few years, white cell blood counts and differential white cell blood counts were made before the first injection, and at the time of the last injection. In over 60 per cent of the latter, the counts ranged from 12,000 to 15,000 per cubic millimeter, in several it exceeded 25,000, in about 15 per cent, no increase was noted. In most instances the rise was due to an increase in the number of small lymphocytes in the circulation. In some, the total lymphocytes exceeded 80 per cent. This vaccine, therefore, not infrequently influences the blood picture as does the disease.

Table 2 forms the basis of proof that 8 cc.

TABLE 2 BASIS OF PROOF THAT 8 CC. VACCINE CONFERS IMMUNITY*				
(Exposure 4 months to 7 years after injection)

6 cc. Approved Vac. Neonatal 1932-4 (Cradle) Infants	400	2	4	4 (all mild)

*Ninety per cent of injected children did not contract pertussis when exposed

of the vaccine confers immunity in a very high percentage of nonimmunes. The average age of the 1609 children at the time of injection was about eleven months. About two-thirds of them were less than two years of age, only 166 were over four years (mostly kindergartners). To determine whether the very young infants can elaborate active immunity from the vaccine 400 homeless ("Cradle") infants (average age six weeks) received a total of 6 cc. of an op

proved vaccine Reactions were usually absent Four of the six, exposed more than four months later (subsequent to their legal adoption), contracted mild pertussis, two escaped Each infant is now given the customary total dosage of 8 cc In the course of years, definite information should be available in regard to the earliest age at which immunization against pertussis should be attempted

In seven years, twenty-seven of the 394 children injected with vaccine made at the Evanston Hospital, were intimately exposed for weeks to their brothers or sisters (controls) who had unquestionable whooping cough All but one escaped, the latter contracted it in aborted form, about four months after the injections,

less remain unexplained, i e., for unknown reasons some children fail to develop an immunity It is possible that children of four or more years, or very fat children, may require more than a total of 8 cc To date, none of the 203 children, injected with approved vaccine No 2, have been exposed

Casual (accidental or transient) exposures (see table 2) are seldom very intimate When an injected child escapes after such an exposure, it might be questionable whether the patient disseminated Bordet-Gengou bacilli at the moment of contact, also, whether the injected child actually aspirated bacilli at the time of the presumed exposure The six failures include all injected children who contracted the

she had just recovered from measles when the vaccine was given In the course of two years, thirty-five of the 612 children, injected with approved vaccine 1*, were intimately exposed to their brothers or sisters (controls), who had unquestionable whooping cough All but five escaped, two of the latter had just recovered from measles when the vaccine was given Three of the six failures (50 per cent) occurred in children who were injected very soon after recovery from measles There may exist a causal relationship in the inability to develop active immunity from the vaccine when it is given soon after other diseases, e g., measles One should try to ascertain the underlying cause of any failure The vaccine should be refrigerated, because room temperature accelerates chemical change, and weakens the immunizing fraction of the antigen Syringes should not be sterilized with alcohol The vaccine should not be given soon after or shortly before any other immunization Some failures will doubt-

disease from four months to seven years after the injections, regardless of whether the source of the infection was in the family or otherwise. The percentage of failures (10 per cent) is computed from a total of sixty-two familial exposures and a total of six failures (three from casual exposure) Therefore, ninety per cent of the injected children did not contract pertussis when intimately exposed The casually exposed children who escaped, are not included in the computation

Indisputable evidence, proving the efficacy of the Evanston vaccine as an immunizing agent, was brought by Macdonald and Macdonald¹⁰, in 1933 They reported four plus complement fixation reactions about nine months after a total of about 8 cc of the vaccine had been injected into two of their four nonimmune sons Five months after injection, the four boys were inoculated with living pertussis bacilli, the immunized failed to contract the disease They were then most intimately exposed to pertussis when it developed in their non-injected, inoculated brothers After recovery from typical pertussis, the complement fixation reactions of the latter were, likewise, four plus positive

*Two reputable biological laboratories now make the vaccine according to our detailed specifications We supply them with freshly isolated strains each month They grow the bacilli on medium enriched with human blood That these approved vaccines should be kept in a refrigerator has been repeatedly stressed

Which of the four immunizations, smallpox, diphtheria, scarlet fever, whooping cough, should be given first? Whooping cough now causes more deaths of infants than do the other three diseases. The age distribution of 42 655 pertussis deaths in the United States in four consecutive years is shown in table 1 B. Over half occurred during the first year of life. The age distribution of 400 consecutive private pertussis patients is shown in table 1, C. Over a third occurred during the first three years of life. The six private pertussis patients who died in the last fifteen years, were infants. Furthermore, on account of the greater prevalence of whooping cough, it seems rational to give the pertussis immunization first. The following immunization schedule, used for several years, has been found practical. To immunize first against whooping cough (at seven to twelve months), four months later, against diphtheria (with toxoid or alum toxoid). When the Schick test is performed and found negative smallpox vaccination is performed; scarlet fever immunization may be completed before nursery school or kindergarten attendance (table 3).

CONCLUSIONS

A total of 8 cc of an especially prepared and refrigerated B. pertussis vaccine (1 cc — 10,000 million bacilli) divided into three, bi-lateral, weekly, subcutaneous injections, should confer prolonged immunity in a high percentage of young nonimmune children, if administered at least four months before exposure. The best age for pertussis immunization is between the seventh and twelfth months of life.

DISCUSSION

DR. PLATT. I have enjoyed this personal account of Dr. Sauer's as much as anything I have heard recently. I think probably the majority of men working with children feel the same way. The merits of the results I think appeal to me more because in the past the results we have obtained and which various others have obtained have made me doubt

ful of the value of vaccine in the disease. I have noticed one striking thing in conversation with my fellow men and I think I understand the reason. The majority of the men I have seen have been very enthusiastic about giving whooping-cough vaccine and quite a number have advised against immunization for scarlet fever. I think the charm of Dr. Sauer's work accounts for that very readily.

Dr. Norton recently in a paper before the Bacteriological Club reported some results with tubercle bacilli in young rats. He found he could not produce any antibodies at all, but in inoculating old rats the antibodies showed in the usual way. He gave another group of young rats of the same age some of the hormones they have in their laboratory and inoculated these young rats again and found that they produced the same immunity reaction as the old rats.

It has been well known that very young babies do not respond very well to many forms of immunization. This clue which Dr. Norton found opens up the possibility of immunizing babies at a very early age.

I should like to know just what age Dr. Sauer recommends for the beginning of whooping-cough vaccine and how late in age he still advises vaccination.

DR. SAUER. Whooping-cough vaccination should be given early—preferably at six to eight months. We have done relatively few after the third year of life.

In children of five or six years more than 8 cc are needed. We inoculated four children—the eldest, a fat girl contracted pertussis a year later the other three (younger) children did not get the disease.

It is best not to give the vaccine as an immunizing agent soon after any contagious disease. Pertussis is more prevalent than diphtheria, therefore we give the vaccine earlier.

DR. CHADWICK. I have been very much interested in Dr. Sauer's discussion.

Diphtheria is well controlled and scarlet fever is mild and therefore whooping cough leads all the other diseases except tuberculosis in the young age group. So if we can have some method of immunization it will be of extremely great value. I have been watching the progress of this work which Dr. Sauer has been doing hoping that we would soon have data enough to consider making vaccine available to the physicians in the state. It is about time we began to think seriously of doing something.

DR. HORTVEL. The treatment of pertussis by the use of vaccine has been of great interest to me as a result of my experience in 1928 with an epidemic of this disease in the New England Peabody Home and my subsequent observations in private practice.

The epidemic at the Peabody Home convinced me that the use of vaccine for prophylactic and therapeutic purposes in whooping cough was of great value. Dr. Sauer and many other observers have arrived at the same conclusion following similar experience with the vaccine as originally prepared.

However in spite of the predominant evidence against the value of this form of treatment it is still being used by the physicians of this community. They say with chagrin that the public demands its use and therefore they must comply. This emphasizes the great importance of medical publicity with regard to public health measures of education. Lay persons cannot be blamed for they were led to believe that vaccine therapy was beneficial by the profession who had accepted the

reports in the current literature based on data of a statistical nature. Many of us are now convinced that these statistics led us into error.

Being a skeptic, and with the thought in mind that Dr Sauer's present contribution, based as it is on statistical rather than biological proof, harbors the same danger, I am prompted to discuss some data that might serve to restrain our enthusiasm until the time when greater evidence is obtained for or against its general adoption.

I feel very strongly that before the public and the medical profession should again be encouraged to believe that an efficient vaccine has been obtained, the evidence should be carefully scrutinized. In this connection, I wish to comment briefly on a few points concerning whooping cough that have fortified me in my stand up to the present time, against the use of all vaccines including Dr Sauer's "immunizing agent."

In the Peabody Home epidemic the following facts stood out:

1. The freshly prepared so-called "Floating Hospital Vaccine," probably identical with various commercial vaccines now in use, had no beneficial effect.

2. A great difference existed in the susceptibility of various children to whooping cough, 80 per cent of the patients taking the disease following their first exposure a few weeks after the onset of the epidemic. Two of them did not contract the disease until after three and four months, respectively, of continuous exposure.

3. It proved that 59 per cent of the susceptible children in the control group even though exposed to the disease consistently for four months resisted infection. Therefore, we must recognize that the transmissibility of this infection is very uncertain and freakish.

In seeking further evidence on susceptibility, and especially the incidence of pertussis in the age group that we would like to protect, I studied the case histories of 500 consecutive private patients and 500 records of children attending the Buckingham School, a private day school in Cambridge.

In both groups the incidence of whooping cough infection under three years of age was 9 per cent. An average of 75 per cent of these children became infected from exposure to older children in the family.

We all admit that this group of 9 per cent of the children under three years of age should be protected if possible. Are we justified at the present time to take the remaining 90 per cent of young children and subject them to universal vaccination without more adequate proof that this procedure is justified?

I have briefly reviewed these data to bring out the fact that the behavior of this infection is likely to be very elusive, especially when we consider its transmissibility, incidence, and finally when we attempt to estimate the value of a prophylactic or therapeutic measure on the basis of a statistical criterion only.

DR SAUER: The 20 per cent that escaped is close to the 24 per cent found by Von Sholly, Blum and Smith. My own experience does not make the percentage so high. As far as the age and the failures are concerned—one child was about four. Of the remaining five, two were six and seven years of age.

The mother was anxious to have them inoculated. Another was the fat girl where the three other children in the family escaped, and the other two failures were between four and five years old when injected.

DR DENNY: We have inoculated about one hundred children in Brookline.

DR MORSE: If I am alive five years from now I shall say what I think.

DR FITZGERALD: A few months ago I gave prophylactic doses of whooping cough vaccine to two children in one family. This morning I received a telephone call from the mother, who reported that both children were coughing and that one had a definite paroxysmal cough. I feel that anybody using the vaccine should be guarded about what he tells his patients.

DR TEFPT: Is there any real evidence that pertussis vaccine and toxoid given at the same time result in less immunity response for either one?

DR SAUER: I have never tried any other way than the method I have outlined. As prolonged immunity is desirable it seems advisable to give no other immunizations until the immunity resulting from the vaccine has reached its peak. As a rule, immunity is completed in four months and should last for years. Failures are not frequent, but they do occur. Either the specific bacterial antigen had lost its potency before it was injected, or the individual lacked the power to develop prolonged immunity. As it is rarely, if ever, necessary to crowd the various immunization procedures, the vaccine should not be given within several months after other immunizations, nor should such other procedures follow within four months of the vaccine. I hope in five years from now we can convince Dr Morse.

DR GOLDMAN: What is the effect of freezing the vaccine?

DR SAUER: The effect of freezing is that the vaccine separates as a gelatinous mass when it is thawed out.

A PHYSICIAN: What commercial houses are approved by Dr Sauer for the manufacture of his own vaccine?

DR SAUER (Naming one): That is one of the two approved vaccines.

A PHYSICIAN: When the course is interrupted by a disease, do you start all over again?

DR SAUER: If the interval is more than two weeks, it is advisable to start all over again.

DR WINOGRAD: How sensitive is this vaccine to being carried around? How can this get to the practitioner, going through the mail for several days? Will this affect the vaccine?

DR SAUER: This vaccine is probably not quite so sensitive to warm temperatures as is smallpox vaccine. To keep the cost down, it is not refrigerated while in transit. Jobbers and druggists, however, are requested to refrigerate it promptly, and to keep it refrigerated. Physicians should not inject any of the vaccine if it has not been kept cold. Unused portions should be returned to the refrigerator promptly. It should never be carried around in the physician's bag.

A MODIFIED TECHNIQUE FOR THE STEREOSCOPIC
EXAMINATION OF THE SKULL BY X RAY*

BY Z. WILLIAM COLSON, M.D.†

IMAGINE that you are viewing a skull made of semi transparent celluloid. For the most accurate observation you will not attempt to study it a yard away. You will take it in your hand and look at it at reading distance say fifteen inches.

Should one attempt to view ordinary stereoscopic films at close range the object would be considerably distorted. This would be true even though the interpupillary shift of the x ray tube were proportionately increased to correspond to the angle of disparateness of the two observing eyes. In the latter case there is only one plane without distortion and that is the horizontal plane at the level of the eyes. When one looks up or down, distortion is apparent in all planes, and this distortion increases in proportion to the difference of the distance from the eyes to the apparent stereoscopic image and the distance from tube to object when the stereograms were taken. In order to make the

stereoscope. The stereoscopic image of the skull does not appear to be 30 inches from the observer, but at just one-half that distance. In this case the proper angle of disparateness is that for 15 inches. Under these conditions each view of the skull is enlarged to double its normal size and each single negative seems enormously distorted. However when these two films are put into the stereoscope the image seems 15 inches away, of normal size and there is no distortion. Of course, under such conditions the stereoscopic image is not so clean cut as when the films are placed closer to the skull.

It becomes increasingly important in close x ray work that the angles the tube makes with the films when the x rays are taken be exactly the same angles that the line of vision of the two eyes makes with the negatives when they are viewed in the stereoscope. The following figure exaggerates these angles to show the point.

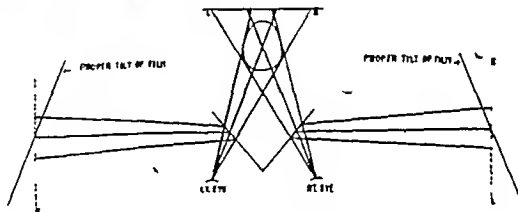

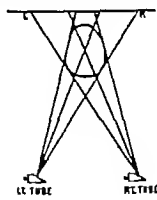

FIG. 1.

stereoscopic image free from distortion in all planes, it is necessary, in making the film exposure, to have the target of the x ray tube at the exact distance from the film that the eyes will assume on viewing the image, and the angle of disparateness that which the eyes would subtend at the target object distance.

It is important in this connection, that one does not confuse the distance from target to object with that from target to film. The unified stereoscopic image will appear to be closer to the observer than the actual positions of the films from which this image is built.

Thus, if skull stereograms were taken at a distance of 15 inches from the center of the skull to x ray target and the films were placed a like distance beyond the center of the skull, the negatives should be placed at a 30 inch distance from the eyes when adjusted in the

stereoscope. Since it is a nuisance to be obliged to measure angles accurately every time the negatives are placed in the stereoscope, it occurred to me that this procedure could be obviated by mounting the films at a right angle to the central line from the x ray in both stereoscopic positions.

One way of doing this would be to mount the tube and film carrier on either end of a pivoting arm with the subject immobilized directly under the axis, thus—

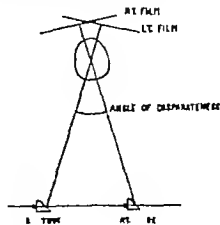

FIG. 2.

Acknowledgment is made to Dr. Harris P. Mosher of the Massachusetts Eye and Ear Infirmary for the use of his laboratory facilities, and to Dr. A. S. MacMillan, Roentgenologist, for his helpful collaboration.
From the Howe Laboratory of Ophthalmology

Massachusetts Eye and Ear Infirmary. For record and address of author see "This Week's Issue," page 1101.

The same thing can be accomplished in a less cumbersome manner by keeping the tube and film holder stationary and rotating the skull through the angle of disparateness required for the given tube-object distance, thus

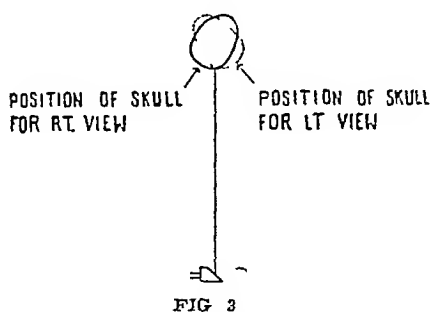

FIG 3

The first piece of apparatus constructed for this work was a chair with a rigid adjustable post which held an arm with the rotating disc and its projecting skull supports over the patient's head. While satisfactory stereograms were made with the patient in this position, some type of cassette holder was necessary to secure the film in its proper position, and any new setting of distance from skull to film was more or less awkward.

A later piece of apparatus is the more conventional box with slanting top. From the back of this extends a rigid adjustable arm which supports the rotating disc. The latter apparatus is more convenient to handle, can be stored away in less space, and is much simpler to construct.*

The rotating disc is slotted so that it can be attached eccentrically to the axis. This allows the point of maximum clinical value in the skull to be placed approximately in the center of rotation, which appears, from my lay observations, to give more perfect stereopsis to that part.

In viewing stereoscopic films one should be very careful in the placement of diaphragms or any other device to limit the viewing aperture to the size of the film used. If the margins are not exactly placed in proper relation to the films, the observer is likely to fix on the margins and thus will break the film stereopsis. Lettering should not be placed on both films in anywhere near the same relative position, as this tends to confuse and may even destroy stereopsis. Also for this reason one should be liberal in choosing oversized films, because the film edges may likewise interfere with proper depth perception.

This technique cannot be applied to stereoscopy of the cervical spine, as the vertebrae do not rotate to the same excursion as the skull and thus gives a flat effect to the cervical column.

Since the roentgenologist is not interested in perfect stereopsis so much as in relative position of various structures, it was thought that he might find it feasible to make exposures at greater target distance for better definition and to rotate the skull through the larger disparate angle employed in close stereopsis. Stereograms were taken at a six foot distance and the proper disparate angles for 30, 20, and 15 inches were employed. At first glance these films seemed to show good depth, but on closely observing details the distortion was so great as to make the apparently good films entirely misleading. For instance, bobbie pins worn by the subject appeared to be embedded in the skull and the middle meningeal artery seemed to rise almost vertically from the posterior ethmoid area.

This brings us back to the point already made that for proper stereopsis without distortion it is essential that there is no disproportion between the distance from the tube to object and the angle of disparateness.

It is the usual practice to place the object of interest as close as possible to the x-ray film to give more clean cut definition to the shadow it casts. On the other hand, when one is concerned with three dimensions, as in stereopsis, he desires structures farther removed from the film to have more value. Thus, should a skull be placed half way between the x-ray tube and the film, the x-ray shadow would be twice the size of the skull and the anatomical relationships would be considerably distorted—the definition would be hazy. On the other hand, the relative shadow value of structures nearer the film and those nearer the tube would be more nearly the same. If stereograms are taken with this technique, there is considerably more uniform value to all the structures in the skull and the distortion and magnification, which would make the films worthless if viewed singly, make all the skull structures stand out in their normal relationship and actual size when the two films are combined stereoscopically.

In a recent article Verhoeff¹ has demonstrated quite conclusively that in stereoscopic vision we do not fuse the two images in the commonly accepted sense of the term. In general words, we see the object with the eye in which the image of the object has the higher attention-value, while the other eye aids in placing the object. He has shown even further with stereoscopic drawings that images of unequal attention-value alternated in various portions of the stereoscopic field will be seen exclusively by the eye to which their attention is drawn. This is done simultaneously in various portions of the field so that the right eye may be dominant in certain areas while the left may be dominant in others. Thus, according to Verhoeff's theory a stereoscopic image is made up of a fine mosaic,

*Should one desire this piece of apparatus it can be obtained from the Crompton Machine Company, Lawrence, Massachusetts.

each unit of which is supplied by one eye only (and placed by the other eye) while the proportion of units supplied by the two eyes is subject to many and varying factors. Both eyes contribute to the proper placement of points in space, although the image of each point is perceived by only one eye at a time.

It would appear from Verhoeff's work that if it were possible to combine a close film made for clear definition with a distant film made for better depth the stereoscopic image would be seen by the eye which observes the clear-cut shadows of the close film and placed in normal relation as to depth by means of the eye which observes the larger shadows of the more distantly placed film. The combining of these two different sized images is made possible by viewing each negative in the stereoscope at the respective target film distances employed when the x rays were taken.

Film pairs have been made in which one close film, taken for clearness, was combined stereoscopically with a larger distant film. To my eye, unpracticed in x ray examinations, the stereoscopic image of the different sized films

could not be distinguished from that of a pair of same sized films. The possible practical value of such an arrangement can best be judged by clinical roentgenologists.

It can also be inferred from Verhoeff's work that it is better, in stereoscopic practice, to take one of the exposures at the angle which would give the best single film view of the anatomical structures in question, letting the angle of the second view fall where it will. Thus at least one film will be ideal as a single plate and the second film will merely place it in proper depth.

An immediate objection which may be raised to this close x ray technique is the gross distortion of the individual radiographs. It is true that, viewed as single plates, they are worthless. It is thus very distortion, however, which gives the true stereoscopic depth in all planes. In fact the single view distortion is an absolute requisite of undistorted near point stereoscopy.

THE NATIONAL FORMULARY SIXTH EDITION

The American Pharmaceutical Association announces that its Council has officially approved December 16 1935 as the date when the new N.F. VI will be released for sale in all parts of the country and has also approved June 1 1936 as the date when the N.F. VI will become official and supersede the N.F. V.

As previously announced the N.F. VI will be distributed for the Association by the Mack Printing Company of Easton Penna.

The new National Formulary represents a complete and thorough revision of N.F. V. Additions and deletions are based on information obtained in the U.S.P. N.F. Prescription Ingredient Survey.

This survey was made to determine the materials prescribed and the extent of their use throughout the country. The N.F. VI therefore supplements the scope of the Pharmacopoeia and supplies additional information on simple formulas diagnostic reagents and standards required by the pharmacist in the practice of his profession.

Of the 689 monographs in the N.F. VI 208 are Drug or Chemical Monographs and 481 are Monographs of Pharmaceutical Preparations. The more important additions have been in the monographs for ampuls, tablets, fluid extracts, syrups, tinctures and ointments.—*American Pharmaceutical Association* 2215 Constitution Avenue Washington D. C. *Bulletin* No. 3—1935-1936.

THE NEW YORK ASSOCIATED HOSPITAL SERVICE

Mr. F. Van Dyk, executive director of the New York Associated Hospital Service is quoted in the daily press as stating that 156 hospitals are now included in this service with thirty-three thousand subscribers for the three cents a day plan. More than 700 persons have already been given hospital treatment under this arrangement and this coöperative movement is now self-supporting. The Commonwealth Fund has contributed twenty-four thousand dollars to this plan. Other smaller grants have been received.

This is a demonstration of a coöperative spirit in New York.

MARRIAGE LICENSES IN CONNECTICUT

After the first of January all applicants for a marriage license in the State of Connecticut must pass a Wassermann or Kahn test before a license will be granted. The certificate must be based on a blood examination by an approved laboratory. The blood examination will exclude the possibility of syphilis. Other states requiring medical examination upon the issuance of a marriage license are Wisconsin, Oregon, North Dakota, Alabama, Wyoming and Louisiana. The State of North Carolina repealed its law this year.—*Science* November 15 1935.

President Mongan called the meeting to order promptly at 12 o'clock. The Secretary, Dr Alexander S Begg, read an abstract of the minutes of the Annual Meeting which was held on June 4, 1935. These minutes were published in full in the *New England Journal of Medicine* for July 25, 1935. There being no corrections, the President declared the record approved.

The President appointed Dr Fitz and Dr Kinney to escort the Vice-President, Dr Channing Frothingham, to the platform.

The President then proceeded to address the Council concerning the situation which faces the Society and spoke of the plans which are now underway. His remarks were greeted with much applause. (See Appendix No 1.)

Dr William Reid Morrison of Middlesex South presented the report of the Committee of Arrangements. (See Appendix No 2.) The report was accepted and the recommendations were approved.

Dr David N Blakely of Norfolk presented the report of the Committee on Membership and Finance. This report showed that two Fellows were allowed to retire, six Fellows were allowed to resign, two Fellows were deprived of Fellowship and five Fellows were allowed to change

their membership from one district society to another without change of legal residence (See Appendix No. 3.) The report was adopted and the recommendations approved. Dr. Blakely next presented a recommendation from the Committee on Membership and Finance that the Annual Dues for the year 1936 be the same as for each of the last four years, namely \$10.00 for resident Fellows and \$6.00 for non-resident Fellows. The recommendation was adopted in due form.

The President called upon the Secretary to announce the recommendations of the various committees appointed to consider restoration to Fellowship of such Fellows as had applied. The committees reporting were (1) in the case of Dr. Charles McGinley of Lynn—Drs. Hottel Fraser and Blair, (2) in the case of Dr. Henry Lutter of Springfield, the committee consisted of Drs. Steele, Stoddard and Walker and (3) in the case of Dr. Mario J. Carami of Springfield the committee consisted of Drs. Birnie, Hosmer and Bacon. All three committees reported favorably and stipulated that the restorations should be made provided the applicants paid the amount due the Society within one month of the date of this meeting. The Council voted to approve the recommendations of these committees. The President asked the Secretary to announce new petitions for restoration. There was but one to be submitted, namely, Dr. Sanford M. Liljestrom from Worcester. The President appointed as a committee to consider this petition Drs. Ralph W. Ellis, chairman, Dr. John M. Fallon and Dr. Raymond W. Cutler. The Council approved the committee.

President Mongan stated that it was customary to appoint the Auditing Committee at this meeting of the Council. This committee consists of Fellows who are not members of the Council. They supervise the examination of the Treasurer's accounts which is done by a firm of certified public accountants. He appointed to this committee Dr. Richard M. Smith of Boston and Dr. Harry P. Cahill also of Boston. The Council voted to approve the nominations.

The President announced that since the work of the Committee on Public Relations had been divided among various subcommittees he would call upon the chairman of each subcommittee for an informal report.

Dr. Michael A. Tighe of Middlesex North recalled the action taken by the Council at the April meeting at which time definite instructions were given to the Public Relations Committee with reference to informing the public of the attitude of the Society toward compulsory sickness insurance. Pursuant to these instructions the Public Relations Committee through its Subcommittee on Social Legislation and Insurance formulated a plan which provided for the formation of district public relations committees so that the work of informing

the public might be distributed. This part of the work has been completed. As a second step it was found necessary to provide information for the medical profession so that its members would be in a position to offer the public authoritative information. Literature prepared by the American Medical Association was sent to each district public relations committee in June so that there might be an opportunity for the study of this material during the summer months. It was hoped that arrangements could then be made to reach civic organizations, service groups, parent teachers' associations and others which would be helpful in the dissemination of the physician's viewpoint on compulsory sickness insurance. Dr. Tighe then proceeded to describe the very successful campaign which he and his local public relations committee had conducted in his district. He showed that it was quite possible to interest the press and to obtain a great deal of favorable comment on the attitude of the Society. The exhibits which he made were most convincing, particularly the editorial comment by laymen. The whole effort seemed to indicate a desire for information from medical sources which appear after all to be those which can be more generally relied upon by the public. The President expressed the appreciation of the Society for the work of Dr. Tighe and his Subcommittee and expressed it as his opinion that other doctors might well use Dr. Tighe's efforts as a model.

Dr. Hunt of the Subcommittee on the Adequacy of Medical Care related the steps which had been taken by that Subcommittee up to the present time and recalled to the Council the inadequacy of the appropriation previously made and the inability of the Subcommittee to carry on its studies during the summer. He described his efforts to have the study of ten thousand families in Worcester designated as an approved subject under the Works Progress Administration. Dr. Hunt recommended that similar projects be offered in other parts of the State so that not only would the information be obtained but work would be provided which would help some members of our own profession since it is apparently the desire of the federal authorities to help the so-called "white collar class." Dr. Hunt's report was enthusiastically received by the Council.

President Mongan stated that Dr. Henry D. Chadwick, Commissioner of Public Health of the Commonwealth of Massachusetts, had been asked to attend the meeting and called upon him to tell the Council something about the Federal Economic Security Law as it affects the practitioner of medicine. Dr. Chadwick then proceeded to discuss the Social Security Act passed at the last session of Congress. This comprehensive document is divided into several sections. One is devoted to unemployment insurance and old age assistance with administration of its provisions assigned to the new

Social Security Board of which Ex-Governor John Winant of New Hampshire is the chairman. It is, however, in the other sections that there is the greater medical interest. One of these relates to the United States Public Health Service to which is allotted the sum of \$8,000,000 for the purpose of improving, strengthening and broadening public health work in rural areas. Allotments to the states are to be made through the State Health Departments. Approximately \$20,000 is allotted to each state and in addition an allotment is made which is dependent upon the amount expended by the state at the present time and also somewhat dependent upon the population. It is expected that Massachusetts would, therefore, receive in addition to the \$20,000 approximately \$75,000 per year under the latter provision. There is likewise a section under which several million dollars will be expended by the Children's Bureau of the Labor Department. This money will be expended for maternal and infant care and is designed to supplement what is now being spent by the states through their health departments. Here likewise each state will receive approximately \$20,000 regardless of the population and the amount now being spent by the state. In addition there will be a further amount which will be allotted according to the ratio of live births within a particular state to the total live births within the country as a whole. Massachusetts should receive approximately \$75,000 under this grant.

Another section has to do with the diagnosis, care and treatment of crippled children. The appropriations under this section are to be expended through the State Health Department and in Massachusetts in cooperation with the Department of Public Welfare since it is under this Department that provision is now made for the treatment of crippled children. It will be a cooperative plan but apparently this section has not been so thoroughly organized as is the case with the other sections of the National Security Act.

Another section provides for the care of the blind. This is not under the State Health Department and Dr Chadwick was unable to give many details on this section. He pointed out that the work under the National Security Act was to be paid for by money provided in the Deficiency Bill which had failed of passage in the last Congress so that no money is available to put the act into effect although preliminary organization was contemplated by the federal bureaus so that the work could go forward when and if Congress subsequently provides funds.

Dr Chadwick next discussed the difficulties of the problems which face the State Health Departments and stated that he was anxious to have the help of the Massachusetts Medical Society in formulating plans. He spoke of conditions in Berkshire, Franklin and Hampshire

Counties and stated that the State would probably make its start in those Counties. He pointed out the possibility of forming county health districts so that the larger and smaller communities could work together more efficiently. He stated that legislation already exists to permit towns to form joint health districts and pointed out that there are at present in the State two such cooperative units. He then proceeded to discuss the various phases of the work which it is necessary to do in such units. Dr Chadwick spoke of the survey which Dr Hunt had discussed and pointed out that the United States Public Health Service has a plan for making a survey on chronic illness within the State. The areas designated are Boston, Fall River, Ipswich, Greenfield and Pittsfield. The Council listened with attention and interest to Dr Chadwick's talk and Dr Mongan expressed the thanks of the Council to him for his excellent presentation. Dr Mongan spoke of the correspondence which had passed between him and the authorities of the United States Public Health Service and stated that he had offered the cooperation of the Society in the undertaking in so far as this can be done. Vice-President Frothingham called for a rising vote of thanks to Dr Chadwick. This was carried unanimously.

Dr Mongan introduced another item which has a medical aspect. This has to do with the activities of the Works Progress Administration. Under the provisions of the law the State has been divided into six districts, each district having a director, and a series of conferences has been held by state and district medical officers with officials of the Works Progress Administration. These conferences have to do with the care of accidents occurring under projects being handled by the Works Progress Administration. He next proceeded to read, for the information of the Council, a letter received from the State Director (See Appendix No 4). The President spoke of tentative plans which had been made for carrying information to the physicians of the State and pointed out that nothing further had been done as the necessary information had not been forthcoming from the federal authorities. The compensation officers were provided with a copy of our catalogue of members.

Dr J B Hall of Norfolk made an inquiry concerning a circular which had been sent to physicians and members of the Society in Boston relative to obtaining information regarding physicians in financial need. He stated that he knew a few physicians who had been interviewed by a social service worker but that nothing further had been heard from the project. He asked for information. At the request of the President the Secretary stated that he had accompanied the President of the State Dental Society to confer with Mr Hobbs in the Park Square Building and that after some prelim

many discussion was referred to Miss Warren, the head of the Social Service Department. She pointed out that the only way in which these physicians could be helped was in connection with projects that had been approved by the Works Progress Administration. It was the Secretary's understanding that one of the projects that had been approved was the physical examination of people on the welfare list and that Dr. Wilensky had been delegated by the Health Commissioner of Boston to supervise this work. The Secretary also understood that, while a considerable group of physicians had been interviewed by the social service worker, all of those interviewed had not been placed upon the list. It appeared that this was all that could be done at the present time.

Dr. Lund, Secretary of the Suffolk District Medical Society, offered some additional information. He stated that eighteen men had finally been placed upon the list but that not all of them were in reality doctors of medicine. He also explained that with the change from the Federal Relief Administration to the Works Progress Administration various projects had to be referred once more to Washington and some of these were apparently still there. He informed the Council that he had learned through the Works Progress Administration authorities within the last few days that they expect information momentarily.

The report of the Committee on Postgraduate Instruction was then called for and was presented by Dr. Reginald Fitz of Suffolk (See Appendix No. 5).

The President referred to a vote taken at the Annual Meeting of the Council which created an Advisory Committee to the President and also to another vote which empowered the President to appoint a full time executive officer at the Society's headquarters. He stated that acting under this authority Mr. Robert St. B. Boyd had been appointed to the position.

The Secretary announced that the Cotting Luncheon would be served at the close of the meeting of the Council although no statement to this effect had appeared on the notice of the meeting.

The President announced the death on October 2 of Dr. Leonard Wheeler who was ninety years of age and who joined the Society in 1870. He stated that Dr. Wheeler had been a beloved practitioner in Worcester and that he had been highly respected by the members of the profession throughout the State. He asked the Council to rise in silence for a moment in memory of Dr. Wheeler.

The Secretary then read a communication from the Secretary of the Veterinary Division at the State House calling attention to the fact that some physicians, members of this Society, had been practicing one or more branches of veterinary medicine in direct violation of the law. Such practice included the vaccination of dogs

against rabies and distemper and the treatment of fractures and other troubles. He stated that fees had been collected for some of this work. He also pointed out that this matter had been called to the attention of the profession through the columns of the *New England Journal of Medicine* and that it should be treated seriously since the person disobeying a law may be fined as well as imprisoned.

The President then referred to the Committee on Membership and Finance the name of a prominent teacher in one of the Boston institutions who had been suggested as an Honorary Fellow.

The Secretary announced that he had received the report of the delegates chosen to represent the Massachusetts Medical Society at the meeting of the House of Delegates of the American Medical Association at Atlantic City, June 10 to 13, 1935 (See Appendix No. 6).

The President announced that the Council would now go into Executive Session and all who were not members of the Council including the reporter were asked to retire.

The Executive Session having been completed, the meeting was declared adjourned at 2:20 P.M.

ALEXANDER S. BEGG,
Secretary

APPENDIX NO. 1

ADDRESSES TO THE COUNCIL OF THE MASSACHUSETTS
MEDICAL SOCIETY BY THE PRESIDENT C. E. MORGAN

Members of the Council of the Massachusetts Medical Society

I desire to take this opportunity of thanking you most sincerely for the honor you have conferred by choosing me to be the President of the Massachusetts Medical Society. The numerous letters of congratulation that I received on the occasion of my election and also the many personal congratulations extended make me feel that already there exists among you a genuine sincerity in all this. This sincerity indicates that your President will not be forced to ask for your cooperation. It is already here and available for his use.

However this spirit of cooperation which is so evident brings to him an appreciation of the responsibility of the office of President of your society. It also engenders in him a feeling of optimism for our future as an organization. The Massachusetts Medical Society has been a society of the highest standards among medical organizations.

It has ever been to the forefront in rendering to the citizens of this state a medical service unequaled in this country. In the past the officers have been unselfish and ever ready to make sacrifices either voluntary or when requested without any hope of material reward. Their only reward has been the satisfaction that comes from deeds well done.

I will endeavor to maintain this standard of the past. I will endeavor to follow the ideals of our organization and to emulate accomplishments of past presidents.

New problems now confront us. Heretofore our Society has been greatly concerned with scientific aspects of medicine. Today we are called upon as a profession to deal with medical problems that are intimately interwoven with our social fabric. It would seem as if every human activity had a medical

aspect The profession will be called upon to act in many fields which before were closed to our services and which now are open because of industrial and social developments We face these problems confident that medicine will play a great part in their ultimate solution.

The Society has not neglected the scientific side of its work The Postgraduate Instruction Course, which is now entering its third year of existence, shows that the society is alert and is giving to its members an excellent opportunity to prepare themselves adequately to serve the community with intelligent medical care that is based on most recent and most scientific principles I must strongly urge you to give support to the excellent work of this activity

PUBLIC RELATIONS COMMITTEE

The work of the Committee has been well done The Committee gives justification for its existence This Committee has no formal report to make During the summer it had one meeting The Chairmen of the Subcommittees of the main Committee have had several conferences, one of which was attended by the Commissioner of the Department of Public Health of the Commonwealth, Dr Chadwick Dr Chadwick is here as a guest of the Council and will address you on some phases of the Economic Security Law as it affects the practitioner of medicine in Massachusetts It was thought that the Councilors should get information in regard to the Economic Security Law from the Commissioner himself, as it is probable that Commissioner Chadwick will be the officer who will carry through the provisions of the law The Chairmen of the Subcommittees will inform you of some work that has been done under their direction, especially by Dr Tighe, Chairman of the Subcommittee on Social Legislation and Insurance, and by Dr Hunt who will give you information in regard to the progress of the Subcommittee on Adequacy of Medical Care

The President and the Secretary of the Society have been in communication with certain federal authorities in regard to the medical phases of the Works Progress Administration Your officers feel that the Society should do all in its power to aid and cooperate with the administrators of this law

STANDARDS OF EDUCATION

This matter has been considered by the Society for many years Proposed laws bearing on standards of medical education have been introduced into the Massachusetts Legislature many times The members of the Legislature do not seem to understand our position and I am sorry to state that there are many members of this Society who do not understand our position Your President feels that it will be necessary to undertake a campaign of education—to use a colloquial phrase he thinks it will be necessary to sell the Society to its members Certain insidious influences place our Society in the position of one that is trying to control for its own selfish interest the practice of medicine in Massachusetts Consequently we have been dubbed a medical trust and a medical oligarchy The time has come when we should go forth to the citizens of Massachusetts and tell them the true condition of affairs bearing on this question

FACULTIES OF APPROVED MEDICAL SCHOOLS

Your President urges that there should be a closer contact of the Massachusetts Medical Society with the faculties of approved schools This proposition is so evident that it scarcely needs comment

GRADUATES OF APPROVED MEDICAL SCHOOLS

The Society should consider the matter of urging that graduates of these schools cultivate closer associations with their respective schools Your President has the assurance that graduates of such schools are always welcome to return and that the schools are ever ready to give information that will help the graduate in his work as a practitioner If such an association could be cultivated, there is no doubt it would be of inestimable value both to the school and to the practitioner of medicine

Your President in his work will ever keep in mind the traditions of this Society and its ideals He hopes that these will furnish him with guiding stars in the work of making the Society a worth while influence in the community

APPENDIX NO 2

REPORT OF THE COMMITTEE OF ARRANGEMENTS

Your Committee of Arrangements for the Annual Meeting wishes to make the following report.

After consulting with the President, Dr Mongan, and the Secretary, Dr Begg, the Chairman of your committee has designated June 8, 9 and 10, Monday, Tuesday and Wednesday for the Annual Meeting of the Society in Springfield Owing to the fact that the city of Springfield is celebrating its three hundredth anniversary, it was imperative to inform the Springfield Chamber of Commerce and the local committee promptly if the Society wished to make use of the Auditorium and Hotel Kimball, which are necessary for the success of our Annual Meeting I therefore designated these dates which agree with the second week in June according to the By Laws, but without the consent of the Council

I make a motion that June 8, 9 and 10, 1936 be approved by the Council, I also propose that fifty cents per person be contributed by the Society so that the price of the dinner be not more than one dollar per person

Your Chairman of the Committee of Arrangements has personally visited the four western county societies, with your President and Secretary and has urged the new members as well as the older men to take a personal interest in the Society's affair and attend the Annual Meeting and Dinner I propose to visit all the other District Societies to inform the members of our plans and ask for any suggestions they wish to make

I have personally inspected the Springfield Auditorium and the Hotel Kimball, and made adequate reservations last month with the proper authorities, including the Chamber of Commerce

We plan to have a larger Scientific Exhibit, and excellent facilities are available for an extensive Commercial Exhibit.

Good clinics, good section meetings, a good dinner, and a good time are offered to all the members of our Society We ask for your support.

An innovation in the form of a good fellowship room is planned, with beer and sandwiches available at any time to our members without charge

Entertainment by the Women's Committee for the wives and members of your families will be available as well as a Kickers' golf tournament with many excellent prizes for the winning participants

An appropriation of \$1600 is asked for the general meeting, and \$400 for the Women's Committee

Your committee expects a large attendance at the Annual Meeting, we shall make every effort to double the registration of the last visit to Springfield

WILLIAM R MORRISON, *Chairman*

APPENDIX NO. 3

REPORT OF THE COMMITTEE ON MEMBERSHIP
AND FINANCE ON MEMBERSHIP

This Committee recommends

1. That the following named two Fellows be allowed to retire under the provisions of Chapter I Section 5 of the By Laws

1. Fogarty William Clemmons Worcester
2. Vose Robert Henry Milton

2. That the following named seven Fellows be allowed to resign under the provisions of Chapter I Section 7 of the By Laws

1. Daly Timothy Joseph Lawrence with remission of dues 1933 1934 1935
- *2. Fitz-Simmons Henry Joseph Boston with remission of dues 1935
3. Morse Joseph Louis New York City with remission of dues 1933 1934 1935
4. Otis Elmer Milo Brea, Calif. with remission of dues 1935
5. Root, Manly Bronson Washington D. C. with remission of dues 1935
6. Smith Roland Leonard North Attleboro
7. Mahony Francis Roman, Lowell

3. That the following named two Fellows be deprived of the privileges of Fellowship under the provisions of Chapter I Section 8 Clause (a) of the By Laws

1. Dervin Lawrence James Somerville
2. McPeake, John Richard Milton

4. That the following named five Fellows be allowed to change their membership from one District Society to another without change of legal residence, under the provisions of Chapter III Section 3 of the By Laws

Two from Middlesex South to Suffolk

1. Weiss, Soma Cambridge
2. Wolbach, Simeon Burt, Sudbury

Two from Norfolk to Suffolk

1. Baird, Perry Cossart, Jr. Brookline
2. Callanan Francis Jervais, Brookline

One from Norfolk to Worcester North

1. Pollaner Saml Richard, Brookline.

DAVID N. BLAKELEY Chairman

Dr. Fitz-Simmons died October 5

APPENDIX NO. 4

Works Progress Administration
Park Square Building
Boston Massachusetts

September 25 1935

Dr. Charles E. Mongan President
Massachusetts Medical Society

Employees of the Works Progress Administration who suffer a traumatic injury while in the performance of duty are entitled to medical and hospital care made necessary by such injury

Under the applicable Compensation Act it is provided that medical treatment will be furnished by United States medical facilities where practicable, and it is necessary that such facilities be used to the extent that they are available.

However in locations where Federal medical facilities are not available or where they are in

adequate to furnish the services required, the State Compensation Officer of the Works Progress Administration is obliged to make arrangements for medical treatment to be rendered by reputable private physicians. These private physicians will be paid fees for their services at rates not in excess of the minimum charge prevailing in the community for similar services.

In preparing a list of reputable physicians the State Compensation Officer is instructed in "contact the local Medical Societies to enlist their cooperation in selecting physicians in the locality who are especially well qualified by training and experience to render service in industrial accident cases and who desire to participate in this service under the regulations of the Commission."

It is our understanding that the Massachusetts Medical Society which is, in effect, a federation of many local and County Medical Societies and authorized to speak in behalf of its local and County units, can supply us with this information on a State-wide basis.

We would call to your attention that, under the Rules and Regulations of the United States Employees Compensation Commission there is to be no discrimination against any physician otherwise qualified because he is not a member of a Medical Society.

A physician qualifies under the regulations of the Commission if he is a graduate of a recognized medical school with a degree of M.D. and is licensed to practice medicine in this State.

In accordance with the Rules and Regulations we should like to have your cooperation in selecting physicians especially qualified to render services in industrial accident cases by having your Society recommend to us a list of such physicians.

Very truly yours

JOHN H. MORRIS,
State Compensation Officer

APPENDIX NO. 5

REPORT OF THE COMMITTEE ON POSTGRADUATE
INSTRUCTION

The Committee on Postgraduate Instruction has prepared a curriculum of postgraduate extension courses which has been submitted to each district society. Twelve places will have the course this fall while the balance will be given next spring. The first courses will start in Bristol South (Fall River Section) and Norfolk South District on October 7, 1935.

Announcement of all the fall schedules appears in *The New England Journal of Medicine*, issue of October 3, 1935.

FRANK R. OWEN Chairman,
LEROY E. PARKING Secretary

APPENDIX NO. 6

REPORT OF DELEGATES HOUSE OF DELEGATES AMERICAN
MEDICAL ASSOCIATION ATLANTIC CITY SESSION JUNE
10 TO 13 1935

Your delegates attended all sessions of the House of Delegates at this 86th annual session of the Association. The total registration of more than eight thousand surpassed that of any other medical convention at any time. From Massachusetts two hundred and sixty-nine registered.

The Canadian Medical Association held its annual meeting at Atlantic City by invitation of our national association and participated in the several

section programs and contributed many scientific exhibits. In the words of Dr. Routley, secretary of that Association, "We moved our organization down here lock, stock and barrel." Of their council of one hundred and twenty odd, seventy six were present. This, the first meeting outside of Canada, was the occasion for complete revision of the constitution and by laws, a better demonstration of international good will, in the opinion of the secretary, than could be shown otherwise.

Of four special scientific exhibits authorized by the Trustees we are pleased to note the participation by three of our Fellows,—Elliott Joslin, chairman of the committee presenting an exhibit on all the aspects of diabetes, Charles McKhann contributed a display on measles in the demonstration of vaccines and serums, Reginald Fitz, chairman of the committee for the second time, showed an exhibit on nutrition.

All received special commendation from the Committee on Awards.

A special certificate of merit was awarded the group exhibit from the Lahey Clinic on surgical treatment of thyroid diseases, exploration of common duct and abdominoperineal resection of the rectum. Other exhibits in surgery were offered by Drs. Berlin, Charles G. Mixter, Freedman and Schlesinger of Beth Israel Hospital, and Drs. Hurxthal and Allan of the Lahey Clinic. In dermatology and syphilology Drs. Downing and Cousins of the Boston City Hospital exhibited fungi pathogenic to man. Drs. Smillie and Wells showed apparatus and charts illustrating airborne infection. Drs. Brett, Green, Ober and Legg presented exhibits, five in number, in the section on orthopedics.

In the scientific program twenty one papers were read by Fellows of this Society and the same number participated in discussions.

In our state group of delegates two new members replaced Roger Lee and William Robey. The election of the former to trusteeship we applaud, the automatic retirement of the latter through serving as our President we regret. Their successors, Reginald Fitz and Richard Milner, able and aggressive, both yet on the upgrade of the journey, we, at or approaching the timber line, receive them cordially.

In the organization of the House of Delegates Dr. Charles E. Mongan, our President, was designated Chairman of the Reference Committee on Legislation and Public Relations. Membership on the Committee on Reports of Board of Trustees and Secretary was given to Edmond Cody.

The retiring president Dr. Biering, addressed the House on the progress of the past year. The incoming president, Dr. McLester, stressed the importance for retaining individualization to maintain the high standards achieved.

The report of the secretary showed as of April 1, 1935 membership as 99,536 and fellowship as 61,406. Massachusetts has 4737 members, 3004 of whom are Fellows. Of 7014 physicians in this state 57 per cent receive *The Journal of the American Medical Association*.

The report of the Board of Trustees showed marked reduction in expenses.

The Treasurer's statement as of December 31, 1934 revealed reserve invested and uninvested \$2,288,051. The total assets \$3,686,443.

Of the publications *The Journal's* gross earnings were \$1,439,751. The net \$613,969. The average weekly circulation was above 85,000. The health journal *Hygeia* showed a loss of \$2059 in 1934 as compared with \$30,127 in 1933. It is of some interest that eighty-one per cent of its subscribers are laymen. The special journals were published at a loss of \$14,936. Their total circulation is 19,384.

The reports of the several councils, bureaus and

committees have appeared in *The Journal* and will not be discussed here save in two instances—The Council on Medical Education and Hospitals, and The Judicial Council.

The Council on Medical Education and Hospitals reported that in accordance with a resolution requesting formulation of standards for schools of occupational therapy, the eleven existing schools had been visited and now the Council presents the Essentials of an Acceptable School of Occupational Therapy.

A resolution was adopted at the Cleveland session to the effect that the staffs of hospitals approved for intern training should comprise only members in good standing in their local county societies. A letter has been sent to all intern hospitals advising them of this action. When the next census of hospitals is taken, the Council will be in a position to know whether further action is needed.

In the matter of compensating radiologists practicing in hospitals investigation and conference with leaders in the field, it was developed that no single method of remuneration is universally applicable, they may accept salary, fees or commission or any combination of these, but in no case should there accrue to the hospital a substantial profit over and above the reasonable cost of maintaining the department, nor should the patient be exploited through excessive fees. During the year the Council's staff has visited 592 hospitals with reference to registration 175, with regard to approval for training in terms 157, for residency approval 30, and 230 tuberculosis sanatoriums.

The Council has prepared and distributed a list of textbooks, reference works and journals suitable for a hospital library.

The Council calls particular attention to the Hospital Number of *The Journal*, issued March 30, 1935, wherein the distribution of hospitals is graphically represented by state maps and the significant fact that the country is already oversupplied with general hospitals is clearly shown. Further it is demonstrated that in those sections of the country where the ratio of beds to population is low and where some are inclined to assume that additional hospitalization is needed, the actual utilization of existing facilities is also low. The conclusion is inescapable that where the public demands hospital facilities they have been provided, and that in sections where the public does not avail itself of more than fifty per cent of the opportunities for hospital care that now exist it would be futile to provide more. During the year 1934 7,730 physicians were licensed to practice medicine in the various states. Of these, 5435 represent actual additions to the number in practice. At this rate, according to the report of the Commission on Medical Education the ratio of physicians to population will steadily increase. This situation greatly enhances the menacing importance of the fact that a number of states continue to examine and license graduates of unrecognized schools. After a quarter of a century of effort on the part of the Association to raise the standards of practice, there are still four states which flagrantly evade the responsibility to protect the lives of their citizens.

The report of the Judicial Council revived an issue of 1932 which we of Massachusetts had assumed to be adjusted following a conference between Drs. Robey and Birnie and the Secretary, Dr. Olin West. The section follows.

MEMBERSHIP IN STATE ASSOCIATIONS

It is a practice in a few state constituent associations to admit to membership in the state association (1) physicians who are nonresidents of the state and therefore not members in any component society

of the state, or (2) physicians resident in the state who for some reason are not members of the county society where they live or practice. Such a procedure is reprehensible in a democratic organization such as the American Medical Association. The theory on which the American Medical Association is built arises from the broad basis of the county medical society, all of whose members are members of the state association and the national body and all of whom have definite responsibilities for maintenance of the entire organization. There should be no privileged group to enjoy the advantages presented by the higher bodies without supporting the lower bodies which makes the higher bodies possible. The constitution of the Association states that "members in good standing of the constituent association are the members of the American Medical Association subject, however to the provisions of the bylaws regarding members."

Nowhere does the constitution or the bylaws state that membership in a component society is essential to membership in the state society though the intent is clear in the bylaw covering membership and Fellowship in the American Medical Association, on transfer of residence from one state jurisdiction to another. Membership in two state associations is as inconsistent as being a voter in two states or two congressional districts. Furthermore representation in the House of Delegates is based not on the number of members in the county societies of the states but on the number of members in the state association. A state association that carries on its membership roll nonmembers of the component societies may very possibly have an unjustified representation in the House. In the opinion of the Judicial Council membership in a component society should absolutely be essential to membership in a state association. This section of the Council's report was referred to the Reference Committee on Amendments to the Constitution and Bylaws which committee reported out as follows:

"Your committee recommends that to remove the menace which the Judicial Council reveals with respect to overlapping membership in state associations the Constitution and Bylaws be so amended as to remove all further difficulty in assigning a member to the state in which he practices.

Accompanying this report was an amendment for modification of the existing bylaw which was laid on the table for twenty-four hours, the provision for amendments to the Bylaws. The following day the Chairman of the Judicial Council stated that the amendment just mentioned did not cover the situation so as to make it necessary that each member of a constituent association be a member of a component society in that constituent association and for that reason it did not fully correct the abuses which the Judicial Council brought up in its report. Accordingly the Council had prepared a resolution embodying the desired change in bylaws. Section I of Chapter XI to read as follows:

"Membership in this Association shall continue only so long as the individual is a member of a component society of the constituent association through which he holds membership.

The report of the Judicial Council was adopted and a motion that the amendment be adopted was carried.

In addition to resolutions and motions incidental to phases presented by the reports of officers and administrative boards twenty-nine resolutions were

offered from the floor. Contraception led all the rest with ten. These were given to a special reference committee which reported during the Executive Session as follows:

The Special Committee appointed to consider all resolutions concerning the control of reproduction begs leave to report that after a careful study of these resolutions it recommends that not any of them be approved as introduced. The committee desires to present as a substitute resolution the following with this preamble: That the House of Delegates declares that nothing in the following resolutions be interpreted as a declaration or action either for or against birth control.

Whereas, Under the stimulus of large non-medical groups the general use of contraceptives is being advocated and encouraged despite the existing law not only by the above-mentioned groups but by commercial interests as well and

Whereas The ultimate effect of these measures on the health and general welfare of the population of the United States is unknown if not questionable and should accurately and extensively be studied by the medical profession, in whose care the health of the people rests and

Whereas The laws both federal and local governing physicians in their advice to individual patients, where such advice is given as a therapeutic measure seems to be complicated not well understood and generally unsatisfactory and their interpretation difficult therefore be it

Resolved That a special committee be appointed after due consideration by the Board of Trustees to study these related problems and to present at least a preliminary report to the House of Delegates at the 1936 annual session and be it further

Resolved, That the trustees be requested to appropriate the funds necessary in order to carry out the purposes of these resolutions.

The report of this special reference committee was adopted.

The resolution presented by Dr. Wesselhoeft at the annual meeting of this Council opposing the continuation of the so-called Dick earlester fever patent was read by Dr. Birnie. Referred to the Committee on Legislation and Public Relations it was returned with recommendation for reference to the Board of Trustees.

Election of Officers resulted as follows:

President Elect James Tate Mason Seattle
Vice-President, Kenneth M. Lynch Charleston S. C.
Secretary Olin West, Chicago
Treasurer Hermann L. Kretschmer Chicago,
Speaker Nathan B. Van Etton New York,
Vice-Speaker Harrison H. Shoulters Nashville
Trustees Ralph A. Fenton Portland Oregon
James R. Bloss Huntington, W. Va.

President McLester renominated Reginald Fitz a member of the Council on Medical Education and Hospitals.

Respectfully submitted
EDWARD F. CONY

VERMONT STATE MEDICAL SOCIETY

HOUSE OF DELEGATES

IN the absence of Dr Stanley Wilson, President of the House of Delegates, the 1935 meeting was called to order by Dr A M Cram, the Vice-President, at 1 15 Thursday afternoon, October 17, 1935, at the Knights of Columbus Hall, Rutland, Vermont

Secretary E J Rogers, called the roll, vacancies therein being filled

On the roll call for Washington County, Delegate R H Bisson not being in the room, Dr Wark moved that he (Dr Wark) be seated as such delegate

The Chair ruled such motion unnecessary, as Dr Wark, being an alternate delegate, would automatically be seated as a delegate, also ruled that if any of the "regular delegates come in there cannot be more votes cast than the county is entitled to, so that the alternate delegate will have to retire"

On completion, the roll call for the one o'clock session stood as follows

Addison County Medical Society	F C Phelps	1
Bennington County Medical Society	H W Elliott	1
Chittenden County Medical Society	C H Beecher W G Townsend N R Caldwell H E Upton W E Rogers	5
Franklin County Medical Society	L E Sample E A Hyatt C G Abell F J Lawliss	4
Lamoille County Medical Society	None reported	0
Northeastern County Medical Society	P E Buck E A Cramton W R Sargent	3
Rutland County Medical Society	O F Clough C B Ross R H Seeley B F Cook E J Rogers H L Frost	6
Washington County Medical Society	R E Avery C H Goyette W R Hartness L B Allen J A Wark	5
Windham County Medical Society	L C Stillings O A. Burton Geo B Hyde	3

Windsor County Medical Society	W M Huntington A M Cram	2
		30

Vice-President Cram called for the report of the Secretary of the Vermont State Medical Society, whereupon Dr W G Ricker, the Society secretary, asked for, and received the privilege of the floor, and suggested that the reading of this report be deferred

Dr Beecher moved that the reading of this report, as printed, be deferred until the five o'clock session of the House of Delegates, which motion was seconded, and so voted

Vice-President Cram called for the report of the Publication Committee

REPORT OF THE PUBLICATION COMMITTEE

The Publication Committee wishes to report that material has been supplied to *The New England Journal of Medicine*, as usual The cost of publication is shown in the Treasurer's Report

WM G RICKER, M.D
C F DALTON, M.D
L H ROSS, M.D

On motion, duly seconded, it was voted to accept the report of the Publication Committee as printed

Vice-President Cram called for the report of the Executive Committee, and on motion, seconded and carried, the report was accepted, as printed on page 7 of the 1934 Proceedings of the Vermont State Medical Society, without reading

REPORT OF THE EXECUTIVE COMMITTEE

The program in your hands constitutes the report of your Executive Committee

B F COOK, M.D
WM G RICKER, M.D
J H WOODRUFF, M.D

Vice-President Cram called for the report of the Treasurer, and it was moved, seconded, and voted that the report, as printed, be accepted

Respectfully submitted,
DAVID MARVIN, *Treasurer*

Audited and found correct

E H BUTTLES, *Auditor*

Sept. 10, 1935

AUDITOR'S REPORT

Sept 10, 1935

I have today finished auditing the accounts of the Vermont State Medical Society, Dr David Marvin, treasurer, for the year ending July 1, 1935. I find the accounts correct, with proper vouchers for all expenses.

Very truly yours,
E H BUTTLES, *Auditor*

Dr Racker called the attention of the House of Delegates to the fact that the Vermont State Medical Society has cash assets of some \$19,000, expressing it as his opinion that this was the wealthiest state medical society, per capita, in the country.

At this point in the proceedings Dr Stanley Wilson, President of the House of Delegates, took the Chair.

President Wilson called for the report of the delegate to the A M A., and it was moved, seconded, and voted that this report be accepted as printed.

REPORT OF THE EIGHTY SIXTH ANNUAL MEETING
OF THE AMERICAN MEDICAL ASSOCIATION

The eighty-sixth annual session of the American Medical Association was held at Atlantic City, June 10 to 14, inclusive, this being a joint session of the American and Canadian Medical Associations and the first joint session of these societies. The good fellowship existing between the two societies was referred to in Speaker Dr F C Warnshuis' address to the House of Delegates, read by Vice Speaker

Dr N B Van Etten, "Scientific medicine knows no national boundaries. Medicine is a republic in which its disciples from every country of the world have worked shoulder to shoulder." The Canadian Medical Association extended an invitation to the A. M. A. to meet in joint session with them in some Canadian city some time before 1940, thereby showing their appreciation.

The registration for the session was 8469, this being the largest number of physicians ever assembled at a medical meeting. The scientific exhibits were exceptionally good and one could have spent all four days of the convention very profitably in this department. It was said to be the largest ever exhibited at an A. M. A. meeting. The commercial exhibits were very large, most of the pharmaceutical houses were there, also instrument companies.

The General Meeting was called to order in the ball room of Convention Hall by President Walter L Bierring Tuesday, June 11, 1935, at 8 00 P M. An organ recital was given by William Jackson on the largest pipe organ in the world. Hon. Harry Bacharach, Mayor of Atlantic City, gave the address of welcome and told us of the attractions of Atlantic City as a playground and as a health resort. He also said that they seldom had an accident by drowning, due to the excellent supervision of the life savers. Short addresses were given by Dr C C Charlton, President of Atlantic County Medical Society, Dr M W Newcomb, President of the Medical Society of New Jersey, Hon. Walter Edge, Ex-Senator and Former Ambassador, and also Dr Allan R. Dafoe, of "quintuplet" fame. Several vocal selections, which received generous applause, were rendered by the noted Welsh tenor, Harry Prosser. Dr Jonathan C Meakins, President of the C M A, delivered a very scholarly address entitled, "The Breath of Life." Dr James L McLester, President of the A M A, delivered an address, "Nutrition and the Future of Man." Dr McLester very ably described in his address how the lower animals had been improved by giving them the proper foods and care, and he believes that this same principle can be applied to man and his destiny. The Westminster Chorus of Princeton, N J, rendered several selections which were exceptionally good and were greatly appreciated, as was manifest by the applause which each number received.

The first meeting of the House of Delegates convened June 10, 1935, at 10 00 A M, in the Renaisance Room of the Ambassador Hotel, and was presided over by Vice-Speaker Dr N B Van Etten of New York, in the absence of the Speaker Dr F C Warnshuis, whose address was read by Dr Van Etten. Reference Committees were appointed by the Speaker. Addresses were given by the President, Dr Walter L Bierring, the President-Elect, Dr James L McLester, and Vice President, Dr George G Reinle. Reports of the Officers and Board of Trustees were given and several resolutions were presented in regard to "Care of Indigent Sick, Broad casting, Medical Service Organizations, Solicitation of Votes, Contraception, Establishment of Courses in Medical Economics in all Medical Colleges in the Country." The delegates of the A M A. and the C M A were given a banquet in the submarine grill of the Hotel Traymore, Monday evening. We were very well entertained. Hon J Hamilton Lewis, Democratic Senator from Illinois, was one of the speakers.

Tuesday, June 11, Session of the House of Delegates—Reports of the Reference Committee of Sections and Section Work by Dr T B Throckmorton, Chairman, Report of Reference Committee on Medical Education by Dr Irvin Abell, Chairman, Refer

ence Committee on Hygiene and Public Health, Dr J N Baker Chairman Report of Reference Committee on Legislation and Public Relations by Dr Charles E. Mongan and the Report of Reference Committee on Miscellaneous Business by Dr John F. Hagerty A Resolution in Opposition of Dick Scarlet Fever Potent was introduced by Dr J M. Birnie of Massachusetts Resolution in Opposition to the Copeland Pure Food Bill and to Advertising of Drugs and Drug Products by Pharmaceutical Houses to the Laity by Dr John F. Hagerty Reports were given by the Board of Trustees Reference Committee on Reports of Officers, and the Judicial Council reported that the first sentence of section 1 of chapter 11 of the By Laws be amended to read "Membership in this Association shall continue only so long as the individual is a member of the component society of the constituent association through which he holds membership Officers of the Canadian Medical Association were introduced by the speaker and made short addresses which were responded to by President Biering and President Elect McLester of the A. M. A. The California situation in regard to compulsory insurance was ably explained by Dr T H Kelley They failed to get their bill passed by the California legislature, but they are hoping the next session will pass a satisfactory bill. The special report of the Bureau of Medical Economics was a very thorough and comprehensive report. Lists were made as far as possible, of State and County medical associations and their methods of classification and care of the sick and remuneration therefrom I quote from the report, "The profession needs and will always welcome the cooperation and advice of all elements affected in health problems not just as the individual physician must constantly assume the tremendous responsibility of decisions that involve life and death with individual patients so the profession as a whole must assume the leadership and responsibility in the organization of medical service in the community

The House of Delegates in the Report of the Special Reference Committee adopted at the special session held February 15 and 16 1935 reported in part "The House of Delegates of the American Medical Association reaffirms its opposition to all forms of compulsory sickness insurance whether administered by the Federal government, the governments of individual states or by any individual industry community or similar body It reaffirms also its encouragement to local medical organizations to establish plans for the provision of adequate medical service for all of the people, adjusted to present economic conditions by voluntary budgeting to meet the costs of illness

The officers of the A. M. A. elected were as follows President Elect—Dr J Tate Mason Seattle Wash Vice-President—Dr Kenneth M Lynch Charleston, So Carolina Secretary—Dr Olin West Chicago Ill Treasurer—Dr Herman L. Kretschmer Chicago Ill Speaker of the House of Delegates—Dr Nathan B Van Etten New York Vice-Speaker of the House of Delegates—Dr H H Shoulders Nashville Tennessee Trustees for five years—Dr Ralph A. Fenton, Portland Oregon and Dr James R. Bloss Huntington West Virginia. The invitations for the next annual meeting of the A. M. A. were from Indianapolis Miami Fla. Chicago and Kansas City Mo. The Trustees investigated the invitations and reported that Chicago and Kansas City had ample facilities for taking care of the A. M. A. annual meeting and the ballot was spread There were 126 votes cast, of which Kansas City received 113 votes and Chicago 13

This was a very successful meeting. The lectures

in the several sections were of a high class and very instructive We were well entertained.

C G ABELL

President Wilson called for the report of the Medico Legal Committee, whereupon Dr C H. Beecher moved that this report, and all remaining reports, be accepted as printed Motion seconded.

Dr Hyatt announced that the name of Dr F B Hunt, of Fairfax, did not appear in the report of the Necrology Committee, and was informed that it would be added

Whereupon, Dr Hunt's name was added to the Necrology Committee's report, and with this correction it was voted to accept the report of the Necrology Committee, and the remaining reports as printed.

REPORT OF THE MEDICO-LEGAL COMMITTEE

Your Medico-Legal Committee has met as a complete committee twice during the year

Only one new case has been presented to us and this is still in the courts

One case that has been on the docket several years has been closed At the present time we have only one case that is unsettled

EDWIN A. HYATT Secretary

REPORT OF NECROLOGY COMMITTEE

Following is the list of deaths of members of the Society during the past year

Dr A. H. Bellerose Rutland December 11 1934.
Dr E M. Brown Sheldon February 8 1935
Dr Rolfe S. Russell Greenfield Mass. March 17 1935
Dr John H. Beao Burlington March 25 1935
Dr Horace L. Watson Montpelier May 10 1935
Dr Rushmore Lape Fair Haven May 3 1935
Dr Wallace M. Pierce Burlington June 1935
Dr J M Stevens Hyde Park, June, 1935
Dr John H. Blodgett, Bellows Falls August 2 1935
Dr A. O. Walker Springfield.
Dr I. R. Doane Springfield
Dr H. S. Ward, Springfield
Dr F B Hunt, Fairfax.

B D ADAMS, M.D.
G G MARSHALL, M.D.
H L. PRACE, M.D.

Under Unfinished Business President Wilson called attention to the resolution adopted at the 1908 meeting of the Vermont State Medical Society as quoted by Dr Beecher at the 1934 meeting of the House of Delegates (appearing on page 10 of the printed proceedings of the 1934 House of Delegates meeting), which resolution is as follows

"On and after the first day of January 1909 no member of this society shall accept the position of club society lodge, or fraternal organization physician or agree or continue to do any medical or surgical work for any club society lodge or fraternal organization at a less rate than the regular or customary charges for like services rendered by other physicians in the same locality for patients not members of such clubs, society lodge or fraternal organization

Also, that in no case shall any physician

agree to attend the families of the members of such club, society, lodge, or fraternal organization, at half price or less price than the regular rate

"Nothing in this section shall be construed as preventing any member from attending the worthy poor, or to give free services to those too poor to pay anything

"Any violation of this article shall be considered unprofessional conduct, and it shall be the duty of the House of Delegates to expel such members when proof of such conduct shall be presented to them"

Secretary Rogers called attention to the statement of Dr Ricker (appearing on page 11 of the printed proceedings of the House of Delegates), reading as follows

"Dr Ricker stated that the resolution quoted could not be adopted as an amendment to the Constitution and By-Laws for another year, that the secretary might supply the county societies with a copy of the same, and that next year the county society delegates should be present with positive ideas on what can be done"

And to the added statement by Dr Beecher (same page)

"that this resolution would continue as a resolution, and would be introduced for action next year as an amendment to the Constitution, in regard to the eligibility of a man doing contract work at less than regular rates"

And to the *Motion* of Dr Beecher

"that the resolution read, and adopted in 1908, be considered as an amendment to the Constitution, to be acted on next year Motion seconded and so voted" (Page 11, printed proceedings, House of Delegates, 1934 meeting)

Dr Wark stated that "at our last hospital meeting in Barre last week these things placed for consideration of the Society last year, were again read over and discussed, and all voted on, each individual one, and accepted unanimously by the staff," also "that the attention of this organization at this meeting be brought to the fact that we voted on that unanimously"

Dr Wark then *moved* that this (resolution) be accepted by the Society this year as it was placed before it for consideration last year

President Wilson inquired of Dr Wark Did you say that was discussed at the Washington County Society meeting? To which Dr Wark replied "The monthly hospital meeting"

President Wilson inquired if any county societies had brought up this matter in their county organizations

Dr Cook stated that the Rutland County Medical Society had considered it and felt that the county organization was the place for a rule of this kind, and not the State Medical Society, and had unanimously voted down the proposition.

Dr Hyatt stated that Franklin County felt

that the physicians were not being treated right, and Dr Sample added that this was in particular reference to contract work and not to town charges

Dr Beecher stated that the committee which brought in this resolution at the 1934 meeting was not sponsoring it, but merely introduced it so it could be brought up at the 1935 meeting, because it had to lie on the table for one year, and that under the provisions of the Constitution it must be adopted by a two-thirds vote of the members present of the House of Delegates, as an amendment to the Constitution

President Wilson stated As I remember last year there was considerable discussion with regard to hospitals accepting town charges at reduced rates - As I read this through I don't find anything regarding the disposal of that question of hospitals In the resolution was that intentionally left out, Dr Beecher?

Dr Beecher stated that the House of Delegates last year took such action as is recorded in the proceedings, but it was not added to this resolution because the resolution had been on the books since 1908 that the resolution had not included towns, and quoted the *suggestion* of Dr Martin (page 11 of 1934 House of Delegates printed proceedings),

"that the resolution be amended to include towns, villages and cities, as well as lodges, fraternal organizations, etc, but no action was taken on this suggestion"

Discussion by Dr Wark, Dr Clough, Dr. Hyde and Dr Seeley

The Thompson Fund, at Brattleboro, was referred to, the question being raised whether it would come under the resolution President Wilson was of the opinion that it would Dr Seeley stated that the patient is allowed \$350, the hospital bill being taken out first and the surgeon getting the remainder

Dr O'Brien moved that this resolution be laid on the table Motion seconded

The question was asked whether this meant that it would be laid on the table indefinitely President Wilson ruled it to be under discussion and that it could be opened up later in the afternoon He then called for a rising vote on the motion of Dr O'Brien, which resulted in "Yes" 21, "No" 7

President Wilson then declared the House of Delegates meeting recessed until five P M.

FIVE O'CLOCK SESSION

At five P M, the recessed session of the House of Delegates reconvened and was called to order by the President, Dr Stanley Wilson

President Wilson called upon Dr Wm G Ricker, the Society secretary, for such remarks as he might wish to make in connection with his report as secretary

Dr Ricker referred to the questionnaire as

proposed on page 9 of the 1934 printed proceedings of the House of Delegates, and read the letter and questionnaire which he had sent out to hospitals, stating that he had neglected to mention this in his report. He also requested that the nominating committee take extreme care in selecting the legislative committee. Referring to frequent communications he receives, as secretary, regarding individuals practicing medicine illegally, Dr. Richer stated he felt it was up to the county societies to collect evidence pertaining to such cases and present it to the state attorney or the attorney general of the state. Also he felt that the matter of socialization of medicine should be left with the legislative committee, and that recommendations, based on information should be in proper form and submitted to the House of Delegates next year. He suggested that 200 be made available for use of the legislative committee. Also that if the House of Delegates felt that more time should be spent on its meetings, would it favor a Wednesday evening session next year? Also, he felt that the incoming secretary should be authorized to appoint an assistant secretary at not less than \$50.

He also felt that the House of Delegates should consider whether or not it wished each voting delegate to be certified by absolute credentials signed by the president and secretary of his county society.

Dr. Beecher moved that the secretary's report be accepted as printed. Motion seconded, and so voted.

SECRETARY'S REPORT

I wish first, to call your attention to the fact that in spite of deaths which have been fairly numerous we have had additions so that we have eight more members than at this time last year. Several names besides those printed have been reported but inasmuch as their official credentials have not been received at this time their names are not included.

The obituary list is as complete as we have been able to make it. I wish to call to the attention of the members of the County Societies that their Secretary should send a notice to the Chairman of the Necrology Committee and to the Secretary of the State Society immediately on the death of a member or even on the death of anyone who is a duly licensed practitioner. The Society wishes to recognize the deceased of each and every one in proper form.

During the past session of the Legislature an attempt was again made to pass a bill licensing a group to practice Naturopathy. A representative of this School was in attendance during a considerable part, if not the greater part, of the time while the Legislature was in session and seemed to be quite active. An attempt was made to effect a compromise with your Secretary who refused even to consider the proposition. The Bill was defeated in due form and no attempt was made to revive it which was not successful. Since that time I have been informed that the School of Naturopathy in New York City has been condemned by the authorities of the State of New York, that their faculty has been convicted of granting a diploma without a charter and that several of the leading members of the faculty were placed under a suspended jail sentence. Since that time I have been informed

that the School has been transferred to the State of Connecticut. Your Secretary some four years ago had visited this School and had reported to the Legislature at its past session and also at the previous session that it did not possess the facilities for giving a medical education. Bitter words were passed in the Senate Chamber but your Secretary still has a clear conscience in withholding his approval of this School of practice. The House of Delegates should take extreme care in selecting their Legislative Committee this year although the Legislature is not in session and it should be the duty of the Legislative Committee to inform themselves thoroughly concerning the background of Naturopathy.

Your Secretary receives frequent communications regarding individuals practicing medicine illegally and that "something should be done about it." I call your attention to the fact that the State Society has no authority to institute legal proceedings. This function belongs to the Board of Medical Registration. Also I wish to call your attention to the fact that the State Medical Society meets once a year only its deliberations being conducted by the House of Delegates, although the function of the Society is continued throughout the year by means of the Council. On the other hand the County Societies hold more frequent meetings. They are duly organized and are in close touch with local situations. Your Secretary believes that it is the function of the County Society to accumulate the evidence and place it before the Board of Medical Registration, and your Secretary is perfectly certain that the Council of the State Society will give the necessary moral support.

Members of the House of Delegates at various times have criticized your Secretary for not maintaining a news column in the *Journal of the American Medical Association*. For several years my private secretary has sent a notice monthly to all County Secretaries for news items. The response to these letters has been extremely disappointing in fact, so much so that we have discontinued sending these letters during the past year. I will be only too glad to maintain a news column both in *The New England Journal of Medicine* and in the *Journal of the American Medical Association* if you as members will communicate with your County Secretary and get him to send to me the items of interest. Needless to say your Secretary cannot spend his time running all over the State picking up personal items. He must have cooperation.

The work of the County Societies the past year has been excellent. Vermont is to be congratulated on the fact that her physicians are active and interested but are not involved in red tape. The County Secretaries are an extremely efficient group. They arrange and conduct good meetings and the fact that they do not bother to write out a report every time or communicate with the State Secretary should not be considered as a criticism.

I wish to call the attention of the House of Delegates to the hold-over amendment to the Constitution and By Laws adopted last year in Burlington. The socialization of medicine is today a live topic for discussion. It may not be known to all of you that when the National Security Bill was proposed in Washington last winter there was a section devoted to the practice of medicine. Vermont, at least, and I assume every State, was supplied with the so-called Model Epstein Bill. (Not the Dr. Epstein who gave us the excellent paper at our State Meeting last year.) This Bill placed the physicians almost absolutely under State control and to my mind was extremely vicious. The American Medical Association called a special session of the House of Delegates to consider this legislation. I did not

attend because after several days of fever my temperature had only reached normal some four or five hours before my train was due to leave for Chicago. However, I sent them a telegram which expressed our view to the effect that Vermont would assume its own problems. The Legislative Committee of this year should keep very close watch on social medical proposals and legislation. I call their attention to the proposals in California, Alberta, Saskatchewan, Wisconsin and other States that may come to their attention, as well as the situation in Europe.

The matter of remuneration of physicians who are treating cases under the various Welfare Department ought to receive careful consideration. At the present time the budget of the Public Welfare Department, if I am correctly informed, does not have sufficient funds to pay physicians, although up to the present they are paying the Hospital bills. From my interviews with various State officials I feel confident that a moderate fee can be secured from public money if the physicians are willing to accept such. I personally do not believe that officials will grant the higher fee of private practice for the care of all indigents. This subject again should receive careful investigation during the coming year.

Again I wish to express to all members, State officials and County officers of the Society, my appreciation of their cooperation and will be glad to continue in my present capacity, if the House of Delegates so desire, and any changes that are wished will be equally acceptable to me personally.

WILLIAM G. RICKER, *Secretary*

President Wilson called for any further unfinished business to be presented at this time.

Dr Wark asked about the responses the secretary had received from different hospitals in reply to the questionnaire he had sent out, and Dr Ricker referred briefly to the replies he had received.

Dr Wark inquired if the fee schedule, accepted some years ago, was obsolete, whereupon Dr Beecher rose to a point of order, claiming this was not unfinished business.

The question arising as to who constituted the delegation from the Washington County Medical Society, the President requested Secretary Rogers to call the roll for Washington County, which he did, the roll call being as follows: Dr Avery, Dr Goyette, Dr Hartness, Dr Bisson and Dr Allen,—Dr Wark being automatically retired as a delegate, the regular delegate, Dr R. H. Bisson, now being present.

Dr Rogers moved that Dr Wark be given unanimous consent to talk on any subject as long as he wished, and the privilege of interrogating any member. Motion seconded and carried.

There being no further Unfinished Business the President introduced New Business.

Dr Phelps moved that the 1936 annual meeting be held in Burlington. Motion seconded, and so voted.

Under Other Business the President asked if anyone wished to make a motion in regard to holding a Wednesday evening session of the House of Delegates.

Dr Cook moved that next year the House of Delegates hold a Wednesday evening session at 8 o'clock, in Burlington, and that all delegates and alternates bring their credentials, signed by the president and secretary of their county societies. Motion seconded by Dr Beecher.

President Wilson put the motion and called for a rising vote, the result being "Yes" 24, "No" 1.

Dr Beecher moved that a majority of delegates accredited to the state secretary, by the secretaries of the county societies, constitute a quorum of that meeting. Motion seconded by Dr Cook.

President Wilson stated that would mean that one more than half of the accredited delegates would constitute a quorum, and upon putting the question declared the resulting vote to be in the affirmative.

President Wilson brought up the matter of \$200 for the legislative committee, as suggested in the remarks of Secretary Ricker.

Dr Phelps moved that \$200 be given for the use of the legislative committee. Motion seconded, and so voted.

Dr Sargent moved that \$50 be granted the secretary for employing an assistant secretary. Motion seconded and so voted.

Dr Ricker read an invitation from the Bennington Chamber of Commerce inviting the Society to hold its 1936 meeting in Bennington, and suggested perhaps the House of Delegates might wish to rescind its vote to hold the 1936 meeting in Burlington, but no action was taken on this.

Dr Tobin said he felt sure the Society would be invited by the Bennington County Medical Society to hold its 1937 meeting in Bennington.

Dr Ricker referred to the Commonwealth Fund, and read two communications, one dated September 6, 1935, addressed to Dr George G. Marshall, and the other dated September 20, 1935, addressed to Dr William G. Ricker, Secretary, Vermont State Medical Society, and suggested this matter be left with the Council, since the funds were not available until December.

After discussion, Dr Beecher moved that if,

when and as this fund becomes available in December, that the secretary notify each member of the Vermont State Medical Society in regard to the provisions of that fund, and that the secretary write to those in charge of the fund, telling them that the Vermont Society recognizes their effort and will do its utmost to cooperate. Motion seconded and so voted.

Under election of officers, President Wilson called for nominations for president for the ensuing year.

Dr Beecher nominated Dr Lester W Burbank, of Cabot.

Nomination seconded.

Dr Hyde moved that nominations be closed. Motion seconded, and so voted.

President Wilson then placed the name of Dr Burbank before the House of Delegates for vote, and declared Dr Burbank elected as president for the ensuing year.

For secretary Dr Allen nominated Dr Wm. G Ricker to succeed himself. Nomination seconded. There being no other nominations the President placed the name of Dr Ricker before the House for vote, and declared Dr Ricker secretary for the ensuing year.

Dr Hyde moved that the Chair appoint a nominating committee of three to bring in nominations for all the remaining officers of the Society and the House of Delegates, and for the various committees. Motion seconded and so voted.

President Wilson appointed as such nominating committee Dr G B Hyde Chairman, Dr F J Lawless and Dr F C Phelps.

On motion, seconded and carried, it was voted that the meeting adjourn until 8 30 Friday morning, October 18, 1935, to meet in the same hall.

President Wilson thereupon declared the meeting adjourned until 8 30 Friday morning.

FRIDAY MORNING SESSION

In the absence of the President of the House of Delegates, Dr A M Cram, the Vice President called to order the adjourned meeting from Thursday afternoon, of the House of Delegates, at 8 30 Friday morning, October 18, 1935, in the Knights of Columbus Hall, at Rutland, Vt.

Vice President Cram called for the report of the nominating committee.

For the nominating committee Dr F C Phelps reported as follows:

Your nominating committee presents the following nominees for the remaining officers and committees of the Society, and officers for the House of Delegates:

President Lester W Burbank Cabot
Vice-President John Trotter Jr., Bennington

Secretary Wm G Ricker St. Johnsbury
Treasurer David Marvin Essex Junction
Auditor E H Buttle Burlington

Concennors

First District E A Hyatt, St. Albans
Second District C M Campbell Manchester Center
Third District F E Farmer St. Johnsbury
Fourth District J H Woodruff Barre.

lington

Anniversary Chairman

O N Eastman Burlington.

Members of New England Medical Council

J H Woodruff, Barre.
G G Marshall Rutland
W G Ricker St. Johnsbury
J A. Stevenson Chester
E. A. Hyatt, St. Albans.

Nominees to Governor for Appointment to the Board of Medical Registration

Officers of the House of Delegates

President F J Lawless, Richford
First Vice-President Ralph Seeley Rutland

Second Vice-President E D McSweeney, Burlington
Secretary E J Rogers, Pittsford
GEO B HYDE,
F J LAWLISS,
FRANK C PHELPS,
Nominating Committee

Dr Beecher moved that the report of the nominating committee be accepted as presented Motion seconded and so voted, and the President declared the nominees elected to the respective offices for which they were nominated

Dr Beecher suggested that inasmuch as the treasurer's report showed an increase of some \$1920 this last year, that it might be well for the Publication Committee to see what arrangements could be made with the *New England Journal of Medicine* in order that each member of the Vermont State Medical Society might receive weekly, instead of monthly, issues of the *Journal*, throughout the year, that under such an arrangement the comparatively few who take the monthly *Journal* might drop that and have the weekly *Journal*

Dr Cramton moved that the Publication Committee be authorized to investigate this matter with the *New England Journal of Medicine* and see if suitable arrangements could be made for weekly copies of the *Journal* to be sent to every member of the Society

Dr Beecher offered the amendment that the committee report back at next year's meeting of the House of Delegates

Amendment accepted by Dr Cramton, and the motion as amended, was seconded, and so voted

Dr Ricker considered this a very good idea and stated that the committee would be very glad to take it up, and also to consider another angle, that inasmuch as the Society is now paying the *Journal* out and out for printing, that possibly a revised printing contract could be secured on the basis of a subscription contract, without its costing very much

Vice-President Cram called for any further unfinished business, and there being none presented, it was moved, seconded and voted that the House of Delegates adjourn

Adjournment

MISCELLANY

VERMONT DEPARTMENT OF PUBLIC HEALTH
OCTOBER, 1935

The incidence of communicable diseases reported to this Department during the month of October

is as follows chicken pox 194, diphtheria 8, German measles 20, measles 138, mumps 29, poliomyelitis 17, scarlet fever 40, typhoid fever 2, undulant fever 3, tuberculosis 7 and whooping cough 130

The Laboratory of Hygiene made a total of 1,976 examinations in October, the detail of which is,

Examinations for diphtheria bacilli	189
" " Widal reaction of typhoid fever	45
" " undulant fever	74
" " gonococci in pus	172
" " tubercle bacilli	242
" " syphilis	655
" of water, chemical and bacteriological	102
" " water, bacteriological	217
" " milk, market	145
" " milk, submitted for chemical only	3
" " milk, submitted for microscopical	25
" " drugs	1
" for courts, autopsies	3
" " courts, miscellaneous	30
Autopsies to complete death returns	1
Examinations, miscellaneous	72

The Division of Venereal Diseases received reports of 33 cases of gonorrhea and 22 cases of syphilis Five hundred and seventy-six Wassermann outfits and 294 slides were distributed by this Division in October

The Division of Tuberculosis has received orders for 8,000 weight picture cards and 6,000 school inspection cards, from the teachers of the state Sets of posters in posture and nutrition have been supplied to about 500 schoolrooms This Division is now organizing the work of the Christmas seal sales

One hundred and forty-five patients were seen by the Poliomyelitis After Care nurses, 140 of these being at their homes Two patients were admitted to the Audubon Hospital and one patient was discharged from the Massachusetts General Hospital Thirty-one new pieces of apparatus were fitted to patients The Vocational Teacher of this Division reports sales made for the month totaling \$157.21.

The State Advisory Nurse of the Public Health Nursing Division visited twenty towns of the state in the interest of the work of this Division, at tending conventions, assisting in P T A. meetings and giving talks to various groups One thousand, three hundred and sixty-four notifications of birth registration, 489 diphtheria consent cards and 107 baby booklets were mailed to parents during this month

MEDICAL PROGRESS

PROGRESS IN TUBERCULOSIS

1934-1935

BY JOHN B. HAWES, 2ND, M.D.,* AND MOSES J. STONE, M.D.*

THIS past year has shown definite progress in tuberculosis not only in accepting new procedures and ideas, but also in discarding those that have been shown to be not worth while. Surgery of the chest has made rapid strides. There is a better selection of cases as well as a constant improvement in surgical technique. Collapse therapy is no longer looked upon as a last resort measure, while at the same time, there has appeared in the literature a plea for conservatism in this regard much needed in certain parts of this country to check those enthusiasts who would use radical surgery in every case of pulmonary tuberculosis. The B C G treatment—the active immunization of patients with an attenuated strain of tubercle bacilli—is not referred to so frequently in the literature as was the case in the past four to five years. With the exception of W. H. Park and his associates in New York, very little work is apparently being done on this subject in this country. We await with interest the result of Dr. Park's investigations.

Laboratory methods, such as differential leucocyte counts and sedimentation tests, are finding their right place as adjuncts rather than supplementing other tests in diagnosis, prognosis and treatment as their supporters believed would be the case.

EPIDEMIOLOGICAL STUDIES

Fellows H. H. (*Am. Rev. Tuberc.* 30 109 [July] 1934) has made a study of the incidence of pulmonary tuberculosis in all applicants for positions at the home office of the Metropolitan Life Insurance Co. In 103 per cent of cases, the x-ray disclosed a definite and characteristic lesion. Among those working in the office and therefore of an older average age, he found an incidence of 3.6 per cent of pulmonary tuberculosis. He calls attention to certain facts which, although recognized for a long time, are well worthy of repeated emphasis.

(1) Routine careful roentgenological examinations disclose a fairly constant and definite percentage of cases of actual pulmonary tuberculosis among the presumably healthy population.

(2) A large proportion of such cases especially in younger persons is apt to be active and in need of immediate treatment or at least careful observation.

(3) Active tuberculosis occurs in older adults more frequently than is generally recognized.

John B. Hawes—President, Boston Tuberculosis Association.
Moses J. Stone—Assistant Professor Diseases of the Chest, Boston University Medical School. For records and addresses of authors see "This Week's Issue" page 1101.

Reisner, D. (*Am. Rev. Tuberc.* 30 375 [Oct.] 1934) reports the results of an extensive study of the relations between extrapulmonary and pulmonary tuberculosis. In 240 cases with clinically manifest extrapulmonary lesions only about one-fifth presented evidence of active pulmonary lesions. He feels as a result of this work that there is no reason to believe that there is a mutual antagonism between pulmonary and extrapulmonary tuberculosis although he does believe that the individual with a pulmonary tuberculous lesion is far less apt to have some nonpulmonary complication than the reverse. In his experience manifest extrapulmonary lesions are conspicuously rare in the common forms of pulmonary tuberculosis.

Brachman, D. S. (*Am. J. Roentgenol.* 30 303, 1933) urges x-ray examinations of healthy children especially those of high school age. In the course of a study of 35,000 school children including 9,000 of high school age fifteen cases of adult tuberculosis, one per cent of the enrollment, were found in one high school. In only one of these cases were physical signs and symptoms sufficiently evident to demand investigation as to the existence of tuberculosis. The adult type was rarely found in grade school children, but occurred in 0.5 per cent of high school pupils.

Banks, H. S., and Weir, J. H. (*Tubercle* 14 385 [June] 1933) point out that the diagnosis of pulmonary tuberculosis in children is frequently made without sufficient evidence. He stresses especially the fact that pulmonary tuberculosis in children between three and twelve years is very rare and that chronic nontuberculous infection of the lungs at this age is very common. He suggests that more attention should be paid to the efficient treatment of the acute lung conditions. (We would rather disagree with this statement as to the frequency of chronic nontuberculous conditions in young children. J. B. H. M. J. S.)

Pollock W. C., and Forsee J. H. (*Am. Rev. Tuberc.* 31 203 [Feb.] 1935) discussing the very controversial question whether a slight tuberculous infection is or is not a good thing in that it causes a certain degree of immunity are of the opinion that tuberculous allergy which follows an initial invasion of the host by tubercle bacilli serves when maintained at an optimum level as a protective agent. They do not believe, however, that all primary tuberculous invasions are so benign in character. The protective quality of small infections they feel may hinder or prevent later exogenous reinfections.

When the cavity is larger, collapse in one of its forms should be immediately resorted to unless there are other contraindications. Secondly, he contends that compression should be confined to the diseased portion of the lung, in other words the collapse should be a "selective" one and should not collapse the unaffected parts of the lung (Exactly how he plans to arrange this we do not know J B H-M J S). Thirdly, he believes that the only criterion of a satisfactory result is x-ray evidence of a closed cavity. Fourthly, he stresses the point that in considering collapse therapy for any individual, one should think of it in all its forms, any one or combination of which may have to be used at the appropriate time.

Peters, A, Pope, A. S, Morriss, W. H, Packard, E. N, and Miller, O. O (*Am Rev Tuberc* 31 85 [Jan] 1935) report the results of their survey of artificial pneumothorax in representative American tuberculosis sanatoria. These men were appointed by the American Sanatorium Association to report on pneumothorax therapy in this country.

They found that the proportion of patients in whom therapeutic pneumothorax was induced or attempted varied from less than one per cent to thirty-four per cent with an average of approximately ten per cent. In their survey exactly twice as many females as males received pneumothorax treatment. By far the largest number of these patients were between the ages of twenty and thirty-five. In only thirty-eight per cent of the cases included could an effective collapse be obtained, while in nearly two-thirds of the series studied, it was necessary to discontinue treatment prematurely, most frequently because of the development of pleural complication, especially obliterative adhesions. The later results, however, one to fifteen years after termination of pneumothorax treatment appeared to be distinctly gratifying. Over seventy per cent of those followed were still living and of these seventy-five per cent were able to work. They conclude that considering its limitations, artificial pneumothorax appears to be one of our most valuable therapeutic measures in the treatment of pulmonary tuberculosis. They add that discontinuance of treatment is warranted in many cases after a reasonable and adequate period of effective treatment. They fail though to explain the term "reasonable and adequate period" (It must be admitted that this painstaking survey adds remarkably little to what we already know on this subject J B H-M J S).

Jones, K. P. (*Am Rev Tuberc* 30 670 [Dec] 1934) discusses the technique of artificial pneumothorax treatment. He finds as a result of a questionnaire sent to ninety different clinics that more than fifty per cent of the men doing pneumothorax work do not use gloves or a sterile gown and that there is a

definite tendency to use ordinary aspirating needles about gauge eighteen and two inches long instead of special ones for this purpose. Fluoroscopy as a check-up to refills is advised by practically all clinics. Opinions varied greatly as to the length of time for the maintenance of pneumothorax treatment, the average time being two and a half years.

Head, J. (*Am Rev Tuberc* 30 277 [Sept] 1934) discussing bilateral artificial pneumothorax states that if pneumothorax is stopped on one side and started on the other, or if the pneumothorax on the side continued in collapse, be kept selective, no increased burden is thrown upon the affected areas in the opposite lung.

Myers, J. A, and Levine, I. (*Am Rev Tuberc* 31 518 [May] 1935) appeal for earlier collapse treatment in the progressive minimal cases of pulmonary tuberculosis. They state that there is no more reason why we should wait to institute collapse therapy until the disease has become extensive and the risk poor than there is for the surgeon to wait until the appendix has ruptured before he operates. They point out that there are two chief dangers from procrastination in progressive minimal pulmonary tuberculosis. The first danger is to the patient himself. The more the disease spreads, the more destruction of lung tissue will result and the more likely he is to become definitely ill from it. Cavities form, and the lung often becomes adherent to the chest wall. The second danger is to his associates. Thus they conclude that if one acts quickly in the institution of collapse therapy, extension of the disease may be prevented, and if the sputum is positive it may readily and early be rendered negative. (The growing tendency toward radicalism in collapse therapy is to be deplored. We still believe that nature should be given a chance and that two to four months of observation in such cases is none too long J B H-M J S).

Kremer, W. (*Beitr z Klin d Tuberk* 83 675 [Nov] 1933) discusses the various indications for collapse therapy. He believes that pneumothorax should not be given in the presence of very recent and destructive infiltration, because of the danger of pleural rupture. He feels that it is better to keep the patient at absolute bed-rest until some fibrosis has replaced the infiltration. He is of the opinion that it is useless to continue pneumothorax over a long period of time in the presence of large stiff-walled cavities. In such cases, pneumothorax should be considered only as preliminary to thoracoplasty, partial or complete.

O'Brien, E. J. (*Am J Roentgenol* 30 315, 1933) is firmly of the opinion that in patients with minimal lesions, the proper use of collapse therapy may lead to recovery in almost all cases. He prefers phrenicectomy as a sim-

pler procedure than pneumothorax and one which accomplishes the desired result in many patients. He finds that temporary paralysis of the diaphragm from simple crushing of the phrenic nerve is sufficient to allow healing in some cases, but that a permanent paralysis with or without pneumothorax is ordinarily desirable. In his experience, the paralyzed diaphragm, although losing its muscle tone becomes a tense firm membrane stronger if anything, than before. (The last statement needs further study and confirmation before being accepted as true J B H M J S)

Morgan, R. (*Am. J Roentgenol* 33 309 1933) makes a plea for artificial pneumothorax therapy in bilateral cases of pulmonary tuberculosis. In his experience unilateral collapse commonly has a favorable effect on both lungs. The most reasonable explanation of this effect on the contralateral lung is because of the decreased size of the thorax due to the shifting of the mediastinum. He found that in many cases of far advanced tuberculosis at first looked upon as hopeless much improvement has followed energetic and persistent employment of collapse measures, and he recommends that patients of this type be offered this chance. (Although it is undoubtedly true that bilateral pneumothorax is not used as much as it should be, the fact remains that it is only in comparatively few cases and only after mature study that it should be tried. J B H M J S)

Nehrl, I. W. and Alexander, J. J. (*Thoracic Surg* 2 549 [Aug.] 1933) give the results of their extensive experience with phrenic paralysis. The best results were obtained in limited fresh lesions, the worst results in cases with extensive fibrotic lesions containing large stiff walled cavities. On the whole, they are satisfied that phrenic paralysis is of genuine value in the treatment of pulmonary tuberculosis. Paralyzing the diaphragm did not cause adhesion formation which might subsequently interfere with induction of pneumothorax.

Schwatt, H. (*Am J M Sc* 187 338 [March] 1934) studying the behavior of the diaphragm after phrenicoexeresis found that the degree of elevation of the diaphragm bears no consistent direct relation to the time elapsed after operation. The amount and time of the maximum rise depend on the combined action of the intra thoracic and intra abdominal pressures, atrophy of the diaphragm, and the character of the pulmonary lesion, especially when it is in the lower lobe.

McCarthy, C. K. (*Am Rev Tuberc* 30 677 [Dec.] 1934) gives his results of oleothorax therapy in a series of fourteen cases. He finds that oleothorax is an effective method in combating progressive pulmonary tuberculosis after other methods have failed. He used it in the oblitera-

tive pneumothorax cases, in cases of pneumothorax treatment where cavities resisted closure, and in cases of pyopneumothorax. He concludes that the procedure merits more extensive study and trial. (While it is undoubtedly true that oleothorax should be used more than it is at present, it still remains a procedure which should be carried out only in an institution and under close expert supervision J B H. M. J. S.)

Dufault, P. L., and Laroche, A. (*Am Rev Tuberc* 31 139 [Feb.] 1935) attempt to answer that very elusive question of how long pneumothorax should be continued. They make an excellent remark that the nature of the pulmonary lesion before collapse is a more important factor than the amount of involvement or the age of the patient. In general they feel that a simple exudative lesion should receive pneumothorax treatment for a period of at least two to three years. In case of older fibroid processes with thick walled cavities a minimum of five to seven years is required. They plead for longer rather than shorter periods of treatment.

Head, J. (*Am Rev Tuberc* 31 386 [April] 1935) reports on the results of a series of fifty thoracoplasties in which different types of operation were used. Fifty-six per cent were arrested, eighteen per cent markedly improved, two per cent unimproved, two per cent died from the operation, and six per cent died later of other causes. He attributes these favorable results to freer and earlier use of this operation and to the fact that in every case the collapse was extremely complete. On the whole, he found that the results in the different groups of cases were in proportion to the completeness of the collapse of the diseased lung.

Crumm, P. D., Strayer, J. W., and Baker, C. S. (*Am. Rev Tuberc* 31 1933 [April] 1935) report on ninety two thoracoplasties on fifty consecutive patients in whom there was no operative mortality. All of their cases were definitely improved. They admit that all the patients selected for operation were good operative risks, and that with one exception the disease was inactive. (Under such circumstances it is not surprising that such good results were obtained J B H M J S)

Alexander, J. (*Arch Surg* 28 538 [March] 1934) describes his method of pneumolysis with pectoral muscle fillings. He is enthusiastic concerning the advantage of this method but the fact that he employed it only seven times in a series of over 1100 other operations for pulmonary suppuration shows that the indications for this operation present themselves only in rare instances.

Joannides, M., and Shapiro, P. (*J Thoracic Surg* 8 815 [Feb.] 1934) recommend subpraeclavicular apicectomy as an additional conservative method to be used for patients in

whom major surgical procedures are contraindicated

Cutler, J W (*Am Rev Tuberc* 30 416 [Oct] 1934) gives a clinical analysis of the treatment of adhesions in artificial pneumothorax. After discussing the various types of adhesions with the indications and contraindications for surgery, he concludes that closed pneumolysis can now be performed with relative ease and safety and is the operation of choice in such cases.

Peters, L S, and Cornish, P G (*J A M A* 101 826 [Sept 9] 1933) discuss the rôle of pneumolysis as an adjunct to artificial pneumothorax. They state that compression is successful only as it is complete. They feel that pneumolysis is of great value by means of which they have converted seventy-five per cent of partial pneumothorax collapse into complete collapse. For patients whose cavities are not closed after a few months time with pneumothorax or an adherent pleura they advise extrapleural pneumolysis, with the introduction of a paraffin pack.

Matson, R C (*Surg Gynec & Obst* 58 619 [March] 1934) urges the use of the electrosurgical method in intrapleural pneumolysis instead of the galvanocautery. He found that the use of the electrosurgical method has eliminated the numerous disadvantages of the galvanocautery, namely heat, smoke, pain reaction after operation, and serious hemorrhage. Of 249 cases treated, sixty-one per cent were technically and clinically successful. There were two deaths, one due to spontaneous rupture of the lung following an asthmatic attack seven days after operation, the other from a profuse hemorrhage after the lung was successfully collapsed. The patient in the latter case was bleeding profusely from an open cavity before operation.

CHILDHOOD TYPE OF TUBERCULOSIS

Nalbant, J P (*Am Rev Tuberc* 30 458 [Oct] 1934) makes an analysis of pulmonary tuberculosis in infancy, childhood, and adolescence. In general he concludes that childhood type tuberculosis is a definitely benign disease with a good prognosis, in contrast to the adult type which is progressive and destructive. He speaks, however, of acute exacerbations characterized by fever, loss of appetite, general malaise, cough and even tubercle bacilli in the sputum, which usually soon subside. He feels that the reason these acute exacerbations behave in this favorable way is due to the fact that in these children sufficient time has not elapsed to permit them to lose their high allergy to the invading organism. Later on, when reinfection takes place after the hypersensitivity has subsided, then the response will be entirely different with more localized disease and less tendency to general reaction and greater

destruction of tissue. He notes especially the importance of early diagnosis and the need of surgical treatment of adult type lesions in the adolescent age.

Wood, W B (*Lancet* 2 797 [Oct. 7] 1933) divides pulmonary tuberculosis in childhood into a benign group and a serious group. In the benign group he includes the following:

- (1) Tuberculous adenitis and epituberculous manifestations
- (2) Chronic miliary tuberculosis
- (3) Tuberculous pleurisy with effusion

In the serious group he lists

- (1) Acute miliary tuberculosis
- (2) Tuberculous pneumonia
- (3) Adult type of phthisis

Among other things, he speaks again of "epituberculosis." He describes the signs of this condition as those of a lobar consolidation which usually involves the right upper lobe. It is seldom accompanied by symptoms of acute disease and runs a chronic course. There is no respiratory distress and neither the fine crepitations of incipient tuberculosis, nor the coarse crepitations of resolving pneumonia are heard. The process resolves, leaving a perfectly healthy lung or in some instances slight evidence of parenchymatous scarring. He feels that this whole condition may be an exudative response or an atelectasis due to compression of a main bronchus by an enlarged node. Despite this we do not like the term "epituberculosis", nor do we feel that it represents a definite clinical entity. J B H-M J S)

Park, W H, Kereszturi, C and Mishulow, L (*J A M A* 101 1619 [Nov 18] 1933) present two groups of children for consideration in order to show the difference between children of tuberculous families after vaccination and without vaccination with B C G. They found that the mortality from tuberculosis among children vaccinated with B C G was definitely lower than that for corresponding controls. They found that B C G is so attenuated that even under the most favorable conditions of artificial cultivation it is difficult to increase its virulence to any degree. Pathological material obtained from children who were vaccinated with B C G and died of other infections showed no evidence that B C G tended to increase in virulence during its residence in the human body. The authors also do not think that slight primary tuberculous infection acquired by natural infection or produced by vaccination diminishes resistance against future superinfections by tuberculosis.

SILICOSIS

Bohme, A (*Beitr z Klin d Tuberk* 84 119 [Dec] 1933) observed a group of 300 patients with silicosis. One-half of the patients were observed five to eleven years. After five years

more than one half of all these patients were dead. Of those who died seventy two per cent had an active pulmonary tuberculosis while in thirty five per cent of all cases tubercle bacilli were demonstrated. He also found that the prognosis of silicosis is much graver in younger people. Silicosis in later age is not infrequently quite stationary. In general he found that in the presence of slight or first degree silicosis pulmonary tuberculosis is not noticeably modified, but patients of second or third degree silicosis show a marked susceptibility to tuberculosis and in such individuals tuberculosis is always progressive.

Merewether E. R. A. (*Tuberc* 15 69 [Nov] 1933) gives his results of a very exhaustive study on the subject of asbestosis. He defines asbestosis as a specific occupational disease of the lungs caused by the inhalation of asbestos dust and characterized by the progressive development of fibrous tissue. The symptoms are insidious in their onset and irregular in their course. They consist mainly of cough and dyspnea. The roentgenograms show a diffuse ground glass appearance together with a fine pinhead mottling. Death usually results from a low grade bronchopneumonia, but may be due to lobar pneumonia, bronchitis influenza or less often a subacute tuberculous infection. In the lungs of asbestos workers are found asbestos bodies and spicules. From case histories, he found that when the dust is highly concentrated the minimum period between the commencement of exposure and the production of a serious degree of asbestosis is approximately seven years, although the average interval is about eleven years.

Ellman P. (*J Indust Hyg* 15 165 [July] 1933) points out that the dyspnea in asbestosis which is one of the earliest symptoms is always progressive and may be out of proportion to the physical signs. Emaciation is also a distinctive feature while all the symptoms are worse in cold weather. He points out that formerly it was considered that tuberculosis was an uncommon complication of asbestosis. It is now, however, known from studies made in later stages of the disease that there is a definite hazard of tuberculosis to asbestos workers.

LARYNGEAL AND INTESTINAL TUBERCULOSIS

Crawford P. M. and Sawyer H. P. (*Am Rev Tuberc* 30 568 [Nov] 1934) present their findings in 1400 autopsies on patients who died of pulmonary tuberculosis.

In this series 68.8 per cent of cases of fatal phthisis showed at autopsy ulcerative tuberculous lesions of the intestines. Tuberculous laryngitis occurred in 36.6 per cent of cases of intestinal tuberculosis but 96.6 per cent of cases of tuberculous laryngitis showed intestinal ulceration. They found that the portal of entry for tuberculous intestinal infection is the lower

ileum. In cases of fatal phthisis with intestinal ulceration the incidence of amyloid disease is only slightly higher than in those without this complication. They emphasize the fact that a large proportion of tuberculous intestinal ulceration is not characterized by any definite symptoms during life. They conclude that the clinical detection of advanced tuberculous enteritis is of prognostic importance only, pointing toward an early fatal termination of the case.

Dworetzky, J. P. (*Am Rev Tuberc* 31 443 [April] 1935) gives a review of his twenty years' experience with laryngopulmonary tuberculosis. In his experience tuberculosis of the larynx is always a complication of pulmonary tuberculosis. The treatment therefore should be mainly that of the pulmonary disease. Colapso therapy will not only prevent the development of laryngeal tuberculosis but will also promote healing of coexisting laryngeal lesion. As to direct treatment vocal rest is of primary importance especially if the laryngeal lesion is of the acute or subacute type. When the lesion is more or less localized cauterization by galvanocautery is the most valuable remedy we possess at present. When cauterization does not relieve dysphagia, he advises blocking of the internal branch of the superior laryngeal nerve with alcohol.

PREGNANCY AND TUBERCULOSIS

Ornstein, G. G., and Kovnat, M. (*Am Rev Tuberc* 31 224 [Feb] 1935) studying the effect of pregnancy on the prognosis in pulmonary tuberculosis found that the had prognosis did not depend on the pregnancy but on the character of the pulmonary tuberculosis. All their deaths were in the caseous pneumonia group. On the other hand in the resolving exudative and chronic productive groups in which the prognosis is better and usually good, there were no deaths. Compared again with the non-pregnant group, pregnancy in itself had only a minor effect on the prognosis of the disease in the caseous pneumonia group. They conclude that the death rate differs very little in the pregnant women from the nonpregnant group if analyzed according to a qualitative classification rather than a quantitative.

Krause A. K. (*Editorial Am Rev Tuberc* 31 254 [Feb] 1935) discusses the subject of pregnancy and tuberculosis editorially. He feels that just as normal and healthy women react differently to pregnancy, there being some for whom pregnancy is a positive physiological boon and again others an unmitigated evil, likewise in case of the tuberculous woman pregnancy may arouse or it may quiet down active tuberculous processes. He points out that pregnancy may exert a harmful effect on tuberculosis in those women who, without tuber

culosis would naturally tolerate pregnancy poorly, and a harmless or even beneficial effect on those tuberculous women who without tuberculosis, would stand pregnancy well or even have their bodily economy improved by pregnancy

MISCELLANEOUS

Frommel, E (*Rev de la tuberc* 1 256 [March] 1933) finds that when primary carcinoma of the lungs is associated with tuberculosis the two were always situated in the same lung, and almost always at the same level in the same lobe, that the tuberculosis always preceded the carcinoma usually by several years, and that at death the tuberculous tissue is usually destroyed by the carcinomatous growth

Beaumont, G E (*Lancet* 2 918 [Oct 21] 1933) studying the relationship of vital capacity to activity in pulmonary tuberculosis found that an early *active* lesion will usually lower the vital capacity more than an extensive quiescent one. He did not obtain any evidence to suggest that the lowering of vital capacity in active tuberculosis was due to toxic weakening of the power of the expiratory muscles

Rienhoff, W F (*Bull Johns Hopkins Hosp* 53 390 [Dec] 1933) reports two complete pneumonectomies. In one case of a child of three, and in another, a woman of twenty-four, the left lung of each was removed because of the presence in one of a benign and in the other of a malignant tumor. Two weeks before operation the lung was collapsed by pneumothorax thus establishing a new circulatory, and respiratory equilibrium. Following removal of the lung, the wounds were not drained, and aspiration revealed only a small amount of serosanguineous fluid. In each case the heart was displaced to the left and the right lung expanded into the left chest within three months

Jackson, C, and Jackson, C L (*Am Rev Tuberc* 30 599 [Dec] 1934) suggest that the primary causes of bronchiectasis are as follows

(1) Excessive viscosity of the primary pathological bronchial secretions

(2) The secondary changes which this putrefactive process brings about in the walls of the bronchi

They conclude that the chief means of preventing bronchiectasis is by forestalling the septic-tank processes by bronchoscopic aspiration of the viscid pathological bronchial secretions before they have time to decompose. They find that the primary pus in bronchiectasis is not coughed up, hence sputum studies are misleading and, autogenous vaccines ineffective. The important organisms are found only in the residual pus removed bronchoscopically from primary foci after the bronchiectatic septic tank has been emptied by bronchoscopic aspiration

Overholt, R H (*Am Rev Tuberc* 31 121 [Feb] 1935) makes an interesting observation in cases of bronchiectasis of the left lower lobe. He points out that only the secondary effects produced in the upper lobes may be visualized on the plain x-ray film as the process itself may be hidden by the cardiac shadow. The secondary effects are revealed in the plain roentgenogram as a difference in density of the lung fields (indicating distention of the upper lobe on the affected side) and as an inequality in the position of the diaphragm best seen in the lateral roentgenogram. He feels that when such changes are seen in the ordinary P-A and lateral views, by inference an atelectatic bronchiectasis of the lower lobe should be suspected. The investigation then can be supplemented by bronchoscopy and bronchography to confirm the diagnosis

Cocke, C H (*Am Rev Tuberc* 31 404 [April] 1935) discusses pleural shock and air embolism. He is of the opinion that shock from air embolism is a rare occurrence, whereas shock from pleural irritation is probably a relatively common occurrence

Wasson, W W and Waltz, H D (*Radrol* 22 432 [April] 1934) studied the relationship of sinusitis to pulmonary infection in 158 children. They feel that there is a definite relationship between sinus disease and non-tuberculous chest disease. The onset in both regions is approximately coincidental and progress in one parallels the other. They also found that cessation of sinus disease is usually accompanied by cessation of progress of non-tuberculous chest disease

CASE RECORDS of the MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

FOUNDED BY RICHARD C CABOT M.D.

TRACY B. MALLORY, M.D., Editor

CASE 21481

PRESENTATION OF CASE

Approximately one year before entry the patient, a forty year old Portuguese-American restaurant worker, began to complain of generalized weakness. He consulted a physician who believed his symptoms were due to a run down condition. His weakness progressed and approximately six months before entry he first noticed shortness of breath on climbing stairs and later even upon walking on level ground. He was forced to stop working and for the past five months remained at home. He was forced to use two pillows at night. Six weeks before admission he noticed edema of his legs, especially after standing, a symptom which progressed during the past two weeks. The edema developed even while sitting in a chair. During this period he had frequent attacks of nocturnal dyspnea. Three weeks before entry he caught a cold which was associated with a persistent relatively unproductive cough. Two weeks before admission he had an attack of chills and fever at which time he had chest pain in the region of the left shoulder girdle and also two or three precordial twinges. For a few days, during which time he coughed quite severely, the phlegm was blood streaked. Ten days before entry he consulted his physician who prescribed some white pills, six to eight a day, which relieved his nocturnal dyspnea and produced some alleviation of his other symptoms. The pills, however, produced nausea and he stopped the medication two days before entry.

His family history is non-contributory. At the age of eighteen he had an attack of acute rheumatic fever with involvement of several joints. This symptom persisted for about seven months. He had had no attacks since then. There was no history of scarlet fever, chorea or pneumonia. He had consumed a large quantity of alcohol in the past, drinking about one quart or so of whiskey a day, but during the past year limited himself to an occasional glass.

Physical examination showed a well-developed and nourished man sitting upright in bed in slight respiratory distress. The neck veins were congested. The chest was slightly barrel

shaped, and examination of the lungs showed numerous râles throughout. In addition, the bases were slightly dull. The heart was enlarged, the left border being 9 centimeters from the midsternal line, the right 2 centimeters. The heart sounds were distant, no thrills could be felt. There were systolic and diastolic murmurs at the apex. No murmurs could be heard at the base. The rhythm was irregular. The blood pressure was 130/90. The abdomen was distended, moderately tympanitic, but in addition contained some fluid. There was pitting edema of the lower extremities.

The temperature was 97.4°, the pulse 118. The respirations were 20.

Examination of the urine showed a specific gravity of 1.010 to 1.020 and a slight trace of albumin. The blood showed a red cell count of 5,650,000, with a hemoglobin of 90 per cent. The white cell count was 13,700, 57 per cent polymorphonuclears. The stools were negative. A Hinton test was negative. An electrocardiogram showed normal rhythm, rate 90, interrupted by ventricular premature beats. There was left axis deviation and slurring of Q-R-S complexes. There were also low, slightly diphasic T waves in all leads. Lead 4 showed absent Q, tall R, and deep T waves. The sedimentation rate was plus or minus 0.30 millimeters per minute. Two blood cultures were negative.

X-ray examination of the chest showed both costophrenic angles and the lower lung fields obliterated by dullness. The lung markings were somewhat increased. The heart was enlarged in both diameters, particularly in the region of the left ventricle. The aorta was slightly tortuous but not widened.

He was put on digitals and in addition was given salyrgan intravenously on the seventh day. Salyrgan was again given on the tenth, fourteenth, seventeenth and twenty-second days without any diuretic effect. He developed edema of his hands and during the fourth week had a thrombosis of the right median vein which had previously been used for salyrgan injection. At about this time his temperature began to rise, reaching 103°. He also had some pleural pain. His white blood cell count was 8,600, and the sedimentation rate was 0.53 millimeters per minute. His fever continued and he rapidly went downhill. The lung fields on both sides were dull and moist râles were heard throughout. He had a hemoptysis and died one month after admission.

DIFFERENTIAL DIAGNOSIS

DR. J. H. MEANS. The history is that of progressive congestive heart failure developing during a period of one year or less, with the added picture at the end of pulmonary infection, chills, fever, chest pain, cough and bloody sputum. The frequent attacks of nocturnal

dyspnea suggest a lesion gravely involving the myocardium

There is a story of rheumatic fever at eighteen but that by no means proves that this man's heart disease is rheumatic in its etiology. Rheumatic fever coming for the first time at the age of eighteen is rather apt to spare the heart. It is much more likely to involve the heart in childhood than in adult life. In this particular case the onset of symptoms of heart failure coming on for the first time at the age of forty incline me to suspect more syphilitic heart disease or some type of degenerative heart disease than rheumatic heart disease. Hypertensive heart disease may behave in this fashion.

The physical examination showed a man with orthopnea and engorged neck veins. Engorged neck veins in the upright position are always important. They indicate of course a high venous pressure. Any type of right sided heart failure may produce such a picture. The conditions which produce engorgement other than ordinary congestive failure are constrictive pericarditis, mediastinal disease which occludes the great veins, and under acute circumstances pulmonary embolism. There is nothing to suggest the last mentioned in the early stages of this case. Later, although we are told of no sudden episode other than hemoptysis it appears that the man had some venous thrombosis from which an embolus could have been derived. The cardiac enlargement present is entirely left sided. The murmurs present could be due to either mitral or aortic disease. We would have to know more about them than we have been told, to say much. Of course the absence of murmurs at the base points more toward the murmurs being mitral but there are cases where aortic murmurs are heard only at the apex. The rhythm is described as irregular but it turns out later that cardiogram shows this not to be fibrillation. There is no mention of engorgement of the liver so we must assume that it was not demonstrable. Some pitting edema of the lower extremities and slight ascites were present.

The most important items in the laboratory findings are the negative Hinton test, which is considerable evidence against syphilis, although not absolutely excluding it, and the cardiogram showing ventricular premature beats and left axis deviation. The first sedimentation rate described is within normal limits and the second one just slightly above the upper border of normal. The two negative blood cultures may be significant.

The x-ray findings are consistent with a slight amount of fluid at the base of each chest.

One other aspect of the case is that the natural therapeutic effort to produce a diuresis with salyrgan was apparently complicated by a thrombosis of his right median vein. If we

were told that he had had some pleural pain subsequent to this incident it might represent an embolism. But since the pleural pain antedated his hospital entry it does not seem to me that embolism is an important part of the total picture. Certainly it had nothing to do with the engorged neck veins which he had before the thrombosis was produced.

There is no doubt that this man died of some kind of heart disease. The question is chiefly what kind. An old rheumatic mitral disease with a very recent fresh bacterial endocarditis on top of it is a possibility. We are not justified in making such a diagnosis with finality because we have no evidence of embolic phenomenon or an infection of the blood stream, nor have we a right to make a diagnosis of syphilitic heart disease, although I believe it is entirely possible. There is no evidence to suggest disease of the coronaries, nor can I say with certainty that there is any involvement of the pericardium. I am obliged somehow to account for the fever. I have mentioned the endocarditis possibility. I believe a more likely one is that the infectious process is in his lungs and is a low grade terminal bronchopneumonia, a type of infection to which patients dying of heart failure are especially prone.

I believe this was a death from congestive heart failure with a superimposed infection, possibly bacterial endocarditis, possibly bronchopneumonia. My alternate diagnoses are syphilitic heart disease with some terminal infection, or hypertensive heart disease with some terminal infection.

CLINICAL DIAGNOSES

Rheumatic heart disease
Congestive failure
Bronchopneumonia

DR J H MEANS'S DIAGNOSES

Congestive heart failure, probably rheumatic in origin
Bronchopneumonia

ANATOMIC DIAGNOSES

Rheumatic heart disease
Endocarditis, chronic rheumatic, mitral and aortic with slight stenosis
Cardiac hypertrophy and dilatation
Petechial hemorrhages of the pericardium
Thrombosis of the right median basilic vein
Pulmonary embolism
Pulmonary infarction
Ascites
Hydrothorax, bilateral
Peripheral edema
Pleuritis, chronic fibrous
Congestion of the liver, spleen and kidneys

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY Dr Means was quite right in believing that this man died primarily from congestive heart failure, and was probably wisely cautious about trying to name the exact cardiac lesion. The murmurs found were consistent with either mitral or aortic disease, as he pointed out, and although their location favored mitral involvement the other clinical findings, such as the predominant left-sided hypertrophy, the very rapid progression of the decompensation, the lack of auricular fibrillation, the left axis deviation, the attacks of nocturnal dyspnea, and the slight anginal episodes, all favored aortic disease.

What we found at autopsy was a considerably enlarged heart, weighing 525 grams with hypertrophy of both the right and the left ventricles, though the left ventricular enlargement was the more marked. Both the aortic and the mitral valves were involved both certainly stenotic and both probably somewhat insufficient. The character of the valve lesions left no doubt of their rheumatic origin and there was no trace of any fresh endocarditis.

The pulmonary complication, which both Dr Means and the clinicians on the wards had interpreted as bronchopneumonia, turned out to be multiple pulmonary emboli with infarcts varying from one centimeter up to five centimeters in diameter. Every year we have two or three cases in which unsuspected infarction of one or another organ has caused fever and leukocytosis, and is consequently mistaken for an infectious process. There is comparatively little doubt that the emboli arose from the thrombosed median vein in the right arm which at autopsy still showed fragments of adherent thrombus. Since none of the emboli were large however, and most of the patient's symptoms antedated them by several weeks, I do not believe that they represented a very important element in his death.

The rest of the body was essentially negative except for the evidences of severe chronic passive congestion and the accumulation of large amounts of fluid in the pleural cavities and abdomen.

CASE 21482

PRESENTATION OF CASE

A seventy year old white American male was admitted complaining of a swelling in the neck.

For about a year before entry the patient had observed a slowly growing mass in the lower anterior portion of the neck, more on the left side, which had gradually increased in size until at the end of six months it was quite conspicuous. There had never been any pain or respiratory difficulty. Occasionally when attempting to swallow a particularly large bolus

of food he had a slight sensation of constriction in his throat but there was no other dysphagia. He had noticed no change in his voice. There had been no nervousness, loss of weight, or abnormal sweating. Recently he had had occasional difficulty in initiating his urinary flow.

His first wife had died of tuberculosis two years after marriage. The remainder of the family history is non-contributory.

Physical examination showed a well developed and nourished elderly white man who was not acutely ill. The left pupil was slightly larger than the right but both reacted to light and distance. The teeth had been removed. A large mass was seen and felt in the lower portion of the neck, more on the left side. The mass was soft and nodular in character and seemed to be fairly well fixed to the deeper neck structures. The heart and lungs were negative. The blood pressure was 184/100. The prostate was symmetrically enlarged, firm and smooth. There was a dermatitis about the scrotum and groins the character of which was not recorded.

The temperature was 98°, the pulse 78. The respirations were 20.

Examination of the urine showed a specific gravity of 1.010 to 1.026. There was a slight trace of albumin. The sediment was normal. The basal metabolic rate was plus 8.

X ray examination showed a large soft tissue mass in the neck which displaced the trachea to the right. There was no evidence of sub-sternal goiter. The lung fields were clear. There was tortuosity of the aortic arch.

Three days after admission an operation was done upon the neck and an infiltrating mass extending from the left lobe of the thyroid was only partially removed because of its extension into the deeper tissues. The patient made a fair recovery postoperatively except for some difficulty in voiding. The wound did not heal so promptly on the left side as it did on the right. The temperature remained normal throughout save for occasional transient rises to 100° during the first postoperative week. He received four x ray treatments to the neck and was discharged four weeks after admission.

After his discharge he was followed in the Outpatient Department where he received several courses of x ray treatment to the neck. His general condition slowly improved. The small non-draining sinus persisted within the operative scar. Two and a half months after discharge this scar was reported to be deeply pigmented and on the left side of the neck there was a large, atony hard, irregular mass extending back to the trapezins. It came to the clinician irregularly for about a year and then did not return until three years later. At this time he stated that he had had a "cold" with hoarseness and loss of weight for two months. There had been some choking sensation and dysphagia.

He had had "shingles" three months before. The mass in the neck was now entirely stony hard and extended from the angle of the left jaw to the clavicle.

Second Admission, six months later, four and a half years after the first admission.

He was again admitted complaining of increased difficulty in swallowing and hoarseness. The dysphagia, which had been slowly progressive, had become much worse during the three weeks prior to entry. He was compelled to chew foods very thoroughly and occasionally wash them down with some liquid. His weight had decreased during the preceding year from 175 to 140 pounds. The hoarseness had become more pronounced. He had occasional dysuria with the passage of dark blood streaked urine which contained many shreds and considerable sediment.

Physical examination showed a fairly well-developed but poorly nourished elderly man. The tonsils were small and buried. The uvula was bifid and the pharynx was slightly injected. The epiglottis was slightly thickened and irregular and was compressed to the right by the mass in the left side of the neck. The left arytenoid was swollen and edematous and the false cords were reddened and thickened. The right cord moved but the left did not. The mass in the neck measured 3 by 3 by 1 inch and was attached to the skin. There were no nodes palpable on the right side. The heart was normal except for frequent extrasystoles. The blood pressure was 124/78. The lungs were negative. The prostate was not enlarged but there was a small nodule in the right lobe.

The temperature, pulse and respirations were normal.

Examination of the urine showed a slight trace of albumin. The sediment contained 25 white blood cells per high power field but was otherwise negative. The blood showed a red cell count of 4,800,000. The white cell count was 9,400, 46 per cent polymorphonuclears, 54 lymphocytes. Hinton and Wassermann tests were strongly positive.

On the day following admission a tracheotomy was performed under local anesthesia. Three days postoperatively a slight reddening was observed about the wound and the temperature rose to 101°. This reaction subsided in two days. On the ninth postoperative day the temperature again rose to 101° and the patient appeared to be quite weak. A red, slightly indurated, sharply outlined eruption appeared on the neck and spread from the tracheotomy wound. This gradually extended to the chest, abdomen and left arm, and the temperature rose to 103°. The patient became progressively weaker and died on the thirteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. MARSHALL K. BARTLETT. We are told that this is a tumor arising in the left side of

the thyroid so we do not have to speculate about other possibilities. It is interesting, however, to speculate as to what type of enlargement this is. I think we can rule out thyroiditis. It is asymmetrical, nodular and soft. It gives pressure symptoms. All of these can be explained by a nodular goiter. None of the symptoms are particularly suggestive of toxicity and the basal metabolic rate is normal. The other possibility that we must consider is malignancy. In favor of that are the following: first, his age, seventy; secondly, the statement in the physical examination that the tumor is fairly well fixed to the deeper neck structures, and thirdly, the fact that it is noted that the pupil on the left side is larger than the right. Against malignancy are the consistency of the mass, which is soft and nodular, and the fact that he has had no weight loss and no voice changes. It would be interesting to know in addition whether the left vocal cord moved but I take it it did. We would also like to know how much the mass moved with swallowing. But in the presence of inequality of the pupils, with a mass which is fixed to the deeper structures in a man of seventy, in spite of inconsistencies, we have to suspect strongly the possibility of malignancy.

The difficulty in voiding is probably explained on the basis of the prostatic enlargement noted in the physical examination.

I would conclude from the operative note that this was a malignant tumor and was only partially removed for that reason. The interesting thing to decide from now on is what type of tumor this is.

"Two and a half months after discharge on the left side of the neck there was a large, stony hard, irregular mass extending back to the trapezius." That is very important in view of the recent series of x-ray treatment that he had had. Apparently this tumor, whatever it was, did not respond well to radiation.

I would like to know the distribution of the shingles. It is believed that, in some cases of malignancy, involvement of the posterior root ganglion leads to shingles over the distribution of the corresponding nerve.

The blood pressure has gone down considerably since the first admission, when it was 184/100.

At the first admission the prostate was described as smooth and symmetrically enlarged. It is now noted as not enlarged, with a small nodule in the right lobe. I think we can probably explain the urinary symptoms and the passage of blood streaked urine on the basis of his prostate, but I do not believe it is related to the process in his neck.

So far I think his story is entirely consistent with that of thyroid malignancy with an attempt at operative removal and x-ray treatment but with steady progress of the disease. I think the most likely diagnosis is carcinoma of the

thyroid Everything fits in with that. It fails to respond to x ray I do not believe that his prostate has anything to do with it, nor do I believe that the Hinton and Wassermann have.

The patient died on the thirteenth hospital day which is about ten days after the first appearance of sepsis in the wound. That is presumably a cellulitis of the neck starting in the operative wound and extending from there I think the diagnosis is carcinoma of the thyroid and the terminal event is cellulitis following tracheotomy.

DR. GEORGE W. HOLMES I have not had an opportunity to go over these films before the clinic I take it that this is one of the early films and shows the characteristic appearance of a man of that age a moderate degree of emphysema in the lung fields slight tortuosity of the aorta, and no enlargement of the heart. That film was taken a year before his death.

DR. HARRIS P. MOSHER The throat department served in this case in a terminal capacity. The man came in requiring a tracheotomy. In these cases the tracheotomies are often extremely difficult but as the tumor was localized on one side the tracheotomy was easy. When however, the tumor involves the median lobe, tracheotomies are best done in our experience with diathermy. The left vocal cord was immovable. That is a pressure condition and well known. About the specimen, I am sorry I did not bring it over but Dr. Richardson informs me that there was very little involvement of the larynx.

I should like to ask for my own information why the disease lasted so long—four years—and whether that is the usual course in these tumors, also what part the x ray therapy played in this long delay of time.

CLINICAL DIAGNOSES

Carcinoma of the larynx

Emphysema

Erysipelas

DR. MARSHALL K. BARTLETT'S DIAGNOSES

Carcinoma of the thyroid.

Cellulitis in the tracheotomy wound.

Lues.

ANATOMIO DIAGNOSES

Recurrent papillary adenocarcinoma of the thyroid with metastases to the lung
Bronchopneumonia

Septicemia, streptococcus hemolyticus
Erysipelas of the abdomen and thigh
Chronic passive congestion of the liver
Splénomegaly, type undetermined.
Hypertrophy of the adrenal.
Arteriosclerosis, generalized, marked.
Operative wound Tracheotomy
Cavernous hemangioma of the liver
Prostatic hyperplasia.
Pleuritis chronic fibrous, right.
(Syphilis)

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY I think a partial answer to Dr. Mosher's question about the duration of life following the appearance of the disease is provided by the type of tumor found. It was a characteristic example of one of the more sharply defined types of carcinoma of the thyroid, a papillary tumor growing evidently at first within a cyst. You can see in the specimen how the pedunculated masses dangled into the cyst cavity from its wall. This type of cancer of the thyroid is of interest from several points of view. It is the one type of cancer of the thyroid that is by no means rare in childhood. We have seen cases in the early teens in several instances. It is also the type which often develops in aberrant nodules of thyroid tissue. It is often fairly sensitive to radiation, more so than some of the other types. The majority of these tumors if they can be got out with the cyst intact offer a perfectly good prognosis. If the tumor has already spontaneously burst its sac or if in the course of operation it is necessary to break it and tumor contents are spilled in the wound, recurrence is the rule. Some cases are on record with long arrests of growth and even apparent cure from radiation. On the other hand there are other cases in which the effect of radiation is not very great. Of all the possible types of malignancy of the thyroid I think it would be fair to say that this is the least malignant and offers on the whole the best prognosis.

At autopsy besides the local recurrence small pulmonary metastases were found. There were no metastases in the bones but possibly if we had done postmortem x rays we would have found them. The terminal infection was rather poorly described in the summary but if Dr. Bartlett had been able to see the case himself he would probably have agreed with the men on the ward that it was erysipelas rather than cellulitis.

DO LABORATORIES COST TOO MUCH?

If the present scheme of medical education is reviewed from the point of view of efficiency and weighed in the balance, it is found wanting. The first defense is that efficiency has nothing to do with education. Then, after consideration, it is conceded that while it may have something to do with education, it is not an adequate test of an educational system. Yet after all why should efficiency be limited to the material production of a factory? It ought to mean doing well whatever is to be done, and is just as applicable to immaterial as to material projects, but the standards of achievement are not the same. The purpose and the end results must be contrasted and compared.

Since an important factor in the increase in the cost of medical education in the past twenty-five years, perhaps the most important factor, has been the development of the laboratories for the preclinical sciences and for what may be called the paraclinical studies, their efficiency

should be studied closely. The laboratory has a double function in the medical school, namely, through its indirect and through its direct bearing on the care of the patient. It is its indirect bearing on the care of the patient that needs sharpest scrutiny.

Consider, for example, the anatomical laboratory and its use in the course in anatomy. As lectures have so largely disappeared, it has become more important than ever. In so far as anatomy is an experimental science, it has one function in education. In so far as it represents a mass of knowledge (or information) to be more or less completely acquired by the medical student, it has another function. In so far as it has a peculiar methodology it has a peculiar function. In so far as dissection develops manual dexterity, it has another function. Perhaps manual dexterity might be developed better in other ways.

How then can the course in anatomy or any other experimental science be arranged to perform the functions mentioned (and any others which may seem important) so that the student gets the most out of the course? In the first place, it is not possible to arrange a course for one hundred students, for example, so that all the students will get the most possible benefit out of the course. It is a matter of the greatest good for the greatest number and at this point the criticism of the usual laboratory course becomes pertinent. It is too often employed chiefly as a means of imparting information and too rarely as a means of acquiring method.

While this is true of all of the laboratory sciences, it is more strikingly true in physiology and in pathology. How many students acquire the habit of thinking of their patients in terms of physiological or pathological processes? It is true that physicians have often been accused of forgetting that their patients are persons, but is this because they are too accurate in their thinking about physiological and pathological processes?

The great inefficiency, the great waste, in the laboratory of experimental science in education, is that its use goes so little beyond the effort to impart mere information. Of course information is valuable, we must know the facts, but that is only a beginning. But the disproportionate cost of the laboratory as compared with books, demonstrations, pictures (still and moving), does not justify the enormous expense, if there is grave misuse.

The real test is the quality of the physician who emerges at the end of the process. Is he more scientific? Does he observe more accurately or acutely? Does he think more clearly? Does he reason more soundly? There is some ground for thinking that, as an educational procedure, the laboratory in the experimental sci-

ence, has not hitherto justified its cost. It has not been given the opportunity to fulfill the promise of its early days. Is it because the mind of the average physician is not capable of becoming truly scientific?

THE MEDICAL WORLD IS SELDOM SET ON FIRE AT ELEVEN P.M.

A SCIENTIFIC medical meeting may be in some of its aspects, compared to a play. At it the speakers have roles comparable to the principal actors of the play, the discussers have secondary roles, and the committee of arrangements and the officers compare to the directors. Films and slides may by a slight stretch of the imagination be compared to scenery.

Now those successful empiricists who direct the theatre have found that audiences are very fickle in their tastes and that all kinds of factors militate for and against the success of their efforts. Scientific audiences are just as fickle. In order to "put on a good show" at a medical meeting or on the stage, certain conditions having to do with the psychology and physiology of the audience must be met. There must be absolute teamwork and subordination of the individual to achieve these ends.

First the meeting must start and finish on time. Very few worlds are set on fire by addressing tired doctors at 11:00 P.M. The responsibility for the time schedule rests squarely with the officers of the meeting. The speakers and discussers make a very poor impression not only on the officers, but also on the audience when they depart from schedule. They must expect to be cut off when their time is up.

Secondly, the subject of the paper must be timely, well presented and attuned to the interests of the audience. For modern medical audiences dogmatic assertions on the authority of the speaker are never well received. If a subject is so well understood by the audience to be true that one can be dogmatic about it, there is no use presenting it, and if the subject is controversial the audience wants the reasons for the assertion. In science authority is a mighty small thing nowadays and does not compare in importance with a few simple observations or a well planned experiment.

Discussers as stated above have subordinate roles, but nevertheless important ones. They also must keep to the schedule. If they are allowed five minutes they must not take twenty. Furthermore, and most important, they must discuss the paper and not give a separate address on some other subject only remotely connected with the paper. They also must not be dogmatic. If they disagree with the author of the paper they should not be content to state this fact, but the reasons why they disagree. Many very fine and important physicians seem

to find it difficult to subordinate themselves to this extent. If they only realized the harm they are doing to their reputations with the audience by infringing these rules of good taste they would often be the last ones to act this way. We must all recognize the reason that many men take the trouble to write or discuss papers is often more a selfish one than an altruistic one. Even from the selfish standpoint the rules given above are exceedingly important.

Boston, Mass Boston, Mass

TREATMENT OF THREATENED MISCARRIAGE

Since statistics show that many miscarriages occur at the time one would be menstruating were she not pregnant, it is well to instruct every patient to be extremely careful of everything she does at that particular time

When a patient first consults her physician, she should be told what to do in order to reduce the possibility of a miscarriage to a minimum Proper instruction should be given as to the care of the bowels and the taking of enemata An enema, either high or low, is not conducive to quieting a uterus that doesn't require much stimulation to cause it to contract at the time corresponding to the menstrual period if not pregnant

If a patient has had other miscarriages she should be instructed to remain quietly in bed at the time corresponding to the menstrual pe-

riod if not pregnant, and this routine should be carried out for the first four months of her pregnancy She should be told that it might be well not to have coitus at that particular time

Although automobile driving or riding does the expectant mother absolutely no harm, if done sensibly and in moderation, it is well, nevertheless, to instruct the patient who shows a tendency to miscarry to avoid riding or driving at particular times

If, regardless of all prophylactic measures, the patient shows signs of miscarrying, either by the uterus contracting or by a slight staining, she should be put to bed immediately One should bear in mind that a very small amount of blood, be it either red or dark brown, may be just as indicative of a threatened miscarriage as is the loss of a large amount of blood

The patient should be placed under the care of a trained nurse and should not be allowed to leave her bed to go to the toilet Urination and bowel movements should be taken care of by a bedpan.

Rest in bed is the all-important method of treatment

The application of an icebag is a procedure that has been passed down from one medical generation to another, but the writer of this article questions the wisdom of following this custom Since ice will probably cause the uterus to contract, why use it?

If the patient is bleeding, and the uterus is not contracting, there is no need of administering an opiate However, once the uterus starts to contract, it would be well to give the patient a hypodermic injection of Morphine gr $\frac{1}{4}$, to be repeated as often as is deemed necessary

The patient should be kept in bed for at least forty-eight hours after all evidence of bleeding or staining has ceased, or for forty-eight hours after all tendency for the uterus to contract has ceased She should be told how absolutely essential it is for her to take things quietly for some few weeks to come, especially at the time she would be menstruating were she not pregnant, and should be advised not to have coitus for at least one week after all signs and symptoms of the threatened miscarriage have disappeared

A RECEPTION TO THE PRESIDENT AND PRESIDENT-ELECT OF THE AMERICAN MEDICAL ASSOCIATION

In response to an invitation by Dr Mongan, President of the Massachusetts Medical Society and Dr Begg, Secretary, Dr James S McLester, President of the American Medical Association and Dr J Tate Mason, President-Elect of the American Medical Association were entertained at the Harvard Club, November 27, 1935

**LOCAL COMMITTEE OF ARRANGEMENTS
FOR THE ANNUAL MEETING**

W R. MORRISON, M.D., Chairman of the Committee of Arrangements for the 1936 Meeting of the Massachusetts Medical Society to be held in Springfield, June 8, 9, and 10, has appointed the following General Local Committee of Arrangements:

H L SMITH, M.D.
T S BACON, M.D.
ALLEN G RICE, M.D.

**THIRD ANNUAL POSTGRADUATE MEDICAL
EXTENSION COURSE**

The following sessions have been arranged by the Committee for the week beginning December 1

Barnstable

Sunday December 1 at 4 00 P.M. at the Cape Cod Hospital Hyannis Subject Kidney and Bladder Diseases (B) Medical Chronic Nephritis Cardiorenal Disease The Use of Diuretics. Instructor W R. Ober J L B Vail Chairman

Bristol South (Fall River Section)

Monday December 2 at 4 00 P.M. at the Stevens Clinic of the Union Hospital Fall River Subject Lung Diseases (a) Significance of Symptoms and Signs in Chronic Lung Disease Tuberculosis Bronchiectasis etc. (b) The Value of Surgery in Above Diseases. Instructors R. H. Sweet and F T Lord. Eugene A. McCarthy Sub-Chairman.

Essex North

Friday December 6 at 4 00 P.M., at the Hotel Bartlett 95 Main Street, Haverhill Subject Pediatrics Abdominal Disease in Childhood Medical and Surgical Aspects. Instructors P J Mahoney and J L Morse Francis W Anthony Chairman

Essex South

Tuesday December 3 at 4 00 P.M., in the Nurses Home of the Salem Hospital Salem. Subject Kidney and Bladder Disease A (Surgical) Hematuria Its Significance in Surgical Diseases of Kidney and Bladder Instructor G O Prather Walter O Philippen Chairman.

Hampden

Thursday December 5 at 4 00 P.M. at the Academy of Medicine Professional Building 20 Maple Street, Springfield and at 8 00 P.M. at the Holyoke City Hospital Holyoke. Subject Lung Diseases (a) Significance of Symptoms and Signs in Chronic Lung Disease Tuberculosis, Bronchiectasis, etc. (b) The Value of Surgery in Above Disease Problems. Instructors J W Strieder and S H Proger George L Sebaldt and George D Henderson, Chairmen

Hampshire

Wednesday December 4 at 4 15 P.M. in the Nurses' Home of the Cooley Dickinson Hospital Northampton. Subject Psychiatry Management of Psychotic States in the Care of General Diseases Especially Chronic Disorders Subpsychotic States Instructors G C. Caner and Maurice Fremont Smith. Robert B Brigham, Chairman

Middlesex South

Tuesday December 3 at 4 15 P.M., at the Cambridge Hospital, Cambridge Subject Dermatology Ten Common Skin Diseases—Diagnosis and Treatment. (1) Impetigo Contagiosa, (2) Scabies (3) Acanthosis (4) Psoriasis and Seborrheic Dermatitis (5) Epidermophytosis (6) Herpes Simplex and Zoster (7) Eczema, (8) Erythema Multiforme (9) Verruca Vulgaris and (10) Dermatitis Medicamentosa and Dermatitis Venenata. Instructor O G Lane Edmund H. Robbins Chairman

Norfolk South

Monday December 2 at 8 30 P.M. at the Quincy City Hospital Quincy Subject Kidney and Bladder Disease A (Medical) Acute Nephritis—Etiology Diagnosis and Treatment. Nephrosis and Its Treatment. Instructor E. M. Chapman David L. Belding Chairman.

Plymouth

Tuesday December 3 at 4 00 P.M. at the Brockton Hospital Brockton. Subject Industrial Surgery and Medical-Legal Problems. Instructor F J Cotton W H Pulsifer Chairman

Warcester North

Friday December 6 at 4 30 P.M., at the Burbank Hospital Fitchburg. Subject Lung Diseases (a) Differential Diagnosis and Treatment of Lobar Pneumonia. (b) The Surgical Problems of Empyema Instructors J H Pratt and R. H. Overholt. Edward A. Adams, Chairman.

MISCELLANY**AN HONOR TO DR. FRED B LUND**

A testimonial dinner was given to Dr. Fred B. Lund at the Harvard Club by his friends and associates at the Carney Hospital on November 6 1935.

This occasion was but a small expression of their affection for their former beloved Surgeon-in-Chief a kindly doctor and a gracious gentleman.

Dr. William E. Browne as toastmaster of the evening introduced the following speakers: Dr. John Cunningham Dr. Louis F. Curran Dr. Louis E. Phaneuf, Dr. William Robey Dr. Irving J. Walker Dr. A. McKay Fraser Dr. William Morrison, and Dr. Nathaniel Huntington.

Among those present were many of Dr Lund's former associates of the Boston City Hospital, where for many years he was Surgeon in Chief

Dr Lund was presented with a ship's wheel mounted clock as a memento of the occasion. The guest of honor responded in his usual gracious manner.

HARVARD MEDICAL SCHOOL

RESIGNATIONS

Effective Sept 1, 1935

George Pengwerne Matthews, Instructor in Anatomy

Effective Sept 1, 1936

Reid Hunt, as Professor of Pharmacology (becoming Emeritus)

Effective Sept 1, 1935

Eugene Beverly Ferris, Jr., as Research Fellow in Medicine

APPOINTMENTS FOR ONE YEAR FROM SEPT 1, 1935

Orville Taylor Bailey, Instructor in Pathology

John Hartwell Harrison, Assistant in Genito-Urinary Surgery

Edward Allen Edwards, Research Fellow in Anatomy

Morris Frank Shaffer, Research Fellow in Bacteriology

Marjorie Allen Benedict, Research Fellow in Physical Chemistry

Jack Spencer, Research Fellow in Medicine

Harold Clifford Wagner, Research Fellow in Medicine

Samuel Jacob Beck, Research Fellow in Psychology

For one year from Jan. 1, 1935

Robert Sidney Schwab, Assistant in Neurology (M G H)

CHANGE IN TITLE

For one year from Sept 1, 1935

Frederic Andrews Gibbs, from Research Fellow in Physiology to Research Fellow in Neurology

RECENT DEATHS

BUCK—MAURIOE ALLEN BUCK, M.D., of Concord Road, Billerica, Massachusetts, died at his home, November 19, 1935, after a few hours' illness.

He was born in Wilmington, June 6, 1874, and acquired his premedical education in the public schools of Wilmington and Phillips Exeter Academy. He graduated from the Harvard Medical School in 1898, was a Fellow of the Massachusetts Medical Society and the American Medical Association, and had served two years in the House of Representatives of the State Legislature.

Dr Buck had served his town for thirty years on the school committee and had been chairman of the board of selectmen for several years. His fraternal associations were with the Masons, Elks, Odd Fellows and the Billerica Grange.

Dr Buck is survived by his widow, Mrs Bessie C (Cole) Buck, a brother, George W Buck, of Wilmington, and a sister, Mrs Charlotte Radeau, of Pawtucket, R I.

BACON—JOHN LOWELL BACON, M.D., of Southboro, and physician to St. Mark's School, died at the Framingham Hospital, November 21, 1935. He was born in Belchertown, in 1876, the son of John Lowell Bacon and Sarah Charles Bacon. He graduated from the Hahnemann Medical College and Hospital of Philadelphia in 1897, and later took postgraduate courses at the University of Pennsylvania Medical School. He served at the State Hospital in Westboro for a time, began practice in Southboro in 1901, and was a Fellow of the Massachusetts Medical Society. In addition to his appointment at St. Mark's Academy, he was the physician at the Fay School. He was chief of the Framingham Hospital Staff, assistant medical examiner, fifth Worcester District, and chairman of the Southboro board of health and water board at the time of his death.

Dr Bacon was a Royal Arch Chapter Mason. He is survived by his widow, Mrs Ruby Barney Bacon, two nephews and a niece.

DuVALLY—NICHOLAS DuVALLY, M.D., died suddenly in his office, 601 Tremont Street, Boston, November 20, 1935.

He was born in 1880 and graduated from the Tufts College Medical School in 1916.

He had formerly maintained an office on Stanford Street, West End, and had served as police surgeon.

He joined the Massachusetts Medical Society in 1919.

Dr DuVally is survived by his widow, Dr Alice Butler DuVally, a son, Jeremiah, aged ten, and two

brothers Dr James F DuVally of Medford and Dr Frank DuVally of Fall River

NOTICES

MEDICAL CLINIC AND STAFF ROUNDS AT THE PETER BENT BRIGHAM HOSPITAL

At 3 30 P.M. on Thursday December 5 in the amphitheater of the Peter Bent Brigham Hospital Dr Henry A. Christian Physician-in-Chief Hersey Professor of the Theory and Practice of Physic in the Harvard Medical School will give a medical clinic. To it are cordially invited practitioners and medical students

On Saturdays in the wards of the Peter Bent Brigham Hospital, from 10 to 12 staff rounds will be conducted by Dr Christian

SATURDAY MORNING CLINICS BY PROFESSOR S J THANNHAUSER

Dr Thannhauser formerly Professor of Medicine at Heidelberg and Freiburg Germany is giving a course of clinical lectures for practicing physicians on Saturday mornings at 9 A.M. in the Assembly Hall of the Boston Dispensary. The subjects to be presented for the remainder of the year are as follows

December 7—Obesity

December 14—Pituitary Disease

December 21—Treatment of Diabetes

Practitioners from any part of New England are cordially invited. This course is made possible by a grant of the Bingham Associates Fund for the Advancement of Rural Medicine

UNITED STATES CIVIL SERVICE EXAMINATIONS

The United States Civil Service Commission has announced open competitive examinations as follows

Children's Bureau Positions

Applications for the positions of director Division of Maternal and Child Health \$5,500 a year and director Crippled Children's Division \$5,500 a year Children's Bureau Department of Labor must be on file with the U. S. Civil Service Commission, Washington, D. C., not later than December 9 1935

The salaries are subject to a deduction of 3½ per cent toward a retirement annuity

Applicants must have been graduated from a medical school of recognized standing with a degree of M.D. and, in addition, must have had certain special experience

Full information may be obtained from the Secretary of the United States Civil Service Board of Examiners at the post office or customhouse in any city which has a post office of the first or the second class, or from the United States Civil Service Commission Washington, D. C.

Principal Medical Officer

Applications for the positions of principal medical officer Indian Service at Large, must be on file with the U. S. Service Commission Washington, D. C., not later than December 9 1935

The entrance salary is \$5,600 a year subject to a deduction of 3½ per cent toward a retirement annuity

Applicants must have been graduated from a recognized medical school with a degree of M.D. and must be licensed to practice medicine in a State or Territory or in the District of Columbia. They must have had not less than 5 years experience in the vaccination of newborn infants with Calmette-Guérin vaccine according to the method of Calmette, and must have had not less than 3 years experience in city State or Federal public health laboratories with work in tuberculosis. The two types of experience mentioned may run concurrently

Full information may be obtained from the United States Civil Service Commission, Washington D. C.

REPORTS AND NOTICES OF MEETINGS

FAULKNER HOSPITAL CLINICAL MEETING

The November clinical meeting was held at the Faulkner Hospital on Thursday November 7 at 5 00 P.M.

Two cases which had come to autopsy were discussed. The first was a man of forty two years of age who had been a patient in the Out Patient Department of the Peter Bent Brigham Hospital for over a period of seven years. Nothing of importance had been made out until May 1935 when a gastric ulcer was discovered on the lesser curvature of the stomach and a note was made that the duodenum ileum and cecum were normal. Upon a diet the symptoms referable to the gastric ulcer disappeared. Four days before his admission to the Faulkner Hospital in August he had diarrhea with blood in the movements and severe pain in the right lower quadrant. It was thought at first that he might have an attack of acute appendicitis but it was felt that he did not. His physical examination and clinical pathology were essentially negative. During his stay of two and a half weeks in the hospital he had, usually loose bowel movements sometimes only one a day sometimes three or four. There was no gross blood in the bowel movements. Some of the time the test for occult blood was positive but other times negative and his diet was not arranged to keep meat or meat extractives out of it. A barium enema showed signs of an inflammatory lesion around the cecum. The barium entered the terminal ileum which appeared to be normal. Suddenly evidences of peritonitis and intestinal obstruction developed and the patient died following exploration. This happened before the gastrointestinal tract was studied by x-ray with the barium given by mouth. The striking findings at the postmortem examina-

tion were multiple ulcerations extending throughout the small intestine and for a short distance in the cecum. Several had perforated. The cause for these ulcerations after exhaustive study was not demonstrable. The lesion did not appear like the lesion of so-called regional ileitis, in that the induration and thickening of the bowel wall were absent. There was a scar in the stomach where the gastric ulcer had healed.

The other case was in a man seventy four years of age. The lesson learned from this case was the importance of not putting too much faith upon any one diagnostic procedure. In this instance a negative x-ray study in the hands of an excellent roentgenologist led the clinician away from the correct diagnosis. This patient for three months had been having epigastric pressure with gas formation and loss of appetite. The pressure was sometimes relieved by food and other times not. There was some vomiting which had become worse as time went on, and a few days before admission there had been some diarrhea and some tarry stools. The patient had lost fifteen pounds in weight. Three years before, a partial thyroidectomy had been performed for symptoms of hyperthyroidism with pronounced relief. The possibility of a recurrence of the hyperthyroidism was considered, but a study of the basal metabolism seemed to rule this out. Shortly after admission to the hospital the patient vomited blood and had more tarry stools. X-ray studies of the gastrointestinal tract just before entrance to the hospital were reported as negative. It was felt that exploration for a bleeding point in the intestinal tract with the gastrointestinal studies by x-ray negative would offer more risk than expectant treatment. A sudden large hemorrhage while under this investigation caused death. At autopsy a large duodenal ulcer was found which extended more than half way around the duodenum and it was from this point the blood came. On recapitulation the roentgenologist felt that the size of the ulcer is what had caused the difficulty in diagnosis, because the cavity formed by the ulcer was so large that the barium went into it and gave the appearance of a good duodenal cap.

Following the discussion of these two cases Dr. Chester M. Jones discussed a few of the conditions which are grouped as enteritis. He called attention to the fact that in some inflammatory conditions of the small and even large intestine, constipation might be present rather than diarrhea. Just why some cases of diarrhea associated with a lack of free hydrochloric acid in the gastric juice or with a sprue or pernicious anemia are benefited by small doses of free hydrochloric acid is not clear but is a clinical fact. The diarrhea of pernicious anemia or sprue is practically always controlled by the administration of liver in some form. He called attention to the fact that functional diarrhea practically

never interferes with the patient's sleep and is usually started up by taking food. This is a diagnostic point of considerable importance. He mentioned four causes which produce symptoms of enteritis: Tuberculosis, Regional or Terminal Ileitis, Ulcerative Colitis and Cancer.

The ulcerative colitis may be subdivided into ulcers of unknown etiology and ulcers due to amebae.

In the tuberculous lesions there usually is diarrhea but not necessarily so. The lesions are usually around the cecum or terminal ileum. If there is pain it is apt to be around the umbilicus. In the past it has been claimed that tuberculosis of the intestine is always secondary to tuberculosis of the lung, but he showed x-ray pictures of the lungs which were normal in a patient in whom tuberculous lesions in the region of the ileocecal valve had been confirmed at operation.

The cause for regional or terminal ileitis is unknown. Usually there is diarrhea. The pain which is generally present is not as a rule so near the midline as in tuberculosis. The lesion is a granulomatous one which starts in one place and spreads. It is similar to the lesion of tuberculosis but there are certain distinguishing features. It is difficult to distinguish it from tuberculosis without the aid of the microscope. It is rare for the process to extend into the cecum, but if it does it is usually confined near to the ileocecal valve. Resection is the best form of treatment and it must be borne in mind that the process may extend into the area where the bowel appears normal. Extension of the process with the need of subsequent operation sometimes occurs.

In ulcerative colitis the ulcers are usually low enough down in the bowel so that they can be seen with the proctoscope and rarely extend into the small bowel. Therefore, by proctoscopic examination this condition can usually be diagnosed.

For the treatment of tuberculosis and regional ileitis, operation is indicated. For ulcerative colitis Dr. Jones had little to offer in the way of specific therapy. He called attention to the need of ileostomy in certain cases as a life-saving procedure or as a means of getting the patient economically established.

Cancer of the small intestine is rare but should be suspected in long continued diarrhea of unexplained origin associated with loss of weight. In some instances it is possible to diagnose it by the x-ray but not always.

He completed his address by giving a short description of a case of terminal ileitis which involved both the cecum and twenty cm. of the terminal ileum. The question was raised whether the first of the cases presented for discussion could represent the early stages of so-called regional ileitis. It was felt by the pathologist that the lesions were not the same and it was also felt that it would be unusual for regional ileitis to start over such an extensive area.

FAULKNER HOSPITAL CLINICAL MEETING

The next clinical meeting will be held on Thursday the fifth of December. In addition to the usual clinical pathological conference Dr. Tracy J. Pntnam will talk on "Surgical Treatment of Athetosis" (With an illustrative case.)

All physicians are invited

PLYMOUTH DISTRICT MEDICAL SOCIETY

A stated meeting of the Plymouth District Medical Society was held at the Moore Hospital, Brockton Mass., October 24, 1935. The meeting was called to order by the President, Dr. Hanson at 11:15 A.M.

Dr. G. A. Moore reported on cases of breast cancer treated at the Moore Hospital presenting patients that had passed the five and ten year period without evidence of recurrence. Patients that had been followed for five years were divided into two main groups. Of those treated by operation alone thirty per cent were living without evidence of recurrence and of the group that received postoperative radiation forty-three per cent were classified as five-year cases. Methods of the early diagnosis of cancer of the cervix were discussed and patients presented who had survived without evidence of disease five and ten years after x-ray and radium treatment.

Dr. A. L. Duncombe discussed narcolepsy and presented a case. The patient, a twenty-one year old white Armenian boy, had been well until three years ago when he began to have a frequent and irresistible desire to sleep. He would fall asleep under all circumstances even while driving his car and eating his meals. The sleep was usually of five to ten minutes duration. The patient awakened refreshed. Two years ago he began to have cataplexy losing all muscle tone and falling to the ground upon any emotional excitement, especially laughter. After terrifying dreams he likewise would be completely paralyzed. These attacks of weakness lasted a relatively few seconds. Physical examination was entirely negative as were the routine laboratory examinations and lumbar puncture. The glucose tolerance was unimpaired. He has been completely relieved of his symptoms by the use of ephedrine sulphate $\frac{1}{2}$ grain every three to five hours. The importance of differentiating this disease and petit mal epilepsy was stressed since narcolepsy is a distinct clinical entity responding symptomatically to a stimulating drug, ephedrine sulphate, while epilepsy is benefited by sedation.

Dr. Francis T. Hunter, Assistant Physician at the Massachusetts General Hospital, gave an interesting talk on "Egyptian Mummification with X-Ray Studies of Mummies at the Boston Museum of Fine Arts." Dr. Hunter discussed the methods of mummification practiced from the earliest times illustrating his remarks with lantern slides of tombs and mummies. Photographs and x-rays of mummies in the Boston Museum were shown, depicting the method of preservation of the dead and pathological lesions of skeletons. The Edwin Smith papyrus

was briefly described and its probable source from the writings of Imhotep many centuries earlier discussed. Dr. Hunter concluded his talk by citing some of the case histories recorded in the papyrus emphasizing the similarity to present methods of diagnosis and treatment.

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held in the Peter Bent Brigham Hospital Amphitheatre (Sbattuck Street Entrance) Tuesday evening, December 10 at 8:15 P.M.

PROGRAM

Presentation of Cases

Types of Syncope: Their Mechanism and Treatment. By Soma Weiss, M.D.

Medical students and physicians are cordially invited to attend.

MARSHALL N. FULTON, M.D., Secretary

CARNEY HOSPITAL

There will be a clinical meeting at the Carney Hospital Monday, December 2 at 8:30 P.M.

Subject: Back Pain—By A. R. MacAusland, M.D. Discussion from a neurosurgical point of view—W. J. Mixer, M.D. from a gynecological point of view—R. J. Heffernan, M.D. from a urological point of view—Roger Graves, M.D. Physicians and medical students invited.

SOCIETY MEETINGS, CONGRESSES
AND CONFERENCESCALENDAR OF BOSTON DISTRICT FOR THE WEEK
BEGINNING MONDAY, DECEMBER 2, 1935

Tuesday, December 3—

2:30 P.M. Pediatric Ward Visit, Massachusetts Eye and Ear Infirmary.

7:45 P.M. Gardner Auditorium, State House, Boston. How Psychiatry Can Aid in Meeting Problems of Modern Life. Donald Gregg, M.D.

Wednesday, December 4—

113 A.M. Clinico-Pathological Conference, Children's Hospital.

5 P.M. Arthritis Clinic, Robert Breck Brigham Hospital, 125 Parker Hill Avenue, Boston.

Thursday, December 5—

8:30 A.M. Clinic, Surgical and Orthopedic Staffs of Children's Hospital, at the Children's Hospital.

3:30 P.M. Medical Clinic at the Peter Bent Brigham Hospital.

5 P.M. Faulkner Hospital Clinical Meeting.

Friday, December 6—

1 A.M. Clinical Meeting of the Children's Medical Staff, Ether Dome, Massachusetts General Hospital.

Saturday, December 7—

9 A.M. Boston Dispensary, 25 Bennett Street, Boston. Clinic "Obesity." Professor S. J. Thannhauser.

*10 1 P.M. Staff rounds at the Peter Bent Brigham Hospital.

Open to the medical profession.

Open to Fellows of the Massachusetts Medical Society.

December 2—Clinical meeting at the Carney Hospital. See notice above.

December 4—Arthritis Clinics at the Robert Breck Brigham Hospital. See page 1055 issue of November 7.

BOOK REVIEW

Clinical Parasitology and Tropical Medicine Dá maso de Rivas 367 pp Philadelphia Lea & Febiger \$5 00

The first three chapters in Part I are devoted to general concepts which should be helpful to those who are beginning the study of parasitology Subsequent chapters dealing with clinical and laboratory diagnosis and with treatment contain much which is based upon the experience of the authors Some of their views are markedly at variance with the opinions of other competent authorities For example, the value of several drugs which are in use for the treatment of amebiasis or for helminthic infestations has not been adequately appraised. Neither has the importance of examining *perfectly fresh fecal* material for vegetative amebæ been sufficiently stressed, and the diagnostic value of culturing the stools for ameba has not been mentioned

Part II "Diseases Caused by Protozoa" and Part III "Diseases Caused by Metazoa" are of interest especially with regard to the striking results claimed by the authors in the treatment of intestinal infestation by means of their thermal method Part IV deals very briefly with a group of diseases caused by well-known bacteria

Some of the subsequent chapters which are included in Parts V or VI practically disregard recent work which has received wide acceptance The use of liver extract which has revolutionized the treatment of sprue, for example, is scarcely mentioned

The "intraintestinal thermal method," which the authors have used against a variety of intestinal parasites over a considerable period of time and in large numbers of cases, has given excellent results in their hands and has caused no serious ill effects On the other hand, the experiments of Maurice C Hall and Jacob E Shillinger (1926) and the work of a few subsequent investigators of the subject indicate that there may be grave danger in the use of the method in man

NUMBER 23

CANCER OF THE LARYNX*

A Study of Two Hundred and Two Cases With End Results

BY SAMUEL W. GARFINK, M.D.†

INTRODUCTION

THIS report is based on a study of 202 unselected and consecutive cases of cancer of the larynx treated at the Collis P. Huntington Memorial Hospital over a period of fourteen years, dating from January, 1919 to July 1933. During this period there were 12,466 cancer patients admitted, 202 of whom suffered from cancer of the larynx, giving an incidence of 1.6 per cent for cancer of this organ.

Unfortunately, in a large majority of these patients the disease had progressed to such an extent that any expectation of a cure was out of the question and the most one could hope for was palliative relief. The unwarranted hopeless attitude assumed among some in the profession, and the failure to recognize the early symptoms of cancer may in great part account for the late arrival of patients for treatment. Early diagnosis offers a patient his best chance of cure. This is especially true, as will be shown later, in the early intrinsic type.

Historical—The modern study of cancer of the larynx is closely associated with the development of laryngology as a distinct specialty in medicine. This dates from the discovery of the laryngoscope by Garcia in 1855 and its introduction into medicine by Türk (1857) and Czernak in 1858.

We are greatly indebted to Sendziak for his contribution to our knowledge of the history of malignant tumors of the larynx. Although the disease was known to the ancients, it was imperfectly understood by them and their observations are only of academic and historical interest. Aretaeus (about 100 A.D.) refers to cancer of the larynx. Galen (about 200 A.D.) gives a description of malignant ulceration exhibiting an infiltrating character and also, of new growth of the pharynx and the base of the tongue, leading to mechanical dyspnea by compression of the upper part of the airway. During the Middle Ages very little, if anything, was recorded in the literature on the subject.

In 1668 Boerhaave of Leyden described a cancerous angina and Morgagni of Padua (1732)

gave a clear description of cancer of the larynx in two cases. These patients succumbed to dyspnea and dysphagia and necropsy showed malignant disease of the pharynx and larynx. During the ensuing century, no contributions of note appear to have been made on this subject.

In 1833 Albers of Bonn reported a case in a man aged fifty-four who died of asphyxia caused by a malignant tumor the size of a nut. In the same year Brauer of Louvain devised a thyrotomy operation for laryngeal polyp, and this procedure was later (1884) adapted by Ehrmann for the treatment of cancer.

In 1836 Bellocq and Trouseau wrote upon "laryngophthisis carcinomatosa." Their work shows that granulomas and neoplasms were still not clearly distinguished. In 1846 Tronseau is said to have performed the first tracheotomy for the relief of laryngeal carcinoma. Before the discovery of the laryngoscope (1855) cancer of the larynx was considered a rare disease.

In 1851 Dr. Gurdon Buck of New York first performed a thyrotomy for the removal of laryngeal cancer.

In 1855 the discovery of the laryngoscope by Garcia, mentioned above, laid the foundation for a more accurate study of cancer of this organ. It is of interest to note that Garcia was not a physician, but a singing teacher in London and invented the laryngoscope in order to observe the vocal chords.

The first total laryngectomy was performed by Patrick Heron Watson (1868) of Edinburgh. The patient survived but a short time. Billroth of Vienna (1873), after experimenting on dogs successfully removed the larynx of a man who survived several months in 1874. Heine and Mars repeated the operation. In the same year Gussenbauer also operated and devised an artificial larynx, the first of its kind.

In 1877 Foulis D. of Edinburgh reported his first case (*Lancet* 2:531 [Oct 13] 1877) and in 1891 published a paper in which he had collected reports of thirty-two complete and six partial laryngectomies. The results of these cases were bad; the method was unanimously and severely criticized (*Trans Internat Med Congress* 3:251 1891).

*From the Cancer Commission of Harvard University.
†Garfink, Samuel W.—Assistant Surgeon, Aural Service, Boston City Hospital. For record and address of author see "This Week's Issue" page 1141.

The first laryngectomy in this country was performed in 1879 by Dr Frederick Lange, a surgeon residing in New York

In 1883, Dr J Solis-Cohen, of Philadelphia, collected sixty-five cases, all of the reports and statistics available and published the results of the operation to date (*Trans College of Physicians* 6 353 [Apr 4] 1883) Fifty per cent of the patients died from the operation. The initial shock was severe, the operation had cost the sacrifice of a certain number of lives, and the conditions of the survivors had often been described as pitiable in the extreme. In the opinion of Solis-Cohen, "laryngectomy had not tended to the prolongation of life, and the prolonged existence of a very few cases seemed purchasable only at the sacrifice of the remnant of existence of many others." It was because of the unsuccessful efforts that the operation was abandoned for a brief period in this country.

About the same time, Gluck of Berlin, adopting the best ideas of his predecessors, had put them in practice and added his own. He suggested the operation in two stages in order to overcome the hitherto dangerous reactions. In the first operation he severed the trachea from the larynx and sutured it to the skin, two weeks later removing the larynx. Later, he performed the operation in one stage, as we know it today.

In 1892, following the improved method of Gluck, Solis-Cohen removed the larynx of a patient and, for the first time in this country, attached the severed end of the trachea to the skin. The whole procedure, including the anesthetization and dressing, occupied one hour. Indeed, a very creditable showing, even in this day. The subsequent care given the patient personally by Dr Cohen and his assistants is deserving of great praise.

In 1895, this patient, Daniel Hickey, was exhibited at the annual meeting of the British Medical Association in London. He was in perfect health, entirely comfortable, breathing freely through a tracheal opening in the neck without a tube, and the first in this country to have acquired a pharyngeal voice, plainly audible at a considerable distance.

The next decade was to witness what is, perhaps, up to the present day the greatest advent in the surgical treatment of laryngeal cancer. With a clearer understanding of the surgical indications, improvement in technique and better postoperative care, the results of operation, both in this country and abroad, showed a most striking improvement.

Topia of Madrid reports 106 laryngectomies with no fatalities, but unfortunately in these there were thirty-two recurrences. F O Lewis, Tucker, Mackenty and others in the country were able to make a comparable showing. The

latter in 130 laryngeal operations as follows: twenty-two thyrotomy, six hemilaryngectomy and 102 total laryngectomy with no operative mortality following thyrotomy or hemilaryngectomy. Two died, one from septic bronchial pneumonia, and the others from general sepsis, both had diabetes.

F O Lewis reports that out of 156 operations, forty-nine patients are alive and well over five years, seventeen extrinsic, thirty-two intrinsic.

Thomson, St C has obtained seventy-six per cent of lasting cures in intrinsic cancer and in his opinion, when operated on early, following his procedure, results can be secured which cannot be surpassed in the treatment of cancer in any other internal region of the body.

The credit is due largely to the zeal and untiring efforts of such men as Gluck, Soerensen, Schmiegelow, Moure, Topia, Semon, Thomson and others in Europe. In our own country, the early efforts of Solis-Cohen and Mackenzie of Baltimore deserve high praise. In more recent times, the contributions of Jackson, Fielding Lewis, H B Orton, J E Mackenty and many others have placed laryngeal surgery on par with surgery in any other part of the body.

OTHER METHODS

Radium—The early use of radium in laryngeal cancer not only produced indifferent results but in many cases, increased the sufferings of the already miserable patient. Until about 1910, the belief was prevalent that "radium did no good", (Sir W Douglas Harmer) "that radium killed more people than it relieved". Because of these opinions, the early workers in the field of radiotherapy met with scant encouragement.

In the past decade a considerable amount of work has been done in radiotherapy throughout the world, so much so that the early opposition to radiotherapy has been replaced by enthusiastic acceptance of radium as a valuable therapeutic agent. Professor Forssell (1931) at the third International Congress of Radiology stated that in the history of cancer surgical treatment was the achievement of the last century, and the formation of radiotherapeutic centers can be considered as the great contribution of our generation to the social struggle against cancer.

Dominici and later Finzi were the earlier pioneers of radiotherapy in England and were the first to suggest interstitial radiation.

Strangeways (1920-1922) studied the effects of radiation on living cells and made observations on the character and behavior of normal tissue cultures preparatory to a study of the effects of x-rays on cells growing in vitro.

Canti and Donaldson (1923) investigated the histological changes produced by radium in cases

of carcinoma of the cervix uteri. After radiation, sections were taken at frequent intervals and studied microscopically, the results confirming the earlier findings of Lacassagne and Monod (1922) that immediately after irradiation there was no longer any mitosis present. It was found however, that mitosis returned on the second day, but that it was strikingly abnormal. Thus it was realized that further knowledge of the biological action of radium was essential in treatment of cancer if success is to be attained. Later considerable experimental work was carried out jointly by these same investigators (Strangeways, Canti and Donaldson) which produced valuable information regarding the biological action of both radium and x rays on tissue cultures.

Both in this country and abroad, there are a number of radium centers or institutions admirably suited for carrying out radiotherapy. In England until 1932, there were nineteen such centers, all supervised by competent men. Sir W. Douglas Harmer (London) is perhaps the best known for his work in radiotherapy in the field of laryngology. In Paris, the Radium Institute is in charge of Regaud. In Stockholm the Radium Hemmot under Forsell and Berven have published good results with the use of radium, likewise, the Institute of Brussels organized by Bayet and Murdock. In this country the Memorial Hospital in New York, Michael Reese Hospital in Chicago and our own hospital, the Collis P. Huntington, are institutions similar to those abroad.

Harmer states that, with cancers strictly localized to the vocal cords (early cases), he has had a high percentage of good results. Recurrences have occurred only at the anterior commissure or below the cord. In advanced cases with fixed vocal cords and subglottic extensions, the results have been bad. He believes this is due to faulty technique, namely, failure to cover the growth and thereby failure uniformly to radiate all parts of the tumor. He suggests the fenestration of the thyroid cartilage (Ledoux's method) and introduction of platinum needles containing radium. In his opinion, small doses over a long period of time produced better results than large doses for a short time. Platinum needles of 0.6 or 0.8 mm. even 1 mm. in thickness are used. He also favors the use of x rays first if the disease is extensive 1/3 of the erythema dose over a period of a week, followed immediately by insertion of radium.

Outler, following the biological radium experimentation of Strangeways, Canti and Spear and their coworkers, believes that the hitherto considered radioresistant squamous-cell carcinoma can be successfully treated by protracting the time during which radiation is administered es-

entially applying the principles used in x ray therapy by Coutard.

Röntgen Therapy

By far the best results obtained with radiotherapy are reported by Coutard. He has modified his former technique so that the reactions he previously obtained are not so severe and the accidents which occurred in the earlier periods have been appreciably reduced. The result of treatment by his method in seventy-seven cases of cancer of the larynx is here cited.

Cases Treated from 1920 to 1926	Survival After Five Years	Survival After Seven Years
77	22 (28%)	21 (27%)

He believes that Röntgen therapy of cancer of the larynx is relatively easy and yields good results in early cases before there is invasion of the cartilages and when the growth has only slightly immobilized the muscles. The cutaneous dose necessary for the healing of these cancers is comparatively small on an average a total of 6000 r (on the skin) with fields of 50 sq. cm. delivered in a period of fifteen to twenty days. Röntgen treatment of radioresistant cancers of the larynx, which have immobilized the hemi-larynx, infiltrated the muscles and invaded the cartilage is generally difficult. In spite of heavy doses, these cases are rarely cured and untoward complications may occur. Doses of 7000 to 8000 r or more, are required and constitute the maximum tolerated by the tissues.

In order to avoid osteochondro-necrosis following roentgen therapy, he practices resection of the thyroid and cricoid cartilage on the side of the lesion especially when they are frankly ossified. He further believes that this operation is indispensable when the growth has invaded the cartilages, is deeply infected and only slightly radiosensitive. Previously resection of the angle of the mandible was practiced for the same purpose, but this has now been abandoned as the Röntgen treatment has been modified to avoid osteoradionecrosis.

Three principal types of epithelial radioreaction are described by Coutard as guides during the x ray therapy and are as follows: (1) The cutaneous "radioepidermitis" of Regaud and Nogier (1913) (2) the "radioepithelitis" of Coutard and (3) the "radioepithelitis" of the columnar epithelial cells. Radioepithelitis of the stratified cells generally appears about the thirteenth to fourteenth day after the beginning of irradiation. This is the earliest epithelial radioreaction of this region. Lower in the larynx, at the level of the vocal cords where the stratified epithelium resembles that of the skin, radioepithelitis appears at about the twenty-seventh or twenty-eighth day at the same time as the cutaneous radioepidermitis. At the level of the ventricular bands and below the

glottis on the mucosa covering the tracheal rings, the epithelium is cylindrical or columnar, the reaction in this region appears at the thirty-ninth or fortieth day

If irradiation is more intense, the reactions appear earlier, on the tenth and the twenty-fourth day respectively for the first two, sometimes the third reaction appears a very few days after the second

Since it has been learned that radioresistance of cancers is the result of excessive daily doses with too high intensity rather than the irradiation having been spread over too long a time, the duration of treatment was prolonged

From 1927 to 1933 Coutard and his collaborator, F. Baclesse, extended the duration of treatment of certain neoplasms from thirty to ninety days by means of weak daily doses (in the order 175, 250 r per day) distributed in two sances without varying the other factors particularly the size of the fields. In this way, they were able to bring about disappearance of growths which up to then were considered radio-resistant

In conclusion, we may summarize Coutard's results as follow

- (1) Cure of cancer by x-rays is still difficult
- (2) Cure of cancer by x-rays is still dangerous
- (3) A very small margin exists between the dose which will determine a cure and the dose which will provoke an injury
- (4) The daily examination of the patients is necessary, modification of normal tissues and of the general condition by x-ray treatment sometimes appears so quickly that it is often necessary to diminish the daily dose or the size of the fields in the course of treatment

He further concludes that there exists no fixed method of treatment, but a simple clinical treatment for each individual patient and for the special type of tumor

At the present time, there is a lack of agreement as to what is the best method of treatment for cancer of the larynx, because not only the size and location, but the grade of tumor must be considered. Laryngologists with extensive experience in this field of surgery still prefer surgical removal with or without post-radiation. If it can be shown that radium or x-rays alone or combined can produce as high a percentage of permanent cures as surgery, it will be a safer method of treatment and will be welcomed by the surgeon and be a blessing to the patient

Etiology—The origin of cancer is still unknown. However, experimental research, notably the work of Rous, Borrel, Murphy, Gye and Bernard, has thrown light on the question of whether there is an external agent concerned in its production. Sir Charles A. Ballance in an address to the American College of Surgeons at Boston, October 11, 1928, speaking on the na-

ture of cancer, summarized our present state of knowledge in the following words: "The efficient cause lies beyond the irritation or injury which are but the partial causes of the disease. The injury prepares a nutrient soil favorable for the growth of the effective agent of malignant disease."

Predisposing Causes—Overuse of the voice, heredity, irritant inhalations, excessive use of tobacco and alcohol have been cited as etiological factors

Use of Tobacco—In the present series of cases, there were ninety-one patients who smoked, forty-one smoked and chewed, four chewed only, six stated they did not use tobacco in any form and in fifty-eight, this fact is not recorded. The ratio of incidence of cancer of the larynx in tobacco users and nonusers of tobacco is such that we cannot draw definite conclusions on this as an etiological factor. Repeated injury and long-continued irritation and inflammation are potential factors of cancer. We recognize leukoplakia as a definite precancerous lesion. There is a pathological slide in my possession showing the transition from leukoplakia to carcinoma

Vocal Abuse—This is frequently cited but is difficult of proof, because of the incompleteness of the records. Most laryngologists are familiar with the patient who by overuse or incorrect use of the larynx, especially singing in the open air beyond one's tonal reach, presents himself with the history of having suddenly lost his voice. Upon examination one finds red-streaked vocal cords, hemorrhage of the cord from abuse. The practice persisted in may lead to hypertrophic laryngitis. Jackson states that out of 582 cases of proved cancer of the larynx in his experience there had been undoubted vocal abuse in 376 (64.6 per cent). Of the 376, approximately one half 187 (49 per cent) were professional or vocational voice users. These included not only speakers, teachers, singers, hucksters, streethawkers, salespersons, foremen, drill-masters, etc., but also mechanics and factory employees required to talk loudly in noisy, dusty places, and persons employed in many other vocations ordinarily little suspected of requiring excessive use of the voice. The balance 189 (50.2 per cent) used their voices for continuous conversation.

When talking every person is for a time mouth-breathing and mouth-breathing is a well-recognized cause of chronic laryngitis. The assertion by certain authorities that although vocal abuse cannot be said to be the cause of cancer it is, nevertheless, one of the commonest causes of chronic laryngitis, keratoses, papillomata and granulomata and that these conditions when perpetuated by vocal abuse and other causes can be suitable soil for the development of cancer. The common observation of vocal abuse is probably best demonstrated by the

hematoma of the vocal cord resulting from improper use of the voice, and the therapeutic effect of absolute silence in certain forms of laryngitis

Malignant Transformation—In this series there were a number of patients in whom cancer developed in an original benign neoplasm. There were eleven cases of papilloma which later developed carcinoma, in seven of which the transition was proved by biopsy, two had laryngeal polyp with subsequent malignant degeneration, one developed carcinoma in a scar following an operation for branchial cleft. Alfred Denk reports a case of carcinoma developing in scar tissue following an attempted suicide twenty years earlier. There was a marked infiltration of the interior of the larynx which required a tracheotomy and later a laryngectomy was performed. In four patients of this series (Nos. 20, 47, 70 and 160) there is clinical evidence that the disease was probably the result of extension of branchial cleft carcinoma to the larynx. Crile and Kearns report a direct extension of a branchial carcinoma to the pyriform sinus of the larynx proved by necropsy. There was one case (151) of thyroglossal duct cancer with extension of the larynx.

Semon, in a collective study of 10 747 cases of benign tumors of the larynx, found a malignant transformation in forty-five cases. Of 2531 benign growths of the larynx in which no operation was performed, malignant degeneration occurred in twelve, whereas in 8216 intra-laryngeal operated cases it occurred thirty-three times. The inference to be drawn from this study is that intralaryngeal operations on benign tumors do not influence the development of malignancy. Hinsberg cites a case of transformation of benign tumor of the larynx into a malignant growth. This was the case of a man of seventy three who had a "walnut" sized tumor removed which upon histologic examination was benign. The patient remained well for some time (sixteen months) when another specimen removed from the original site showed carcinoma.

The transformation of a benign, papillomatous growth into a malignant process is explained by Ewing in four possible ways

1. The original disease is a simple papilloma which really changes its clinical character and develops infiltrative growth
2. The original disease is carcinoma, but the examination is from tissues which are inadequate as specimens
3. An original papilloma is removed but the disease occurs elsewhere as a carcinoma.
4. An original papilloma is imperfectly removed and the remnant is stimulated to a typical cancerous growth

TABLE 1
INCIDENCE OF LARYNGEAL CANCERS BY YEARS

Year	Male	Female	Combined
1919	15	1	16

1933	9	8	12
	182	20	202

Age—Age is an important factor in the incidence of the disease as shown by the following table

TABLE 2
AGES AND SEX
Age of Onset by Decades

Ages Years	Males	Females
20-30	0	1
31-40	9	0
41-50	34	4
51-60	72	3
61-70	47	8
71-80	15	4
81-90	2	0
Age not stated	3	0
	182	20

The greatest number occurred between fifty and sixty seventy-one or 34.6 per cent. The next in frequency is between sixty and seventy, with fifty six or 26.8 per cent. The two oldest cases in our series were eighty two and eighty six respectively, both males. Our youngest case was a woman (20354) of twenty years of age of proved cancer, case No. 24. The oldest female was seventy five (163). The youngest male was thirty four, the oldest was eighty-six. In studying the age table, one must bear in mind that there are fewer people living past the age of sixty and there is, therefore, a drop in the incidence of cancer after this period.

Sex—There were 182 males and twenty females.

The table shows that the condition is not very rare between thirty and forty, and is less frequent in the aged. McBride records the case of a girl, aged twenty four, with postero-lateral involvement. Lally reports a similar case in a young woman, aged twenty two. F. H. Figg and Gordon New report a case of intrinsic cancer in a youth of fifteen and in a woman of twenty four. Garl treated a girl of eighteen for cancer of the larynx and Chiari had a case

of epithelioma of the vocal cord in a girl of sixteen. Our figures agree with those of other clinics which show the greatest number of cases in the fifth decade of life.

Nationality—It is of interest to note that all the laryngeal carcinomas were in white people, there being no Negroes or Chinese among them. That may be because there are very few Negroes or Chinese that come to our clinic for any condition. Practically one half of ninety-nine cases were in American white, there being twenty-five Canadian French and the remainder Europeans.

Occupations—The occupations of the patients cited in our series comprised all industries and professions.

SIGNS AND SYMPTOMS

Duration—In forty-five cases the duration of the symptoms before the first visit was less than six months, in forty-six cases from six months to one year, in thirty-four cases, one to two years elapsed before the first visit, in sixteen, two to three years, in five cases, three to four years, in three cases, four to five years. In one case, the duration was six or seven years. This was in a male sixty-five years of age with a growth on the right vocal cord which began as a papilloma and later became malignant by transformation. The shortest duration was that of a man sixty-five who complained of a sore throat for one month before admission. The longest duration was in a man fifty-seven years of age who was hoarse ten years.

Where there is a history of three years' duration or more before admission to the hospital a number of explanations are possible. A lesion starting on the cord, particularly at its anterior edge, may remain more or less dormant for a long time before invading the surrounding structures. This may be explained by a very meagre lymphatic supply, by the anatomico-histological structure of that part of the larynx, low grade malignancy, and long presence of a papillomatous growth undergoing transformation. Frequent instances of this have been shown by Jackson, Thomson, Semon and others.

Symptoms—The symptoms will vary with the site of the lesion and will depend largely upon how much the normal function of the larynx is impaired. A growth situated on the edge of the cord near the anterior commissure will cause more hoarseness, because it prevents complete closure of the glottis, than a larger growth on the cord in the region of the posterior commissure where the closure of the glottis is not so much affected. There may, therefore, in early stages be no symptoms or mere fatigue of voice or transitory hoarseness. As the growth progresses and invades the glottis the hoarseness becomes more pronounced. This may go on for months or even years, as some of our cases have, and the patient or perhaps his medical attendant, regards it as "cold." With the advance of time the voice becomes altered, and the breathing is impaired, especially on exertion, and the voice may be reduced to a coarse whisper, finally leading to aphonia.

The mild symptoms very often complained of by the patient bear a disproportionate relationship to the size of the lesion and the seriousness of the condition. A man aged sixty-seven (case No. 8) complained of a tickling sensation in the throat with no other discomfort. Examination showed an extensive lesion involving the arytenoids and posterio-cord regions. The patient died a month after his first visit to the hospital. With the exception of urgent dyspnea, in advanced cases of intrinsic carcinoma, and dysphagia in the extensive extrinsic cases where there is involvement of the esophagus, the symptoms are not very alarming, nor is pain very severe. This is especially so in the early stages. Many patients are able to continue their usual occupations and some have even been accepted as good risks for life insurance, the examining physician not being aware that cancer is present.

Only the patients' chief complaint is recorded in this study. Generally speaking, the intrinsic type is characterized by a varying degree of hoarseness in the early stages. As time progresses, the hoarseness is increased and normal respiration is interfered with, often leading to aphonia and dyspnea. Pain is usually not a factor in this type of lesion.

In the extrinsic type, the symptoms vary greatly with the site of the lesion and its extent. There is at first some vague discomfort in the throat such as feeling a lump or perhaps some slight difficulty in swallowing. As time goes on, these symptoms increase in severity. Pain is at times quite common in this type and is very often referred to the ear.

SYMPTOMS

Enlargement of the Cervical Glands as the First Symptom

In twenty-two patients, the sole complaint was a swollen neck with no other discomfort.

Hoarseness was a predominant complaint in 100 cases, in forty seven patients, the chief complaint was sore throat of varying degree. Dysphagia was present in nineteen cases. Swollen neck or enlarged cervical glands with no other complaint was recorded in twenty two instances. Loss of voice was the only discomfort complained of in four cases. Two complained of feeling a lump in the throat. One had a tickling sensation in the throat. Four had dyspnea. Thus, it may be seen that the symptoms depend largely on the location of the tumor and the extent it interferes with normal function. Generally speaking, in the middle-aged and elderly people, any kind of abnormal sensation persistently felt in some part of the throat should be regarded seriously.

Site of the Lesion—As recently as 1880 Stoerk, professor of laryngology in Vienna, remarked that carcinoma is rarely found limited to the larynx, but most frequently arises in the mucous folds between the epiglottis and the tongue, or between the epiglottis and the esophagus and then spreads to the larynx. Our present conception is that it is primary in the larynx and may extend by contiguity from the pharynx to involve the larynx, the so-called laryngopharynx type of extrinsic cancer. Among the male pa-

tients, eighty-one were of the intrinsic type and eighty seven were extrinsic. In nineteen males the site was not stated. In the females, fourteen were of the extrinsic variety, five intrinsic and in one case the exact location is not stated. The location of the lesion as found upon admission to the hospital is shown in the following table. In a number of instances the exact site of the lesion is not stated in the record.

The above table shows that the site of original lesion is extremely variable, although certain parts of the larynx are particularly vulnerable to the disease. Out of seventy six intrinsic cases the cords were the site in sixty three patients. The posterior cold type is especially noticeable in the female patients.

Contrary to the statistical reports published by many laryngologists our records show a predominance of the extrinsic type over the intrinsic, as shown in table 5. This may be explained by the fact that most of the intrinsic operable type were treated at other surgical hospitals and the more advanced extrinsic or mixed type were referred to us. Another explanation is that probably a great number of the extrinsic group began as intrinsic and by extension became extrinsic or a mixed type.

Cords—It is of interest to note the frequency of cordal cancer in the intrinsic type. Out of a total of eighty-one intrinsic cases, the cords were involved in sixty three instances. Schmiegolow noted the greater frequency of cordal involvement in intralaryngeal cancer, his series showing thirty-six instances in forty-eight cases. In the females of the five intrinsic cases, four involved the cords the ventricles were involved once, and the site of the lesion was above the cords once.

Subglottic Type—Comparatively speaking this site is less frequently encountered being present in nine cases. In two patients there was subglottic extension from the lesion on the right cord. In one instance there was involvement of the ventricle band from extension of the neoplasm on the left cord. In cases where the cord

is the site of the neoplasm with simultaneous subglottic involvement it is difficult to be certain of the origin of the tumor. It was pointed out by Butlin (quoted by St C Thomson), that in a subglottic type of lesion if the motility of the cord is impaired, although no growth is seen on the cord, it is nevertheless involved and a fissure operation does not cure the patient. This has been our observation in several instances. This type of lesion was not encountered in our female patients.

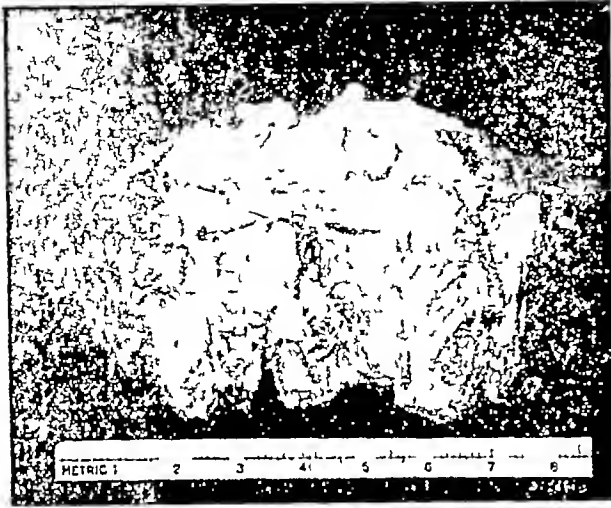

FIG 1. Picture of larynx (Chaney). This shows a typical subglottic type tumor, Case No 178, described in detail below.

CASE 178 (Admitted March 28, 1932)

Male, aged fifty six. Hoarseness of one and one-half years' duration.

Examination. Ulcerated mass on the left side of the larynx situated subglottically. Fixation of the left cord. There is marked induration of the entire left half of the larynx and beginning edema of the arytenoid on that side. The right half of the larynx shows some edema with questionable edema of the right ventricle. Breathing space fairly ample. Glands in the neck not felt.

Diagnosis. Intrinsic carcinoma of the subglottic type. Pathologist reports Epidermoid Cancer Gr II. March 30, 1932—*Laryngectomy.* One-stage resection of larynx from below upward. The patient made an uneventful recovery. Two weeks later a suspicious, small area on the left side was discovered. Biopsy showed malignancy. The lesion was at the level of the fourth tracheal ring and four gold seeds 1.1 mc were inserted. The patient died September 15, 1932 from metastases and secondary infection.

This illustrates a typical case of subglottic cancer. The one and one-half years' duration before the patient presented himself for treatment gave ample time for metastases so that at the time of operation metastases was already present, but could not be seen or felt. The prognosis in the type (subglottic) is not very favorable especially if more than six months have elapsed since the onset of the lesion. In this type of cancer there is early invasion in the deep nodes about the larynx and trachea. The

subcarinal and peritracheal, as well as the inaccessible posterior groups along the recurrent nerves and those nodes behind the esophagus are also frequently involved. The metastases may be present but cannot be seen or felt. This was particularly so in this case as the subsequent clinical course of this patient showed.

Extrinsic Form.—The epiglottis was involved in twenty-five cases in males, two in females. It is a striking observation to note the relative infrequency of the posteriocord type of lesion in the male as compared with the female. Out of a total eighty-seven extrinsic cases in the male only seven were recorded as posteriocord, whereas out of fourteen extrinsic cases in females seven or fifty per cent of the lesion was posteriocord. Involvement of the esophagus was present in this three times in the females, twice in the males. Both arytenoids were noted as the site of the lesion in ten patients, on the right alone five, on the left alone four, in males. In females, both arytenoids were involved also and once the right alone. In males, the pyriform sinus was involved nine times, three on the right, three on the left and in three, side was not stated. In the females, it was noted in two patients. The pharynx was the site of the lesion twice in males and once in females.

Diagnosis.—It is not always possible to make an early diagnosis and the following are some of the reasons for this:

- 1 The remote location of the tumor
- 2 The symptoms may be slight, especially in the early stages of the intrinsic type
- 3 Rapidity of the growth which may be very marked in some instances
- 4 Early necrosis and metastases, especially in the extrinsic variety
- 5 Early and rapid invasion of surrounding cartilages

The early diagnosis of cancer of the larynx, especially in the intrinsic type, is of the greatest importance. Contrary to the opinion held by many physicians, the prognosis in this type is good when diagnosed early and treated promptly. Unfortunately our records show that patients do not present themselves for treatment until the disease has become so extensive that operation is out of the question, and the best that can be expected is palliative relief. There are several explanations for the late appearance of the patient, especially the hospital type case. (1) The symptoms at the onset such as slight hoarseness or mild discomfort are not taken seriously by the patient. (2) The apparent well-being of the patient in spite of a very serious condition in the larynx.

In the early stages the diagnosis is not always easy, and mistakes have been made by very competent laryngologists. The first laryngectomy performed by Billroth (1873) for cancer

presumably of the larynx upon examination proved to be a tubercular larynx. Semon²¹ states, "Out of thirty three patients on whom thyrotomy was performed presumably for intrinsic malignant growths in eight the diagnosis was either found to have been at fault or remained doubtful."

We endeavor to do a biopsy in every case except in those patients in whom the disease has progressed to such an extent that the physical condition contraindicates even this minor procedure.

Differential Diagnosis—In the differential diagnosis of laryngeal cancer, one must consider chronic laryngitis, syphilis, tuberculosis, pachydermia, perichondritis, angiomas, laryngeal polyps and benign growths. Of course in the advanced cases, diagnosis is not so difficult but even here one must constantly keep the other two members of the triad syphilis and tuberculosis, in mind.

Tuberculosis—The tubercle shows a predilection for the posterior part of the larynx especially the posterior interarytenoid commissure and depending upon the stage of the disease there may be either infiltration, proliferation or ulceration. Primarily tuberculosis is an ulcerative process and does not have the same tendency to proliferate as cancer. Tuberculosis is usually ingrafted upon an anemic basis and the rest of the larynx may show evidence of anemia. At any rate, this is a most common mistake that one is likely to make. It is more probable to mistake tuberculosis for cancer than vice versa. Also, it is practically always secondary to pulmonary tuberculosis. An examination of the chest will help to rule this out. One must always bear in mind that tuberculosis and carcinoma may coexist in the same larynx.

Syphilis—Syphilis is usually more widely disseminated in the larynx. The larynx is marked by congested. In counterdistinction to tuberculosis, there is an absence of pallor. Usually there is early fixation of the cords and it occasionally leads to dyspnea. The diagnosis is greatly aided by the history of infection and serological examination.

Fixation—Especially in the intrinsic type of cancer, early fixation of the cord on the affected side denotes a considerable progression of the lesion. This is particularly so in the subglottic type, and this fixation must be differentiated from a fixation that may be caused by an arthritis of the crico-arytenoid articulation. A slight limitation of movement is highly significant. This particularly brings to mind a recent case of a patient who had a fixation of a cord which was pronounced to be an arthritis of the crico-arytenoid articulation but subsequently proved to be a fixation due to a malignant infiltration. Experience therefore teaches that a limited movement of the cord in a pa-

tient over forty which cannot be definitely explained should be looked upon as malignant until proved otherwise. Too, palsy of the vocal cord due to lesions of the central nervous system must also be ruled out. From this it must not be construed that in every case of cancer there is fixation and just because there is no fixation one should not rule out malignancy. Because when fixation has occurred it means there is deep extension of the growth or there is infiltration at the arytenoid articulation. Limitation or impaired motion may also be caused by a neoplasm originating in the subglottic region where the growth is very often not seen above the cords. Should there be the slightest doubt, a biopsy should be resorted to. A specimen should be obtained from the most prominent part of the growth and one must be sure that it includes a portion of the neoplasm.

Pathology—Most of the cases were of the squamous or epidermoid variety of carcinoma. Case No. 56 was of the basal cell type. Cases Nos. 37, 90 and 136 were of papillary carcinoma. Case No. 77 was reported as fibroma but, clinically, it followed a typical course of carcinoma with metastases and subsequently, reexamination showed Grade II cancer arising in a papilloma. Cases Nos. 79 and 124 were reported polypoid tissue but both were carcinoma, clinically, and pursued a typical course of laryngeal cancer. In eleven patients there is histopathological and clinical evidence that the disease began as a benign papilloma and subsequently transformation to carcinoma occurred. The transition period was very variable, three months in one case and ten years in another. Case No. 78 was that of a male, aged fifty-seven, who complained of hoarseness of ten years' duration. At the onset the growth removed from his vocal cords was reported papilloma. Ten years later he presented himself at our hospital where biopsy showed squamous cell carcinoma. Case 55, very similar to the above, with a history of six or seven years' duration as papilloma, at the end of seven years a specimen removed showed carcinoma. Two patients, cases Nos. 94 and 165 had gone two years as papilloma. The remaining six cases of papilloma had an interval of from five to ten months before transformation took place. It is of interest to note that all the patients in this group were males. In three patients, cases Nos. 67, 70 and 160, the laryngeal cancer was probably of bronchiogenic origin. One case No. 151 began as carcinoma of the thyroglossal duct and invaded the larynx secondarily through the crico-thyroid membrane.

Grades—Broders' grading of potential malignancy modified by Gates and Warren, has been employed in our hospital since 1928 and since then thirty-eight cases have been so classified. There were as follows: Grade I, 13, Grade II, 19 and Grade III, 6.

TREATMENT

Intrinsic cancer of the larynx, although insidious in its onset, has the favorable characteristic of remaining localized for a long time, before spreading to the neighboring lymphatics. Just how long it may remain localized, one cannot say with any degree of certainty, but in some probably as long as two or three years. Furthermore, the greater number of these tumors are of low grade, Grades I and II. Therefore, if the patient can be seen early, and if he will consent to have an adequate operation performed, his chances of a permanent cure are very good. In this series, unfortunately, there were only nineteen cases considered at all favorable for operation and two submitted to operation.

The treatment carried out in this series was as follows:

Total laryngectomy	7
Laryngofissures or hemilaryngectomy	12
Partial operation with radium	20
Radium alone	33
X-ray	37
Radium with x-ray	40
Resection of glands with irradiation	6
" " " only	2
Partial operation	2
Tracheotomy alone	17
No treatment	19
Seeds to glands	1
Branchial cleft Op. with Ra. to neck	1
Treated elsewhere—no data	4

Laryngectomy—There were seven patients who had total laryngectomy operations, one of these (case No. 175) although first seen at our hospital, was operated on elsewhere. Three are living and well, one approximately four years and the other two, three years each and four are dead. Of those dead, one survived three months, one five months, one four years and one four years and ten months.

The following is a brief detailed description of the patients who had a laryngectomy and no longer living:

(1) Case 136 was a male patient, aged fifty-one, who had a bilateral involvement of the vocal cords in a papillary carcinoma. This is a very malignant form of neoplasm. His chief complaint was hoarseness of eight months' duration. A total laryngectomy was performed, followed by an external radium pack of 550 mc hrs. The patient survived three months and died of pneumonia without any evidence of local recurrence. (2) Case 141 was a man, aged fifty-four, with a tumor mass involving the right vocal band and cord with marked fixation. Although this patient was hoarse only five weeks prior to admission, there was a history of intermittent hoarseness over a period of years. The pathologist's report was Gr. I cancer. A laryngectomy was performed and two years la-

ter a small gland in the neck appeared which was removed followed by x-ray treatment. He survived four years and ten months following the laryngectomy and died of pulmonary hemorrhage. (3) Case 175 was a male, aged forty-seven, who had a tumor of the left vocal cord of six months' duration. Biopsy report was Gr. I cancer. A laryngectomy was performed elsewhere. This patient survived four years and one month and died of cancer of the stomach with no evidence of local recurrence. (4) Case 178 was of the subglottic type and has already been described in detail.

Of the three surviving patients (1) case No. 172 was a patient, aged forty-five, with involvement of the vocal cord (Rt.) anterior commissure and epiglottis. The duration of his symptoms prior to admission was two months. The tumor was reported as Grade I from one part and Grade II from another section. The patient has been alive and well almost four years. (2) Case No. 176a was a patient, aged fifty-four, with a tumor on the left vocal cord of ten months' duration. The pathological report was epidermoid cancer Grade I. The patient has been alive and well approximately three years. This patient had diabetes of quite marked degree at the time of operation and was given diabetic treatment before and following the operation. He also had Roentgen therapy following the operation. (3) Case No. 187 was a patient, aged forty-eight, with a Grade II tumor on the left vocal cord and band of two years' duration. In addition to laryngectomy, he also had some x-ray therapy following the operation. He has been alive and well approximately three years.

All the total laryngectomies were performed by the one stage operation. A combination of the Gluck and Peiser methods were employed, resecting the larynx from below upwards. The prelaryngeal muscles were resected in two cases. There were no operative mortalities in this series.

Laryngofissures or Hemilaryngectomy—In this series, there were twelve operations, nine males and three females. Of these, four are living and well, one over fifteen years, one twelve years and one ten years and five years and three months without recurrence. Of the eight dead, one died four years later of carcinoma of the stomach, there being no recurrence of the laryngeal cancer. Another patient, female, the youngest in our group, aged twenty, had a hemilaryngectomy with a bilateral window resection and died three and one-half years following her operation. One case, No. 78, had an operation ten years previously, suffered a recurrence and then died thirteen and one-half years after the original operation. Radium was used in addition to the operation in this case. Two sur-

vived one year and two months following the operation. The remaining two survived approximately seven months. There was one operative death in this series. The patient died four days following the operation from pulmonary abscess. Laryngotomy with removal of the right vocal cord and part of the arytenoid was carried out in one case.

In view of our present experience, better results by more radical primary removal should be obtainable, more complete hemilaryngectomy and more frequent total laryngectomy.

The first patient is case No 60 (H. H. No 23-1131) a male aged sixty admitted to the Huntington hospital September 1923 complaining of sore throat and hoarseness of nine months duration. A laryngoscopy was performed and a growth was found involving the false and true vocal cords. A specimen was removed and three radium seeds 2.3 mc and 1.5 mc, were inserted into the growth. The report of the biopsy (Path No 23-86) was early epidermoid carcinoma arising in papilloma. Jan 17 1923—Laryngoscopy—Considerable mass removed from region of left true and false cord anterior part, and from the subglottic portion of anterior wall of the trachea. Total mass was considerably greater than appeared under indi-

RESULTS FROM OPERATIONS—LARYNGOFISSURES AND LARYNGECTOMIES

Duration of Life Following Operation	Type of Operation	Results
15½ years	Laryngofissure with Ra.	L & W

1 year 4 months	Hemilaryngectomy with Ra pack	Died of recur
1 year 2 months	Hemilaryngectomy with x ray	Died Ca uterus.
7 months	Hemilaryngectomy with Ra pack	Died of recur
6 months	Hemilaryngectomy Diath and Ra. pack	Died of recur
6 months	Laryngectomy	Died of extension into trachea
3 months		Died of pneumonia
1 week	Laryngofissure	Died of pulmonary abscess following operation Op death

Partial Operation with Irradiation—There were twenty-one patients in this series and for various reasons a major operation was not carried out. In some of these a more radical operation was either contraindicated because of the location and extent of the lesion or the patient declined operation. The prognosis in many of these patients was bad to start with and no hope of cure could be expected. Palliative relief was the most one could expect and this was obtained in many cases.

The procedure was to remove as much of the growth as possible sometimes with the aid of diathermy and the implantation of radium seeds into the remainder of the growth or the region from which the growth was removed. There were five patients in this group who survived over three years as follows seven years nine months, six and one-half years, four years three months and two patients three and one-half years. One of these case 24 had a bilateral Harmer operation plus seed insertions. The first two cases are of interest because of the comparatively long duration of survival and they are therefore, described more in detail

rect laryngoscopy. Five seed 10 mc each were inserted into base of growth at intervals of about 5 mm.

October 22 1930—Patient died at the Pondville Hospital. At autopsy there was a recurrence of the tumor in the larynx with regional metastases. The pathologists report (Path. No 30-2092) showed epidermoid cancer Gr I.

This patient also had carcinoma of the stomach but this was not the same tumor that was in the larynx and therefore not metastatic from the original lesion.

The patient who survived six and one-half years (case No 55) was also a male aged sixty five, who had complained of hoarseness of six or seven years before coming to the hospital. His lesion involved the right vocal cord. The biopsy report was carcinoma. This also began as a papilloma. A tracheotomy was performed followed by partial removal of the growth and radium seed insertion.

The remaining patients in this group although they survived less than three years nevertheless were considerably relieved from their suffering. Here too were patients who very likely would have fared much better with a more

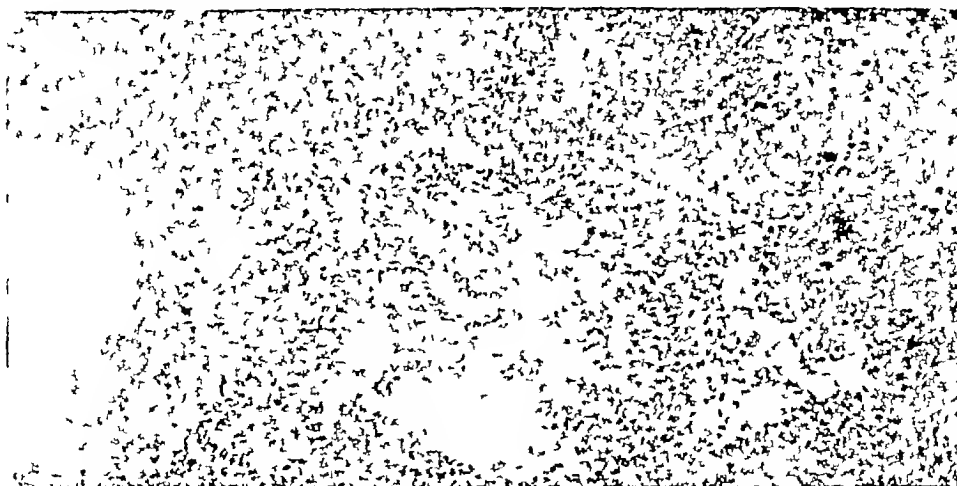

FIG II This is a photomicrograph of pathological section Case No 60 described above It shows a papilloma with typical multiple areas of malignant transformation

radical procedure, particularly in the cordal type of lesion

The following table shows the results of treatment in this series

means of the radium externally or with radium emanation seeds

The results obtained in the past by radium treatment alone are not particularly encouraging

RESULTS OF PARTIAL OPERATION WITH IRRADIATION

Site of Lesion	Type of Operation	Duration Following Operation
1 Rt V cord and band	Intralaryngeal remov, seeds implanted	7 years, 9 months
2 Rt V cord	Intralaryng remov, seeds implanted Trach	6½ years
3 Aryepiglot fold	Partial Op 4 years later, seed implant	4 years, 3 months
4 Vocal cords	Trach Part Op Ra Re Op	3½ years
5 Vocal cords	Bilateral Harmer and Ra	3½ years
6 Lt Int Larynx	Part Op Ra	2 years, 3 months
7 Vocal cord	Part Op X-ray seeds	2 years, 3 months
8 Epiglottis	Trach Part Op removal of Epigl with Diath	1 year, 6 months
9 Epiglottis	Diath Seeds Ra bomb 4000 mc hours	1 year, 6 months
10 Vocal cord	Trach Part Op Ra Pack	1 year, 4 months

12 Aryepiglot fold P; Sin	Part removal, seeds implanted	1 year, 3 months
13 ———	Part. Op Ra and X-Ray	1 year, 2 months
14 Epiglottis	Part Op seeds Trach	1 year
15 Aryepiglot	Excision with Diath, seeds	11 months
16 Rt Voc cord arytenoid	Trach Part Op Ra	8 months
17 Ary ep fold	Part Op seeds	7 months
18 Ary ep fold	Part Op seeds	5 months
19 Epiglottis	Part removal seeds X ray	3 months
20 ———	Part Laryngectomy, Ra Pack	?
21 Vocal cords	Excision by Ext	4 days foll operation Died of hemorrhage Operative death

There was one operative death in this group This was in a patient who was found to have an extensive lesion involving both cords and originating in what appeared to be a thyroglossal duct carcinoma. He died of hemorrhage four days following a laryngotomy and radium pack

Treatment with Radium Alone—There were thirty-four patients, most of whom (twenty-six) were of the extrinsic type Many of these had metastatic glands at the time of admission The remaining seven were of the intrinsic variety, and an operative procedure would no doubt have given better results, but for some special reason, radiation therapy was carried out The patients in the earlier years were treated by

ing It is striking to note that the intrinsic type in this series fared no better, and in many cases not so well as the extrinsic This poor result may be accounted for by several factors (1) radioresistance of the tumor cells, (2) the patients may have been debilitated or alcoholic and such patients rarely show a good resistance to cancers or respond well to treatment, (3) inadequate dosage or improper distribution of

radiation (4) It has been observed that, occasionally, growths may be stimulated to greater activity when the dose employed is too small.

The center of the growth may disappear but the periphery having received insufficient dosage continues to proliferate. The best results in this series were obtained with the first irradiation treatment, when it was adequate. Subsequent treatments were not so effective especially if applied too soon after the primary treatment, because it is known that previous treatments often make a cancer radioresistant. If the irradiation treatment is intensive fear of radionecrosis is great, especially so in the larynx since the cartilages are particularly vulnerable to this complication. Delayed burns have occurred years after treatment (eight years—Chevalier Jackson). Harmer believes it is due "to progressive endarteritis obliterans following irradiation in excess of local tolerance of the tissues." This type occurs more commonly in the larynx than elsewhere.

The best result was obtained in case No 162 in spite of the fact that the lesion was an extensive one involving the epiglottis, the aryepiglottic fold and the pyriform sinus and the tumor was a Grade II, which is not particularly radioresistant. The patient was relieved for three years. This may be explained on the basis of the relatively high dosage the patient received.

There were five patients each of whom survived one year and four months following treatment. The remaining patients were relieved approximately six months on the average. A tracheotomy was performed in nineteen patients in most cases preliminary to radiation. In a few cases, it became urgent during or immediately following treatment. There was one death which occurred on the third day following the insertion of seeds.

Results of Treatment with Radium and X Ray—There were forty patients in this series, some were of the intrinsic but the greater number were of the extrinsic type. The results obtained here by the combined treatment show a decided improvement over the results of either radium or x ray therapy alone. There were twelve patients in this group who were relieved and survived over one year.

The best result here was in Case 64 (II II 22 1365) in a patient who lived five and one half years following the treatment by irradiation. Unfortunately this was a clinical diagnosis as no specimen was removed but I don't believe that there is any doubt as to this being anything but malignant. This was in a male, aged sixty-six who presented himself at the hospital with the complaint of a "lump in the throat, and hoarseness." The patient further stated that three years ago he noticed a swelling in the left side of his neck which gave no symptoms except hypersensitiveness when tak-

ing hot foods. Prior to coming to the hospital, the patient consulted Dr Abbott in Providence who referred the patient to Dr D C Greene who later referred him to our hospital.

Examination—Upon the laryngoscopic examination under ether anesthesia, the growth was found to involve the left lateral margin of the epiglottis, the aryepiglottic fold, the arytenoid and the false cord.

Treatment—5—15 millicurie seeds were inserted in different portions of the growth less than 1 cm apart. The patient showed signs of dyspnea and became cyanotic whereupon it became necessary to do a tracheotomy. This was carried out while the patient was still under ether anesthesia. His operation was done on November 8, 1922. In January, 1923 the patient received Roentgen treatment by Dr Morrison.

The patient remained well and was followed in our clinic until 1928 and on June 10, 1928 a letter was received from the Town Clerk stating that the patient died of carcinoma of the esophagus.

A good result was obtained in Case No 188. This was a male, aged fifty-six, with a Grade I lesion in the right pyriform sinus. Ten seeds of 1 mc each were inserted throughout the growth followed by 5100 r units of Roentgen therapy. This patient has been living and well for three years.

Another (Case 96) survived two years, ten months.

Not unlike the previous group, most of these patients required tracheotomy prior to treatment.

There was one death in this series. This occurred in a male patient of seventy-seven who had seed implantation followed by Roentgen therapy. After the treatment the patient began to have signs of dyspnea, an emergency tracheotomy was performed and he died several days following operation.

Roentgen Therapy Only—The patients in this group were the most unfortunate in that the disease had already extended widely and in practically all cases metastases were present.

There were thirty-seven patients in this group of which sixteen required a tracheotomy on admission. Three patients had gland dissections in addition to Roentgen therapy. One received surgical diathermy to the lesion in addition to x ray. One patient had a positive Wassermann and in addition Roentgen therapy was treated with potassium iodide. This patient survived three months dying from hemorrhage due to cancer of the rectum. There were only four patients in this group who survived one year or over. The best result was in the patient (Case No 184) who lived one year, eleven months following treatment, having received

6000 r units probably one of the largest dosage to date. The average duration of life following treatment in the remaining cases was six months.

No Treatment—There were nineteen patients who received no treatment. In twelve of these the duration of life following the first visit is not known. Three of this group lived over one year. One patient, Case No 102, was a man, aged seventy-two, who had an early lesion on the right vocal cord which was still mobile. He refused treatment and survived five and one-half years, finally dying from involvement of the esophagus. This illustrates an early intrinsic type of carcinoma of the larynx, its slow growth and finally the extension of the growth to involve the esophagus. The average life in the remaining cases was five months.

Complications—With the exception of cervical metastases, the most frequent complication was involvement of the esophagus. This was present and recorded in seventeen patients of whom thirteen were in males and four in females. The ratio of postcricoid involvement in females is much greater than it is in males and for this reason, the incidence of esophagus complication in females is much higher. Death from hemorrhage occurred in four patients. Pneumonia accounted for two deaths following operation. Mediastinal abscess and abscess of the throat, one each. In two patients, carcinoma of the stomach is recorded as the cause of death, one four years and one six and one-half years following treatment for cancer of the larynx. One patient died of carcinoma of the uterus one year and two months following treatment of the larynx.

I wish to express my sincere gratitude to Dr Edwards W Herman, the chief of the Laryngological Staff, and Dr Shields Warren for their many helpful suggestions in the preparation of this paper.

SUMMARY AND CONCLUSIONS

- 1—This series embraces 202 cases, 81 intrinsic and 101 extrinsic cases of cancer of the larynx. In 20 cases, the site was not stated.
- 2—We recognize leukoplakia as a precancerous lesion, and that papilloma not infrequently undergoes malignant transformation.
- 3—The relative infrequency of laryngeal cancer in females compared to males.
- 4—The fifth decade of life shows the greatest incidence of cases.
- 5—The triviality of the symptoms in proportion to the seriousness of the disease.
- 6—The relatively slow course of intrinsic carcinoma and the relatively low-grade malignancy offers ample time for thorough surgical treatment with a good prognosis.

- 7—The early diagnosis offers a patient his best chance of cure.
- 8—It is our opinion that surgical removal of the growth in the early operative intrinsic type offers a good chance of permanent cure.
- 9—In certain types of not entirely operable tumors, which are highly radiosensitive, the combination of surgery and irradiation have produced good results.
- 10—In the far-advanced cases of metastases, we rely entirely on irradiation for temporary relief.
- 11—We feel that the treatment by irradiation, up until very recently, has been inadequate, and our entire conception of this method of treatment is being revised.
- 12—Out of a total of nineteen operative cases of proved cancer, seven are living and well, the longest duration fifteen and one-half years, the shortest three years, to date of publication.
- 13—If it can be shown that radiotherapy can produce as high a percentage of permanent cures as surgery, it will be a safer method of treatment and will be welcomed by the surgeon and a blessing to the patient.

GIANT DIVERTICULA OR REDUPLICATIONS OF THE INTESTINAL TRACT*

Report of Three Cases

BY HENRY W HUDSON, JR., M.D.†

CONGENITAL cysts and diverticula (other than Meckel's) and partial reduplications of the intestinal tract are unusual congenital anomalies. They may be of clinical importance because of the symptoms produced and the possibility of surgical relief. We have found eight such reduplications or giant diverticula reported to which we may add three.

CASE 1

A. C. S., No 153126, a male infant of three months was admitted to the surgical service of the Boston Children's Hospital on September 16 1931. The family and birth histories were not important. He had developed normally and been well until one week before admission when he developed a greenish watery diarrhea. For three days he had from five to seven defecations. The stools then decreased in number and size and for the five days preceding admission had been soft and black in color. He had vomited once three hours before admission the vomitus consisting of part of a recent feeding. He had not appeared ill until twelve hours before admission when he developed periods of pallor during which he appeared to have abdominal pain cried and drew his legs upward toward the abdomen. There had been no medication. There was no history of pica or of purpura. The physical examination was normal except for pallor and the local abdominal examination. There was slight generalized abdominal muscle spasm with tenderness more marked on the right. An ill-defined mass was felt just above and to the right of the umbilicus.

Intussusception was considered a probable diagnosis. Hemochs purpura was also considered. Bleeding and clotting times were normal.

Abdominal exploration was made soon after admission.

First operation September 16 under ether anesthesia a right rectus musculo splitting incision was

made. There was no free fluid within the peritoneal cavity. A search for an intussusception or evidence of reduced intussusception revealed neither. Throughout the base of the mesentery of the small intestine were numerous petechial hemorrhages and there was enlargement of the mesenteric lymph nodes. About eighteen inches above the ileocecal valve and within the leaves of the mesentery of the ileum a walnut sized mass was encountered. In this mass, and adjacent to the ileum a small perforation about 2 mm. in diameter was noted. Through this perforation clotted blood was extruded. The perforation was incised thus exposing the inner men of the mass which presented a mucosa similar to that of the ileum but it did not appear to communicate with the ileum. It was filled with blood clot which was removed. There was one small bleeding point which was easily controlled. The infant's condition was unsatisfactory and it appeared unwise to remove tissue for examination. The cystic mass was sutured and the abdominal wall closed in layers. The infant was returned to bed in fair condition with diagnosis undetermined.

COURSE The infant was transfused and parenteral fluids were administered with improvement. For six days after operation there was a decreasing amount of blood in the stools. He was afebrile. The wound healed well and he was discharged October 3 1931 in apparently good condition.

Laboratory data Urine negative at five examinations except for acetoneuria at the time of admission. Red blood cells 2 900 000 and hemoglobin 45 per cent on admission 1 400 000 and 63 per cent on September 22. White blood cells 11 400 and 8 200 with normal differential. Bleeding and clotting time normal. Platelets 250 000. Stools guaiac positive from September 18 to 28 and guaiac negative on October 1 and 2.

Interval note The infant did very well gained four pounds apparently had no pain and his color improved. There were one or two stools daily apparently normal.

Second admission December 31 1931 at six months of age. Thirty six hours before admission he had a greenish watery stool. Twenty-four hours before admission and the day of admission there were similar stools. He was admitted for observation.

From the Surgical Service of the Children's Hospital.
From the practice of the author.
Hudson, Henry W. Jr.—A. C. S. as Surgeon, Children's Hospital. For record and address of author see This Week's Issue page 1117.

Except for the healed abdominal scar, the physical examination was normal. The stools were found to contain blood. He was observed from December 31 to January 6, 1932 during which all stools contained blood and his red blood cells fell from 4,500,000 to 2,790,000. He was transfused on January 5.

Second operation January 6, 1932 under ether anesthesia. An incision was made over the right rectus muscle parallel to the previous operative wound and the muscle belly was retracted laterally. The peritoneum was incised and a mobile cecum with primitive mesentery presented. The ileocecal valve was identified and the ileum inspected. The mesentery was of the primitive type. About two feet above the ileocecal valve a diverticulum running in the leaves of the mesentery was identified. The mesentery was split and the diverticulum found to be about the caliber of the ileum for perhaps two inches, then to constrict to a cordlike structure which disappeared in the root of the mesentery. This diverticulum was resected from the root of the mesentery up to the reflection of the mesentery over the ileum and it was then noted that the diverticulum curved to run distally, parallel to the ileum and within the leaves of the mesentery, toward the ileocecal valve for about sixteen inches. No point of communication with the ileum was demonstrated. The operation had occupied nearly an hour and to complete the resection would have extended the procedure unduly and would have required partial resection of the ileum as well. For this reason the diverticulum was closed. The wound was closed in layers without drainage and the infant returned to bed in good condition but with the expectation that at some future time the remainder of the diverticulum would be excised, possibly with resection of the ileum.

Histologic report S326 GROSS DESCRIPTION. The specimen has the appearance of a part of the intestinal tract. It is definitely in four sections. The whole length is 95 cm. Part A is 1 cm in length and was described at operation as being lost in the root of the mesentery. This has the appearance of a cord about 4 mm in thickness. On cutting it open it is found to contain a small lumen and in the resection this lumen has been cut across. Adjacent to this is Part B which measures 2 cm x 2 cm when opened. Part C is 15 cm in length and 3 cm in width when opened. It has a similar appearance to Part A except that it is a little more hemorrhagic. The fourth section, Part D being the largest, is 5 cm in length and when opened out is 2 to 2.5 cm in width. The lumen which is patent throughout the specimen is lined with a mucous membrane. The mucosa of the largest section is folded in fairly normal looking rugae which run across the specimen for the distal 15 cm and in folds generally along the length of the specimen for the next 25 cm. At approximately the junctions of these two portions distinguished by the configuration of the rugae, there is a small punched out ulcer with raised and undermined borders 2 mm in width, the base of which is quite hemorrhagic. The serosal surface outside this ulcer is definitely thickened. The mucosa of Part B is paler and the rugae are arranged in less definite folds of a more or less circular configuration. When opened at operation, there was no fecal material seen within the lumen.

MICROSCOPIC There are six sections taken for microscopic study. These sections are taken as indicated in the diagram No 1 from Part A, No 2 and No 3 from Part B, No 4 from Part C, No 5 through the ulcer, and No 6 through Part D.

Section No 1. This section is cut across the unopened lumen of Part A. The mucosa is in a gen-

eral way characteristic of the small intestine. It is thrown up into numerous villi and lined with a simple columnar epithelium. There are a moderate number of goblet cells which give evidence of mucous secretion. The muscularis is composed mostly of circular muscle fibers with only a few longitudinal bundles. There is no evidence of inflammation or hemorrhage in this section.

Section No 2 is cut across the point where the small lumen of Part A opens into the larger second portion. At this point there is a transition from the mucosa described above to a mucosa resembling gastric mucosa. This is characterized by the appearance of rather typical gastric glands. The mucosa is thrown into numerous folds. Scattered through the tunica propria are abundant eosinophiles. The submucosa and muscularis are not unusual. A second section (No 3) farther along in this portion shows the same type of mucosa. In addition there are a few small, highly cellular lymph follicles.

A section (No 4) through the thin connecting portion (Part C) shows a reversion to the type of mucosa found in Part A. The mucosa here is thinned out and less well preserved.

The large portion (Part D) shows again a fairly typical gastric mucosa similar to Part B. Here again there is abundant eosinophilic infiltration such as is frequently found in adult gastric mucosa. There is a greater number of lymph follicles here than are seen in the previous sections, and the propria is somewhat more dense and cellular, containing a larger number of lymphocytes. One section transects the ulcer which was described grossly. The ulceration has entirely destroyed the mucosa and extends through the submucosa involving part of the muscularis. There is a dense fibroblastic reaction at the base of the ulcer and a serosal proliferation of fibroblasts. Numerous pyknotic nuclei and polymorphonuclear leucocytes are scattered through the regions just below the base of the ulcer. There is considerable hemorrhage into the underlying serosa. No blood vessels can be seen to be eroded by the ulcer. One neighboring vessel is partially occluded by an organizing thrombus.

SUMMARY This specimen consists of an anomalous diverticulum which shows a transition in the type of its mucosa from that of the small intestine to that of the stomach. The latter contains a small ulcer.

Course Blood transfusion was performed immediately after operation. There was a postoperative rise in temperature to 103.4° which subsided within thirty-six hours and thereafter remained normal. His condition was good at the time of discharge on January 19.

Laboratory data Urine normal at the examinations. Red blood cells 4,650,000 on admission, hemoglobin 70 per cent, on January 4, 2,790,000 and 46 per cent, on January 6 (after transfusion) 5,750,000 and 70 per cent. Stools guaiac positive from January 1 to January 13 and guaiac negative on January 16, 18 and 19.

Interval history The infant did well, gained in weight and there was no melena. On March 23, 1932 he developed a respiratory infection. He was readmitted March 27, 1932 and discharged March 30, 1932 to the Infants' Hospital with bronchopneumonia. There he ran an uneventful course and was discharged relieved on April 12, 1932.

Interval note The infant was well, weight and development normal. His appetite was good, the bowels regular.

Fourth admission June 15, 1933 at two years of age. The day before admission he passed a black stool. He was admitted for observation. The physical examination was not noteworthy. He was observed until June 23. His stools always con-

tained blood. His red blood cells fell from 4 000 000 on admission to 3 750 000 and the hemoglobin from 60 per cent to 40 per cent. Marked achromia developed.

Third operation. June 22 1933 under avertin and ether anesthesia an incision was made between the two scars of earlier operation and developed through the rectus sheath. With some difficulty the mass was retracted. The peritoneum was opened without incident, except for the escape of an excess of clear fluid (culture negative). The terminal ileum and its reduplicated portion were demonstrated. It was evident that removal was possible only by resection of a part of the ileum. The ileum in its duplex segment was resected for about fifteen inches. Following resection and just as an anastomosis was begun the infant ceased breathing and became pulseless. The change was sudden and a minute or two earlier the anesthetist had reported a pulse rate of 132 and general condition satisfactory. Various methods of resuscitation were unsuccessful. There had been practically no bleeding and although the operation had occupied an hour and might be considered to have caused shock, there was no warning of this fatal accident. Whether or not there was embolism was a matter of conjecture.

Histologic report. S-33298 and S-33125 GROSS DESCRIPTION. The specimen consists of a portion of resected ileum measuring 33 cm. in length. It averages 3.2 to 3.6 cm. in width when fully flat. Within the mesenteric attachment throughout 35 cm. of its length there is a secondary portion of bowel which communicates with the main ileum by two small openings 3 mm. in diameter through which there may be expressed small amounts of clear mucinous fluid containing white flocculent material. The mucosa of the ileum contains occasional petechial hemorrhages and localized areas of congestion. The mucosa is in general pinkish yellow to pinkish brown in color and possesses a slightly edematous pale gray mucosa with circular rugae. In the proximal end of the blind pouch there is a black silk suture put in at the time of the previous operation. At the distal end of the blind segment there is an ulcerated area 1.8 x 1 cm. in its various diameters. Within the mid portion of the blind segment there is a rather sharply demarcated segment of mucosa 3 cm. in length in the center of which are two small punched-out ulcerated areas 4 mm. in diameter one of which communicates with the ileum. Throughout the remainder of the mucosa of the blind segment there are occasional petechial hemorrhages.

MICROSCOPIC. Seven sections including four of the diverticulum two of the ileum and one of the communication between the two structures show a diverticulum with gastric mucosa showing chronic ulceration and slight acute ulceration. The ulceration occurs at the communication between the ileum and the diverticulum. At this site the mucosa of the diverticulum is ulcerated and the mucosa infiltrated by lymphocytes and eosinophiles. There is slight secondary lymphoid nodule formation. There is one small area of acute ulceration right at the junction between the two structures resulting in intense polymorphonuclear leucocytic infiltration of the submucosal stroma. The other four sections of the diverticulum show intact gastric mucosa. This is composed of typical large mucous crypts at the base of which are numerous small typical gastric glands containing acid and chief cells. The mucosal stroma is somewhat edematous and lightly infiltrated by eosinophiles. There are a few areas of lymphocytic infiltration around the base of the gland. The two sections of ileum are essentially

negative with typical ileal mucosa, the stroma of which contains moderately hyperplastic lymphoid tissue with a few secondary lymphoid nodules

CASE 2

L A No 168771 a white female infant of six months was admitted to the surgical service of the Boston Children's Hospital on February 15, 1933. The family, birth, and developmental histories were not unusual. Two months before admission she was ill with cough and fever and a diagnosis of bronchitis was made. She grew irritable and slept poorly. Two weeks before admission she began to vomit occasionally between feedings. The abdomen enlarged and vomiting increased. There was loss of weight. The stools became infrequent and enemata were administered with good returns. No blood was recognized in the stool except for one "speck" two days before admission. The stools were green and contained mucus. Several days before admission the vomitus was bile stained. There was intermittent fever for several days preceding admission.

Examination on admission revealed a well developed and fairly well-nourished infant appearing chronically ill. The rectal temperature was 99°. The general examination was essentially negative. Local examination. The abdomen was markedly distended and splinted. A firm nontender mass occupied the right lower quadrant. This mass was palpable through the rectum.

Laboratory data. Two examinations of the urine were not abnormal. Red blood cells 5,050,000. Hemoglobin 80 per cent. White blood cells 12,000. Differential normal for age. Wassermann and Hinton negative. Tuberculin 1:1000 negative. Nonprotein nitrogen 14 mg per cent. Phenolsulphonphthalein excretion 60 per cent in two hours and ten minutes.

X-ray examinations. February 15, 1933. "The lung fields are essentially clear. A film of the abdomen shows considerable distention which is due not so much to gas in the intestines as to fluid in the peritoneal cavity. There is also some free air under the liver in the right upper portion, evidently the result of a ruptured viscus." February 16. "Re-examination of the abdomen. There is more distention due to the peritoneal fluid. I can no longer make out definite free air."

Operation. February 16, 1933. Ether anesthesia. By means of a right rectus muscle-splitting incision the peritoneal cavity was exposed and found to contain a large amount of bloody fluid. A large mass presented in the right lower quadrant. When delivered it appeared to consist of over a foot of greatly distended small intestine with markedly enlarged lymph nodes in its mesentery. There were also within the mesentery several cysts which apparently did not communicate with the intestine. Both the intestine and cysts were deep purple in color and in several areas there was a yellow fibrinous exudate. A resection of the affected intestine and mesentery was made and a "double-barreled" enterostomy performed. The infant was returned to bed in poor condition.

Course. The infant's condition was poor for the first three days after operation. Parenteral fluids were administered and by February 20 her condition had improved. There had been great fluid loss through the proximal stoma of the enterostomy. On February 21 a clamp was applied opposing the proximal and distal loops (Mikulicz procedure). One week after operation the wound edges separated allowing eventration of a part of the small intestine. The wound was resutured and at this time

there was evidence of peritonitis. Twelve hours later the infant died.

An autopsy was performed. A33 39. The anatomic diagnoses were

Jejunum duplex
Enterostomy
Peritonitis, organizing
Bronchopneumonia.
Splinitis and perisplinitis
Esophagitis
Lymphadenitis, mesenteric and mediastinal.
Decubitus ulcer, occipital
Extracortical adenoma of adrenal glands
Persistence of "Jackson's veil" and of anterior mesentery

The resected specimen is described. **GROSS DESCRIPTION.** The specimen consists of a segment of jejunum and a portion of its attached mesentery opened in the operating room. The segment of bowel measures 45 cm in length and the mesentery varies from 2 to 5 cm in width. The serosa is extremely congested, slightly dulled and shows irregular areas of ecchymosis. The mucosal surface of the jejunum is of normal pinkish to brownish gray in color, soft and shows the usual prominent plicae circulares. At approximately 15 cm from one end there is an irregular depression in the mucosal surface which is rather smooth and measures 2 x 1.3 cm. Lying within the leaves of the mesentery is an extremely thick-walled cystic mass of irregular form but shaped much like a pancreas in that there is dilated portion at one end 6 cm in diameter tapering off at the other end to an average diameter of 2.5 cm. The whole structure is 22 cm in length possessing a thick double muscular wall varying from 7 to 8 mm. The lining is generally smooth and shiny although extremely hemorrhagic in some areas and varies from pale yellowish gray to pinkish gray. The most hemorrhagic portion of the lining is associated with the large dilated end. At the opposite (tapered) end there are two constricted areas 1.5 cm in length, the lumen of which is 3 mm in diameter. Between them there are two dilatations of this elongated cystic structure measuring 1 cm in diameter. In the mid portion 8.5 cm from one end near the portion of the structure adherent to the jejunum there is an irregular mucosal ulceration, the serosa and wall over which is less than 1 mm in thickness. There is no perforation in this region. The serosa overlying the entire specimen is extremely congested and in places there are small accumulations of yellowish brown, fibrinopurulent exudate. Another area of acute ulceration exists within the large, dilated portion 1 cm in diameter, the serosa over which is dulled, congested and brownish gray. The wall at this point is approximately 1 mm thick but there is no perforation.

MICROSCOPIC. Seven sections show a chronic ulceration and gastric mucosa in the wall of a diverticulum. The mucosa of the typical gastric type showing large open crypts at the bases of which there are branching gastric glands containing acid and chief cells. The stroma is markedly congested and hemorrhagic especially between the openings of the crypts. There are variable numbers of infiltrating polymorphonuclear leucocytes throughout. Two areas of chronic ulceration are devoid of mucosa. The surface contains a small amount of fibrinous exudate, while the underlying wall is markedly fibrosed and infiltrated with variable numbers of mononuclear phagocytes, polymorphonuclear leucocytes and lymphocytes. A portion of the wall taken from the extreme tip shows a mucosa somewhat different from the rest, in that

there were no active secreting cells. The crypts and glands are of mucous type although the general form and arrangement of the gland is similar to that seen in gastric portion. The submucosa in the non-ulcerated portion shows mild congestion, but beneath the ulcerated portions it is more or less scarred. The muscularis is of two layers with areas of diagonally running smooth muscle fibers in addition. The serosa is edematous congested and infiltrated by a variable number of lymphocytes polymorphonuclear leucocytes and mononuclears. There is no evidence of fibrinopurulent exudate upon the serosal surface. Several lymph glands included within the loose edematous serosa and from the mesentery show a mild hyperplasia with occasional infiltrating mononuclear phagocytes in the follicles. The medullary cords of the nodes are densely packed with small mature lymphocytes.

DIAGNOSIS Jejunum duplex type with gastric mucosa showing acute and chronic ulceration.

NOTE There is no communication between the jejunum and the diverticulum. Sections through the dilated areas where the two structures are adjacent show a double muscular wall with a slight amount of intervening fibrous tissue.

CASE 3

D. M. a white female of twelve years was admitted to the Peterborough Hospital at 3:30 A.M. March 2, 1935. The family and birth histories were not unusual. From infancy she had failed to gain normally, was undernourished and was considered "sickly." As an infant she cried for hours at a time apparently from abdominal distress. At two years she was said to have had "Bright's disease" characterized by hematuria for two months. From the age of three years she had frequent attacks of cramp-like abdominal pain referred to the umbilicus and lasting from a few minutes to several hours. These were usually accompanied by nausea and vomiting. During some attacks relief was obtained from a carminative and eructations occurred. During the attacks the child usually flexed her thighs on the abdomen or if seated would bend forward and place her head on her knees. She could not be

induced to change position until the attack was over. At times she would fall asleep in this position.

In November 1934 she was observed for a two-week period by the pediatric service of the Children's Hospital. During this time she had several attacks of pain which were not severe. A gastrointestinal series pyelography by the intravenous method and various examinations of the blood gave negative results and she was discharged undiagnosed. The attacks continued and during the two months preceding admission had become more frequent and severe. Hardly a day passed without some discomfort.

At 3 A.M. March 1, 1935, twenty-nine hours before admission she awakened from sound sleep with severe cramp-like abdominal pain located in the umbilical region. The paroxysms lasted two to three minutes, gradually diminished and the child would doze to be awakened in five to ten minutes by more pain. This cycle lasted from 3 A.M. to 4 P.M. and was accompanied by nausea and vomiting. The vomitus consisted of the fluids that she had taken eagerly. She was very thirsty. At 3 P.M. her physician administered 1/8 gr. of morphine and she rested comfortably without pain or vomiting for about five or six hours. She had passed flatus and there was a defecation of fecal material following an enema at 8 A.M. When the mother tried to rub the child's abdomen, she complained it was too tender to be touched.

During the twelve hours preceding admission there was pain of the character described. She vomited frequently until fluids were denied her several hours before admission. During the automobile ride to the hospital the pain became more steady and severe and the child cried continually with pain. She begged for water.

On admission examination disclosed a very pale, undernourished and underdeveloped child in great distress. The month temperature was 100.6, the pulse rate 160 and the respiratory rate 44. Her breathing was difficult, and irregular and she grunted frequently. She lay in bed with the knees flexed and her hands were held in the region of the umbilicus. She cried continuously and begged for water. The skin and mucous membranes were pale. She appeared dehydrated. The abdomen was moderately distended, there was voluntary generalized muscle spasm and diffuse tenderness. An indefinite tender mass occupied the entire hypogastrium. Two physicians considered her moribund.

The white blood cells were 20,000 with 74 per cent neutrophils, the red cells were 3,820,000. The hemoglobin was 54 (Sahli). The urine showed slightest possible trace of albumin, a trace of sugar and the sediment a few hyaline casts and a rare white blood cell.

By infusion 200 cc. of normal salt solution and 250 cc. of citrated blood were administered and 600 cc. of salt solution was introduced beneath the skin. One-twelfth gr. of morphine was administered at 8:30 A.M., 10:30 A.M. and 1 P.M. Her general appearance and color improved.

It was felt that intestinal obstruction, cause unknown, was the probable diagnosis and operation was elected.

Operation March 4, 1935 3 P.M. Peterborough Hospital.

With novocaine infiltration a right rectus incision with mesial retraction of the muscle belly was made. When the peritoneum was incised sanguinous fluid escaped in large amounts. Ether anesthesia was induced and the wound enlarged to about eight inches. The peritoneal cavity was filled with cold liquid blood and great masses of clotted blood. No fresh blood was apparent. The blood

clots were most numerous over the mesentery of the small intestine adjacent to the umbilicus. A mass which proved to be a volvulus of the terminal ileum was delivered. The volvulus involved about four feet of the lower ileum, and had rotated clockwise for about 80 degrees. The ileum was edematous but not greatly distended. Within the mesentery, parallel and intimately opposed to the mesenteric edge of the ileum, was a reduplication of the bowel for a distance of about four feet. Near its proximal end was a large perforation about one and a half inches in diameter from which a small amount of bright blood escaped. There was no evidence of intestinal contents escaping, nor was the peritoneum inflamed. Through the perforation a mucosa thrown into rugae was clearly visible and within the folds of mucous membrane a small ulcer was seen from which there was a steady ooze of fresh blood. The volvulus having been reduced there was no apparent obstruction. The child's condition was poor and it seemed unlikely that she could survive resection. Accordingly the bleeding area was cauterized and the ruptured area sutured. The intestine was returned to the abdomen and the abdominal wound closed. The child returned to bed in poor condition.

Course. Following operation, the child was white and even more colorless than before. Radial pulse could be obtained, but not counted. However, she improved gradually and nine hours later she was talking and seemed very comfortable. Her after-care consisted of Levine tube, morphine sulphate, gr 1/12 every three or four hours as necessary, sips of clear liquid by mouth, Fowler's position.

March 3, 1935 9 A.M. Patient had a reasonably good night, sleeping in naps. Complained of nausea once, but there was no vomiting. Temp 103.6° rectally, pulse 140/160. Very pale. Passing no gas per rectum. Abdomen shows moderate high distention for first time. Levine tube is clear. RBC 3,400,000, Sahli 42 per cent. WBC 5,850, Polys 59 per cent. Catheterized and four ounces of urine obtained which showed the slightest possible trace of sugar, few hyaline casts, few granular casts, rare red and white cells.

12 25 P.M. The patient has suddenly become very restless and very pale. Has severe air hunger and has pulled Levine tube from her nose. Given one ampule of adrenalin chloride and oxygen inhalations. She has quieted down and is resting comfortably.

1 30 P.M. Upper abdomen seems much more distended. Swathe loosened. Levine tube is clear. It is impossible to get a radial pulse and respirations are becoming labored.

2 45 P.M. Has vomited a small amount of dark brown fluid. Died a few minutes later.

DISCUSSION

The anatomic relations and the gross and microscopic structure of these three reduplications or giant diverticula place them in the category of developmental anomalies of the gastrointestinal tract. These are to be differentiated from the lymphatic or chylous cysts, urogenital cysts, and the dermoids and teratoids which occur within the peritoneal cavity.

The anomalies of gastrointestinal origin form a rather well-defined group (Ewing¹) characterized by a smooth musculature arranged in layers as in the tract proper. A well-defined mucosa is often demonstrable which may resemble closely the mucosa of any part of the nor-

mal tract. This mucosa is not infrequently altered or disrupted by inflammation, heterotopia, intracystic pressure and, perhaps, by digestion from the secretions produced. A well-defined submucosa is usually present. There is wide variation in size, form, histologic arrangement and in position with reference to the several segments of the digestive tract. Thus they occur at any part of the tract including the mediastinum. Their distribution in 102 cases is shown in table 1. They may communicate

with or be separated from the lumen of the digestive tube. At times they may be intimately attached to the wall of the intestine and present as cysts within its lumen, or within its wall in either submucous, intermuscular, or subserous positions. They occur between the leaves of the mesentery and in retroperitoneal positions. They may be single or multiple large or small and may or may not be associated with other congenital anomalies. There are six theories to explain their development.

(1) Atavism. Reversion to an earlier phylogenetic form based on the occurrence of bifid ceca in certain fowl and multiple diverticula in certain fish.

(2) Twinning in which case "the stimulation to reduplication, although acting at an early stage of cell division has affected a certain section only of the embryo" (Edwards²). This theory is applicable to the reduplications of segments of the intestinal tract but less clearly to the cysts and diverticula.

(3) Through the development of a median septum. The support for this belief is a specimen in the Museum of the Royal College of Surgeons of the small intestine of an ox. To one side of the intestine is a long tubular cyst of the same calibre as the intestine itself. There is no communication with the intestine and the mucosa of the cyst and intestine are dissimilar.

(4) Sequestration of a segment of the intestinal tube. For this theory evidence is adduced by the arrangement of a collected series of cysts (by Evans³) which shows successive steps in the hypothetical passage of a cyst from the

lumen of the intestine through its wall and into the mesentery. This presupposes a segment to be sequestered, however, and as Evans points out the most likely explanation is that of the epithelial buds described by Lewis and Thyng.¹

(5) Persistence and alterations of the vitelline duct or Meckel's diverticula in their several forms. The persistence of a normal fetal structure, the vitelline duct, accounts for many cysts and diverticula. However only those which occur in relation to the distal portion of the ileum may be so classified and the presence of multiple cysts or diverticula precludes such an explanation in certain cases as two diverticula of Meckel never occur in the same individual. In many reports any enterogenous cyst or diverticulum occurring in relation to the ileum, and particularly in the ileocecal region has been classified as Meckel's in type. This may be true or false and other interpretations are possible as some of these examples are similar to cysts and diverticula found in relation to jejunum, duodenum, stomach, or esophagus. Heterotopia of the lining mucous membrane is common in Meckel's diverticula (67 per cent Hudson²) but also in other anomalies. Heterotopia is also observed following the healing of an inflammatory lesion in the otherwise normal intestinal tract.

(6) The nodules of Lewis and Thyng.¹ These investigators found very regularly in pig, rabbit, and human embryos nodules of epithelial cells occurring along the course of the esophagus, stomach, and intestine which become vacuolated and may be separated from or be in continuity with the lumen of the intestinal tract. Normally these disappear or coalesce to form a part of the lumen of the digestive tube but they may persist. Evans³ has represented diagrammatically their translation from positions adjacent to the lumen, through the wall and into the mesentery. Evidence in support of this origin is found in Evans' collected cases some of which have an anatomic similarity to the embryologic structures pictured by Lewis and Thyng. Additional evidence for this belief is found in a consideration of those mediastinal cysts which are enteric in type since the nodules are present at a period of embryonal development consistent with their inclusion within the thorax. It is stated also (by Poncher and Miles⁴) that mediastinal cysts and abdominal cysts of enteric origin occur in the same individual but that no combination of mediastinal cyst and typical Meckel's diverticulum has been reported.

The evidence then, favors the belief that the nodules of Lewis and Thyng are the antecedents of those cysts and diverticula of enteric type which are not typical of those described by Meckel. This view is held by Evans,³ Drennen,⁵ and Poncher and Miles.⁴ Edwards⁶ favors the explanation by twinning for the giant diverticula and reduplications.

Anomalies of this type do not necessarily cause symptoms and in some instances have been incidental findings at the autopsy of an individual dead of an unrelated cause. Frequently they are responsible for serious symptoms and death of the individual. The symptoms produced by those located within the abdomen may be broadly grouped as, (a) intermittent abdominal distress or pain (as in No 2 and No 3 of our cases), (b) intestinal obstruction (as in No 2 and No 3), (c) hemorrhage into the intestinal tract or peritoneal cavity or both as in No 1 and No 3 and, (d) a palpable abdominal tumor as in No 2 and No 3. These symptoms are readily understood since obstruction partial or complete may be produced by encroachment of a cyst or diverticulum on the lumen of the intestine, and by the production of volvulus and of intussusception. These explanations are in accord with the observations made in the reported cases. Hemorrhage, which may be of serious degree as in No 1 and No 3 of our cases, is best explained by the formation of ulcers in the mucosa adjacent to heterotopic gastric mucosa. This is a relatively frequent occurrence in Meckel's diverticula (31 per cent Hudson²) and in a few instances the presence of a secretion chemically similar to gastric juice has been demonstrated.

A correct diagnosis previous to operation is nearly always impossible but it is a wise rule in infancy and childhood to consider a congenital anomaly as a possible cause of obstruction of melena or of a confusing clinical picture. Thus in sixty seven of the reported cases where the patient's age is stated there were fifty under twenty years of age. Thirty two were two years of age or younger. As might be anticipated the sex incidence is essentially equal, eighteen male and twenty two female in forty reported cases.

In the eighteen instances of reduplication or giant diverticulum which we have found in the literature only five were demonstrated at operation.

The anomaly in Fairland's⁷ patient was similar to that in our case No 2. He performed an enterostomy for imperforate anus. The infant died and autopsy revealed a diverticulum, thirteen inches long, which arose from the duodenum "about 1½ inches" below the pylorus.

Fitz⁸ described a specimen from the Warren Museum. It is from an infant about ten months old who had been under the care of Dr Joseph Stedman of Jamaica Plain who reported that the infant died with symptoms of intestinal obstruction. It would be presumptuous indeed to alter Fitz's description which accompanies illustration No 6. The specimen is similar to the anomalies found in our cases No 1 and No 3.

Garnott Wright¹⁰ demonstrated, at operation, a diverticulum thirty seven inches long commencing at the upper end of the sigmoid colon and running obliquely downward between the

leaves of the mesosigmoid loop and passing behind the posterior parietal peritoneum. The blood supply in Fitz's case (qv), Wright's case, and in our three were similar in that the vessels supplying the normal intestine were peripheral to or branches of those supplying the diverticulum or reduplication. Technical-

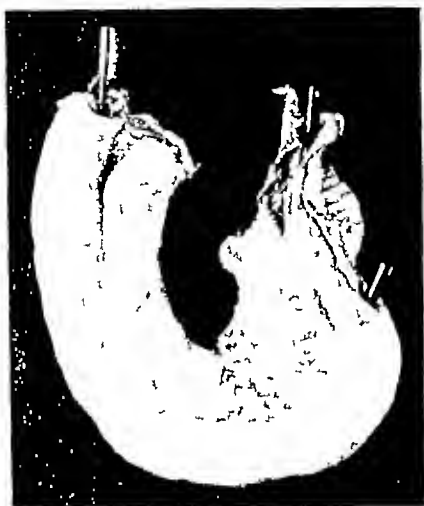

ILLUSTRATION NO 6

The specimen described by Fitz (From the Warren Museum)

Two more or less parallel intestinal tubes cut transversely across in their continuity are continued within a single mesentery. The blood vessels of the latter terminate in the wall of the outermost tube first supplying branches to the inner tube. The diameter of the outer tube is relatively uniform throughout while that of the inner in general somewhat narrower becomes dilated in the immediate vicinity of an opening through which the canals of the tubes communicate with each other. The contiguous portions of the walls of the two tubes are in close proximity to each other throughout the greater part of their course and are fused near the common opening.

The walls are composed of mucous muscular and peritoneal coats. The mucous membrane of the outer tube shows slightly projecting transverse folds in the vicinity of the opening while that of the inner tube is relatively smooth. Villi and crypts are present in both.

The opening between the tubes is rounded sharply defined one third of an inch in diameter and appears to be covered with mucous membrane. The canal of the inner tube is contracted in the immediate vicinity of the opening and its wall at this point is thickened and fibrous.

ILLUSTRATION NO 7

Warren Museum specimen 7732 transilluminated. Transillumination is suggested as a useful procedure during operation as the relations are difficult to demonstrate.

ly this is of importance as resection of the reduplication necessitates resection of the adjacent intestine whose blood supply is sacrificed by the resection of the reduplication. Drennen⁷ has stressed this point in connection with the ileocecal cysts not Meckel's in type.

A second important technical consideration is the requirement of meticulous palpation and inspection of the entire intestinal tract and its mesentery. It is difficult to demonstrate these anomalies at operation. The suggestion is made that transillumination of the mesentery will be helpful. In our case No 1 the anomaly was not recognized completely at the initial operation but was at the second. At this time the operator quite easily followed the intramesenteric course of the diverticulum but nearby spectators could see it indistinctly. In case No 2 the character of the anomaly was not recognized at operation but in No 3 it was recognized at once probably because of the operator's experience in case No 1. Wright¹⁰ recognized his case at operation. It was in relation with the colon.

Consideration of these three cases adds weight to the opinion expressed in connection with a study of experience with Meckel's diverticulum⁶, i.e., that infants and children presenting a long history of symptoms referable to the abdomen are entitled to and should receive a gentle but meticulously thorough exploration of the abdominal viscera when other diagnostic methods prove inconclusive. This is all the more true if melena is a symptom. There is every reason to believe that resection of such anomalies is feasible and will relieve symptoms if an opportunity is afforded to perform a deliberate laparotomy at a time when the patient is in good condition.

SUMMARY

Three additional instances of giant diverticulum or reduplication of a segment of the intestinal tract are reported.

The theories explaining the development of these anomalies are summarized.

The technical problems involved because of the blood supply and the difficulty of demonstrating the anomaly are discussed.

The three cases reported confirm our belief that exploratory laparotomy, at a time when the patient is in good condition, is indicated for those infants and children who present a long history of undiagnosed abdominal symptoms.

Since this paper was prepared, Dr D E Robert son of Toronto has operated on a similar case. I am indebted to him for permission to quote from his letter.

Yesterday I examined a girl, twelve years of age who has a large intestine which has two lumens I do not know where the two lumens begin at the central end but suspect they begin in the caecum They are separated throughout from the splenic flexure to the distal end at all events The one opens through a normal anus and functions normal ly the other opens with a minute opening in the vagina and this was the cause of an impaction of faeces which occurred in it and made a large mass which extended half way up the ascending colon I did an anastomosis just inside the anus between the two recta, and they each had a normal musculature and muscle coat I was very disappointed to find that this case did not have two appendices as it seemed to me to have two caeca."

DIABETES INSIPIDUS*

Treatment With Posterior Lobe Pituitary Powder Intranasally

BY ALEXANDER MARBLE M.D.

ALTHOUGH diabetes insipidus is an uncommon condition, the usual effectiveness of treatment with posterior lobe pituitary extract is universally recognized. Since Blomgart's studies, the convenient intranasal route of ad-

ministration has been widely used to supplant subcutaneous injections. Most clinicians, however, in using this method have employed liquid pituitary preparations either as a spray or on cotton pledgets inserted into the nose, pituitary jelly has also been used. It has not been generally appreciated that the intranasal insufflation of pituitary powder is equally if not more, convenient and effective and is far less expen-

From the George F. Baker Clinic, Elliott F. Joelin, M.D. Medical Director at the New England Deaconess Hospital, Boston.

Alfred Alexander—Physician, New England Deaconess Hospital, Boston. For record and address of author see "This Week Issue," page 1147.

sive than other forms of therapy. Recent reports on this subject have been made by Smith³ (whose paper stimulated us to use pituitary powder), by Canelo and Lasser⁴ and by Adlersberg⁵. The purpose of the present note is to record briefly our own experience.

Our series includes four cases. In three of these the condition is idiopathic in type, in the fourth a brain tumor (glioma of the optic chiasm) was demonstrated at operation in December, 1927.

CASE 1—Miss R S, was first seen on September 13, 1933 at the age of eight years. She had always been a nervous child. She had had no illnesses except pertussis at the age of five and an attack of tonsillitis in the spring of 1933. Polyuria and polydipsia had been noted since about August 1, 1933. Physical examination showed her to be pale and undernourished, the tonsils were moderately enlarged and scarred. Upon examination of the urine a specific gravity of 1.001 was noted, the tests for albumin, sugar, bile, and diacetic acid were negative. Examination of the blood showed slight anemia, the fasting blood sugar was 0.07 per cent, nonprotein nitrogen, 25 mgm per cent and plasma cholesterol, 197 mg per cent. Ophthalmoscopic examination and roentgenograms of the skull gave normal findings.

At the New England Deaconess Hospital in September 1933, the antidiuretic effectiveness of pituitary extract given subcutaneously was quickly demonstrated and treatment by the nasal route attempted. The liquid extract was introduced into the nostrils on small cotton pledgets, but in our patient this procedure caused considerable discomfort and irritation. Consequently administration by means of a nasal spray was used with good results. The parents were instructed to use at home the nasal spray supplemented by subcutaneous injections when nasal irritation or nose colds made the intranasal route unsatisfactory.

Treatment with posterior lobe powder was begun during a two-day hospital stay in February, 1935. Unfortunately the time was too short to permit desirable studies. During the first day no specific medication was given, during the second, approximately 200 mgm of pituitary powder was blown into the nose in four doses. Despite the short period of observation and despite a coryza with nasal discharge, the urinary volume during the second twenty-four hour period was kept down to 3090 cc. as compared with an output of 5310 cc. in the previous twenty-four hour period when no medication was given. The comparative results are shown in table 1.

TABLE 1
EFFECT OF POSTERIOR LOBE PITUITARY POWDER
INTRANASALLY

Case No 1, Miss R S		Urine Output cc	Specific Medication
1935	Fluid Intake cc		
February 1-2	4590	5310	None
2-3	3450	3090	Approximately 200 mgm Pituitary powder intranasally in 4 doses

Letters received from the parents since hospital discharge indicate that treatment by insufflation of powder has been much more convenient, though perhaps not quite so effective, than by subcutaneous injection. They find that the effectiveness is definitely reduced in the presence of a head cold with nasal discharge. During the two months from June 19 to August 20, 1935, the cost of treatment with pituitary powder has averaged less than five cents a day.

CASE 2—Mr D D, was sixteen years of age when he first came for treatment on January 5, 1934. Thirst and polyuria had been present since August, 1933; the onset of symptoms had apparently been gradual. On the advice of his home physician, pituitary extract had been taken with a good antidiuretic effect both subcutaneously and intranasally in the form of a spray. For three weeks, however, he had suffered so much from irritation of the nasal mucosa that he dreaded to use the pituitrin. Roentgenograms of the skull taken elsewhere on November 20, 1933 had shown a normal sella turcica. Blood and urine studies showed no abnormalities other than the low urinary concentration (specific gravity 1.004). Examination, including ophthalmoscopic study, showed him to be in good general physical condition.

The patient was not admitted to the hospital. He was advised to try a nasal jelly containing the pituitary principle and to use subcutaneous injections of liquid pituitary extract at such times as intranasal medication was uncomfortable.

When seen on November 2, 1934 he was found to be in good general physical condition. He had soon given up the nasal jelly since he could not secure satisfactory results with its use. He had come to rely chiefly on the intranasal spraying of posterior pituitary extract with at least five applications a day.

Following this visit we suggested that he try the intranasal insufflation of posterior lobe powder. On January 21, 1935 he wrote, "I started using the powder you had sent to me from the Deaconess Hospital Dec 1st and it lasted me until Jan 10th, taking it four times a day. I have found it much more effective than the liquid and would much rather use it. There were only two or three days out of this time that I did not use it as I had a very bad head cold and it did not seem to have any effect. There is certainly a great difference in the price between the powder and the liquid, which is fortunate for us."

Again on April 4, 1935 his mother wrote "The bottle of powder that we got from our local drug gist

lasted from January 10th to March 1st. Mornings it will last about three to four hours, afternoons from four to five hours. He takes about one sniff up each nostril four times a day, that is, mornings, noon, after supper and on going to bed. The powder seems much more effective than the liquid and, of course, there is a decided difference in the cost. For convenience there does not seem to be much difference."

A four gram bottle of powder then lasts this patient from forty to fifty days. Such a bottle is sold at retail from \$3.75 to \$4.00. Hence the medication in this form costs him less than ten cents a day as opposed to thirty-five to seventy cents a day using the liquid preparation as a spray or subcutaneously.

CASE 3—Mrs L H, forty-four years of age, was first seen on March 25, 1935. For twelve years she had suffered from excessive thirst and polyuria. Except for measles, mumps, and whooping cough in childhood and jaundice at the age of seventeen, she had had no noteworthy illnesses. She had five sons living and well. Eleven years before she had

been studied at the Massachusetts General Hospital where treatment with pituitary extract (intranasal spray) had been used with success. The patient had had difficulty in getting the drug in her home town, however so that for the most of the ten years she had received no medication nor had she sought medical advice. She stated that at times she had voided as much as four gallons of urine a day. Although now she awakened only once or twice a night to urinate in the past she had at times arisen as many as twelve times. She regularly was drinking two quarts of water during the night.

Physical examination showed her to be in good condition except for acne rosacea, slightly enlarged tonsils, hyperactive patellar reflexes and varicose veins of the lower legs. Studies of the blood and urine together with a roentgenogram of the skull gave essentially normal findings except for the large volume and low specific gravity of the urine. The basal metabolic rate was —3.

Following a control period during which no specific medication was given pituitary extract was administered by intranasal insufflation. The results are shown in table 2.

TABLE 2

EFFECT OF POSTERIOR LOBE PITUITARY POWDER
INTRANASALLY

Case No. 3 Mrs. L. H.			
Date	Fluid In	Urine	Remarks
1935	take	Volume	
March 26-27	3950	4380	No specific medication
27-28	4200	3630	"
28-29	3080	3660	"
29-30	3190	1230	Pituitary powder approximately 200 mgm intranasally in 4 doses
30-31	930	1080	

The patient was allowed to go home on a varied low-salt diet and instructed to use the pituitary powder as often as necessary to control her symptoms. On April 28, 1935 she wrote "I am getting along fine with three doses a day and one capsule (200 mgm.) will go three days. When I feel that I must have more I take it. I never have to get up nights and I feel better in every way."

Again on August 13, 1935 she wrote "I cannot begin to tell you how much more comfortable I have been this summer. Even the hottest days I did not care for as much water as others. I have not had to get up at night more than three times since I came home (a period of 4½ months). I only have to take the powder 8 times a day." She further stated that the first bottle of four grams lasted from April 1 to July 10 or one hundred days thus the actual cost was about four cents a day.

CASE 4—Miss H. E. L. was ten years of age when first seen on June 7, 1935. The diagnosis of diabetes insipidus had been made a year before in the Canal Zone because of extreme polydipsia and polyuria, with the urinary volume ranging between 3,500 and 5,500 cc per twenty-four hours and a urinary specific gravity as low as 1.001. Pituitary extract had been given subcutaneously.

In Boston in 1935 the findings were essentially the same. Ophthalmoscopic examination and roentgenograms of the skull gave no evidence of brain tumor. Was this diagnosis thought likely by neurological consultants. She was not seen again until November 1937 when she was brought back for

observation because of total blindness which was said to have come on in the course of a few days. Ophthalmoscopic examination then showed bilateral optic atrophy. She was transferred to the Peter Bent Brigham Hospital where on December 12, 1937 a right transfrontal exploration was carried out by Dr. Harvey Cushing and a biopsy of a tumor (glioma of the chiasm) performed. Following this four irradiations of the skull were given at intervals up to March, 1938.

The operation and x-ray treatments had relatively little immediate effect upon the polyuria and polydipsia. At the Peter Bent Brigham Hospital in December 1937 the urinary output on three successive days had been 4100, 8000 and 8300 cc. with fluid intakes of 6100, 4000 and 4800 cc. respectively. During a second stay in the hospital in March, 1938 the urinary output was 4200 and 5000 cc. on two successive days with fluid intakes of 5400 and 4200 cc. respectively. In late years however there has seemed to be some lessening of the severity of symptoms and except for the blindness she has been well. Physical examination has been essentially negative except as regards the eyes.

At periodic office visits made since December 1931 the specific gravity of the urine has varied from 1.002 to 1.005 and the volumes of a single specimen has been as great as 940, 1000 and 1,225 cc. Since December 1931 until recently the patient had not taken pituitary extract subcutaneously because the total blindness made self-medication difficult and because she had adjusted herself to the polydipsia and polyuria. She regularly got up two or three times a night to void large quantities of urine.

In April 1935 the use of pituitary powder intranasally was suggested. The patient has used it more or less regularly since, giving it to herself at bedtime (none during the day) by intranasal insufflation. At first she found the powder irritating to the nose and complained of a choking sensation after its use but this no longer bothers her. On August 12, 1935 her mother stated that with the single dose at bedtime the patient was able to sleep through the night (until 6 A.M.) comfortably without arising because of thirst or desire to void.

COMMENTS

Results with the intranasal use of posterior lobe powder in the above cases have obviously been highly satisfactory. In the first place, the mode of administration is much more convenient and less painful than the injection of pituitary extract subcutaneously. It is possibly less irritating than liquid pituitary extract applied on cotton pledgets and just as convenient as the administration of the liquid by intranasal spray. Secondly, there is a great saving in expense over other forms of treatment. The cost of pituitary powder averages from four to ten cents a day as compared with at least thirty-five to seventy cents a day for liquid pituitary extract (in preparations ordinarily available) given intranasally or subcutaneously.

One of our patients has tried with success the use of the powder as snuff as was also used by the patient of Canelo and Lasser. Case 2, Mr. D. D., takes a pinch of the powder between the thumb and forefinger, inserts it into one of the nostrils and by sniffing draws the powder into the upper part of the nose.

As aids in treatment it is helpful to advise

patients to limit the amount of salt in their diet, to avoid stimulants as tea and coffee and to restrict fluids after 6 or 8 P M in order to help insure a comfortable night. We have not used amidopyrine (pyramidon)

SUMMARY

In four cases of diabetes insipidus the intranasal insufflation of posterior lobe pituitary powder has been used with success. The convenience and lower cost of this mode of administration are emphasized.

A DEPLORABLE DEVELOPMENT IN THE ECONOMICS OF RADIATION THERAPY

BY FRANK EDWARD WHEATLEY, M D *

THIS paper was inspired by the rather insistent request of a physician that I treat a superficial growth on his patient's ear by deep therapy. As this was not the first indication I have had that there is a general misunderstanding in regard to the value of various types of x-radiation, I believe there is need for a general reconsideration of this subject. The reason for the confusion is easy to understand when we consider the recent developments in radiation technique. Up to about thirteen years ago, the radiologist's armamentarium consisted of radium, and x-rays produced by voltages below 140,000. Radiation therapy was an accepted method of treatment in a large number of pathological conditions, but our early hopes that radiation would prove a cure for internal malignancies were disappointed.

About that time rumors came from Germany that they had developed x-ray tubes and apparatus operating at 200,000 or more volts and consequently capable of delivering more penetrating x-rays. Soon our medical literature was flooded with dramatic case reports of patients apparently hopelessly infected with cancer who had been "cured" by massive doses of penetrating x-rays. American radiologists were not slow to follow this lead and American manufacturers developed the necessary apparatus. Medical literature was further enriched by sanguine statements of the men who were pioneers in this work. The magic term "Deep Therapy" was evolved and we had high hopes that science had at last discovered a most formidable weapon against the cancer scourge. Soon, however, reports from Germany indicated that many of the early cases treated by massive doses of deep therapy were dead, not from the disease but from the effects of the radiation. As time went on it was realized that while deep therapy was a decided advance in the treatment of internal cancer, it was capable of producing very serious consequences, so that gradually the practice of

applying massive doses was discarded and smaller doses were adopted.

Recently, following the method of Contard in the relatively successful treatment of laryngeal carcinoma, some radiologists are using a large number (20-40) of small doses of penetrating rays in the treatment of many other unrelated conditions. The total dosage given is much greater than heretofore thought safe. It may be that the method will prove to be an answer to the problem of the treatment of malignancy, but the returns are not in, and time will be the final arbiter. Meanwhile, the economic aspect of the method would tend to limit its use in all except the more desperate cases.

Laboratory and clinical experience have shown that the beneficial effect of radiation is due to that portion of the beam that is absorbed in the tissue under treatment, so that extreme penetration is probably of advantage only for the purpose of reaching a deep seated lesion. In addition, it is believed by most authorities that the therapeutic action of radiation is not a function of its wave length, so that there is no particular difference between the effect of deep therapy or short-wave x-rays, and that of x-rays produced at moderate voltages, provided only that the intensity of the ray in the tissue under treatment is the same.

At this point it may be well to explain that when we speak of deep therapy, we are speaking of x-rays produced by voltages of 200,000 or more and having a wave length of about 15 or less angstrom units, and when we speak of moderate voltage x-rays we are speaking of those produced by voltages up to 140,000 and having wave lengths of 23 to 30 angstrom units. These wave lengths are those that emerge from suitable filters. When we come to treat a patient with the short-wave therapy, a term which I will substitute for the term "deep therapy", we find that at depths of four inches the dosage, depending on the portal, may be about 35 per cent of that at the skin surface. In contrast to this is the fact that the dosage with moderate-wave length with the same por-

*Wheatley Frank Edward—Roentgenologist, Goddard Hospital, Brockton and Milton Hospital, Milton. For record and address of author see *This Week's Issue* page 1147

tal at four inches depth is approximately 20 to 25 per cent that at the skin surface. The significance of these facts is that with short wave therapy we get about 1/3, and with moderate wave therapy about 1/5 of our incident beam, to reach the depth of four inches. If the depth of the disease is less, the difference is less and with lesions in or near the skin great penetration is not desirable. By suitable cross firing we can accomplish practically the same result with either wave length but, of course the short wave therapy accomplishes the result more satisfactorily in the deeper lesions.

As a practical matter, however, a large percentage of lesions requiring radiation therapy do not call for intensive doses of penetrating rays, and can be handled equally well by moderate-wave therapy. As a proof of this statement, it is interesting to review the early literature of x ray therapy. Dr. F. H. Williams of Boston, in his book "The Roentgen Rays in Medicine and Surgery," 1901, reviews the current literature. Freund in 1897, two years after the discovery by Roentgen, treated hypertrichosis successfully with twenty hours (12 hours) exposure, producing no other skin reaction. The length of exposure shows the feeble ray available at that time. Schiff treated lupus successfully in the same year. Kummell in 1898 treated lupus with two treatments of fifteen minutes each per day for two months, when the lesions were healed. Williams in 1900 was enthusiastic about the use of x rays in eczema, scabies, favus, and acne. In 1901 he reported success in treating epidermoid cancer of the lip (biopsy done by Dr. Mallory) with submaxillary gland involvement, using in all about two hours exposure. He relates several other successful cases all of which were studied microscopically by Drs. Mallory, Wright, and Councilman. Dr. Mallory noted, in a biopsy made after treatment, that "the reaction on the part of the normal tissue was surprisingly slight" and Dr. Williams stated, "It would seem that the x rays have a selecting action." He sums up his experience in the use of x rays in external new growths as follows:

1. Treatment is adapted to external new growths which have not great depth though they may cover much surface.
2. The treatment causes no pain.
3. No delay because of operation.
4. Pain and odor are relieved.
5. Healing follows without causing burn.
6. Cosmetic results excellent.
7. Treatment carried on without patient giving up work.
8. Operation may be done on larger growths, followed by x rays.

He classified new growth cases coming to the Boston City Hospital for several years and found out of a total of 635, 318 were internal

while 317 were external and amenable to x ray. Certainly, if Williams in 1901 with the inadequate apparatus then available, was getting good results, and believed from his experience that about one half the cancer cases at the Boston City Hospital could be helped with x ray, it is certain that with even the poorest equipment we now have, we can do considerably better.

The literature up to the advent of short wave apparatus abounded with reports of successful treatment of all sorts of lesions with low or moderate voltage radiation. Modern literature, which is based upon experiences both with short wave therapy and moderate-wave therapy, has many references in which moderate wave therapy is preferred to short wave therapy, although some authors believe that short wave therapy is superior.

For example, Ledy of the Mayo Clinic, "One purpose of this paper is to validate the exclusion of high voltage in inoperable carcinoma of the breast." He advocates the use of 130,000 volts maximum in inoperable carcinoma of the breast where no deep metastases, or bone metastases exist. Lauritsen of the Institute of California, "It is reasonable then to conclude as Meyer does that there is no advantage and probably even harm in using hard (short wave) roentgen rays or radium rays for superficial and intermedially located lesions." Portmann, Cleveland Clinic, Cleveland, Ohio says, "Therefore, I am of the opinion that in the postoperative treatment of mammary carcinoma, the radiation should, as far as possible be limited to the chest wall by a low voltage technique (140,000 volts maximum). Dosage over the chest wall should be modified to prevent damage to the organs of the chest and the elements of the blood." Grier of Pittsburgh states, "I believe that the effect on cancer cells produced by Roentgen rays of different wave lengths (produced by different voltages) is not greatly different for the same dosage." Pfahler uses 130,000 volts maximum in treatment of cervical adenitis. Groover and Christie in a paper on roentgen treatment of hyperthyroidism use 140,000 maximum. Hirsch and Holzknecht advise the use of deep therapy only in internal carcinoma, glioma, inoperable sarcoma, medullary tumor, cerebral tumors, hypophyseal tumors, hypernephroma, and syringomyelia, on all other lesions amenable to radiation including carcinoma of the skin, they advocate voltages less than 150,000 maximum. Widmann, Philadelphia General Hospital discussing carcinoma of the lip states, "The effects of different qualities of radium and Roentgen rays have been observed to be equally good."

The apparatus necessary for the shorter wave length x ray is highly expensive, the maintenance cost is great, and the exposure time is often several times that used with moderate wave

length x-rays due to the heavy filtration necessary. All these factors add to the expense.

A limitation of all x-ray therapy is that resulting from radiation sickness, so that it is impossible to utilize full dosages without producing serious discomfort to the patient. In many institutions using short-wave therapy, divided doses are given, the maximum being twenty-five per cent of a full dose, partly to avoid radiation sickness. It is my observation that this untoward reaction to radiation is considerably more likely to occur when short-wave rays are used than when equal doses of moderate-wave rays are employed, especially when the treatment is directed to the abdomen. This complication results in the necessity of giving a series of small doses and when this is done the short-wave apparatus costs mount accordingly.

As an illustration of this point, I recently treated, with moderate-voltage, a patient for menorrhagia, completing in one dose a series given elsewhere by deep therapy. She had received six treatments at a cost she could ill afford, and was agreeably surprised to learn that the proportionate cost of moderate voltage therapy was considerably lower. In my experience, the average menorrhagia case can be handled equally well with moderate-wave therapy at an expense of about one-half that of deep therapy.

I do not wish this paper to be interpreted as antagonistic to short-wave therapy which has a distinct field, and is a great advance over previ-

ous radiation in certain limited conditions. I do, however, want to impress the fact that there is a misconception in the minds of many physicians who believe that short-wave therapy is superior to any other radiation in every case—a misunderstanding that results in the deplorable situation that an unnecessary economic burden is placed upon the unfortunate patient. I believe that in these days where the "high cost of medical care" is a public issue, the physician should not prescribe short-wave or "deep" therapy, but should refer his patient to the radiologist, and let him determine the type of treatment that should be given, taking into account, not only the pathological condition, but also all other factors which should influence the choice of the type of treatment to be given.

NEW ENGLAND SURGICAL SOCIETY

RECONSTRUCTION OF THE VAGINA FROM A PORTION OF THE SIGMOID*

Report of a Case

BY HERMAN C PITTS, M D †

MRS J C, twenty-nine years old, was sent to me September, 1930 by Dr Sullivan of Newport complaining that "water comes away all the time." Her story was that she had been delivered by forceps of a dead baby four years before while still living in the Cape de Verde Islands. Since then she had had another pregnancy terminated successfully by Caesarian section.

Examination showed a deep healed laceration of the tissues to the right of the urethra and involving the urethra to a considerable extent. The perineum was badly lacerated. The caliber of the vagina was small—would admit the little finger only as far as the cervix. This contraction was due to masses of scar tissue, evidently following trauma from forceps.

I felt that her incontinence could be helped by some plastic work on the urethra and that at the

same time the caliber of the vagina could be enlarged.

The operation was done October 7, 1930. The result on the urethra was excellent. The patient reported in May, 1931, that she had good control. The vagina, however, was not so satisfactory. Sexual intercourse was impossible. So on May 12, 1931 I tried again—this time turning in a flap from the side of the vulva on the right. The result, as before, was very disappointing. In October, 1933, the vagina was little better than a cord of scar tissue. Both she and her husband were very insistent that something be done—the condition present was ruining their family life.

I talked to them at that time about making a new vagina from the bowel but did not encourage the undertaking.

Nothing more was heard from the patient until June, 1934, when she came in declaring she was ready to do anything to end the present uncomfortable situation.

June 13, 1934 Operation Rhode Island Hospital

*Read by title at the Annual Meeting of the New England Surgical Society at Manchester N H. September 28 1935

†Pitts Herman C—Surgeon Gynecological Department, Rhode Island Hospital Providence. For record and address of author see *This Week's Issue* page 1147

Under ether anesthesia the vaginal mucosa in cluding all scar tissue was removed from the in-
troitus to the cervix. The abdomen was opened—
a complete hysterectomy done and the left tube and
ovary removed. An attempt was made to find a
loop of ileum long enough to serve the purpose but
the mesentery proved too short. Failing this a 10
inch segment of sigmoid was isolated and an internal
anastomosis of the cut ends of the bowel done above
to restore its continuity. Then the isolated seg-
ment was folded on itself and carried down into
the prepared vaginal cavity to the introitus. The
peritoneum was drawn over the operative site above,
the abdomen closed and patient again changed to
the lithotomy position. The folded end of the bowel
presenting at the introitus was opened and the edges
stitched to the raw edges of the vaginal entrance.
This left a double-horrelled passage extending up-
ward about five inches. The two canals were packed
with iodoform gauze.

The patient made a satisfactory recovery. When
I saw her July 10 1934 there was some discharge
and the entrance to the new vagina had contracted
a little. The median septum was very apparent and
acted as an obstruction.

In October 1934 she was sent to the hospital
again and clamps were applied to the septum in
the new vagina. The pressure of course caused
sloughing as far as the clamps reached so that
when she left the hospital there was a single canal
for about four inches. At the time the clamps were
put on the constricting band surrounding the vaginal
entrance was cut with a tenotomy knife.

I saw this patient last, May 24 1935 not quite a
year after the new vagina had been made. Inter-
course was still painful. The tube was well open
and certainly seemed perfectly capable of fulfill-
ing the function for which it was intended. The
remains of the septum high up should be gotten rid
of and I mean to do something for this at a later
date. At the time of this last examination the lin-
ing of the vagina was still soft and velvety like
that of newly opened intestine. I had hoped it
would become tougher and more like vaginal mu-
cosa.

In reviewing this case I have regretted that I
used a loop of sigmoid and not a contracted section,
but at the time the bowel was so contracted that I
thought a single tube would not be large enough.

DR WILLIAM BEAUMONT*

BY WALTER F. STENER, M.D.†

ON June 1st of this year, the citizens of the
town of Lebanon, Connecticut, united with
the Beaumont Medical Club to dedicate at
Lebanon, the Beaumont Memorial Highway.
At that time the memorial address, with Pro-
fessor Russell H. Chittenden presiding was
given by Dr. Harvey Cushing of New Haven.
His lucidity of expression and charm of style
will cause that address to be long remembered.
On that occasion also our Governor the Hon-
orable Wilbur L. Cross and Lieut. Col. Robert H.
Duennen of the United States Army spoke upon
Beaumont. The wealth of material then exhib-
ited upon him naturally causes me some em-
barrassment and would force me to decline this
honor, were it not for the fact that I have in
previous years spoken upon him in Plattsburgh,
Chicago, Philadelphia and New Haven so that
I hope I may be able to gather together now
some references to him which had not been
mentioned, for lack of time, one month ago. Es-
pecially would I like to dwell somewhat upon
the letters which he wrote home to his family
here in Lebanon.

He was born in Lebanon on November 21
1785, being the son of Samuel and Lucretia
(Abel) Beaumont. He was a farmer's boy
was fifth in descent from William Beaumont
who came to Massachusetts in 1635 and mi-
grated with John Winthrop, Jr., to Connecticut,
where he appears at Saybrook in 1640. Cour-
age was one of Beaumont's prominent charac-

An address delivered at Village Hill on July 1 1935 at the
opening of the Beaumont Highway. Village Hill is situated on
the Beaumont Highway half way between Williamstown and
Lebanon.

*Walter F. Stener—Consulting Physician, Stamford Hospital.
For record and address of author see "This Week's Issue"
page 1147.

teristics which caused him at one time, on a
dare to stand nearer a cannon that was being
fired than any of his playmates. It probably
was an important factor in the permanent de-
fective hearing which later developed. After
being educated at the village school he stayed
home to help his father till the fields of their
farm until he had arrived at man's estate, when
seeking adventure, he set out from home jour-
neying northward with a horse a cutter, a bar-
rel of hard cider and \$100 of hard earned
money. Reaching Champlain in the spring of
1807 he found favor in the eyes of the people
there, was given the job of school teacher, ten-
ded store, and in his spare time whenever there
was any, began the study of medicine, borrow-
ing books from the library of Dr. Seth Pom-
roy of Burlington. In one of his letters home
on December 29, 1807, we learn he is now upon
the last half of the quarter term and his school
consisted of sixty and odd scholars who were
daily increasing. He thought the prospects
there "more encouraging than they were in
Connecticut", and wished to remain there unless
his return would contribute to his parents'
"ease, happiness and satisfaction". Later we
learn on March 8, 1808 he was in his fifth quar-
ter in teaching school. An uncle living in
Champlain, being a strong Federalist called
him on account of his Jeffersonian principles,
"the ump of his father". These strong Demo-
cratic tendencies are exhibited in a number of
letters in one of which he writes "Since the
election (or Freeman's meetings as they are
called in Connecticut) the Feds stand aghast,
their eyes distended with wrath and indigna-
tion, their countenances disfigured with mingled

expressions of shame, chagrin and disappointment" Later he thus responds to a taunt of Luther Newcomb of Lebanon that he had become a Federalist "Sooner might they move the everlasting hills than to bribe my integrity waver my faith, shake my belief or divert my course from the polar star of Republicanism while reason holds her empire over the province of my intellect"

He seems to have gone to Lebanon in the summer of 1808, but had returned to Champlain by the fall In January of the following year we learn from another letter that he had between sixty-five and seventy scholars to look after so he was "in constant employment with scarce time to unbend his mind at night" In a letter to his brother Abel at this time he writes him the following advice in the high flown language of that period "let virtue, truth and honesty be your planetary guide, temperance, justice, fortitude and prudence your cardinal points, faith, hope and charity your horizon, philanthropy, benevolence, friendship and philosophy your atmosphere and the elements of life will be smooth, transparent and pleasant, gently gliding over your imagination like the eastern morning breeze across the swelling field of wheat" In another letter on April 3, 1810, we are informed that he had closed his pedagogical career and was then pursuing the study of medicine under Dr Benjamin Chandler at St Albans After two years spent thus, he was granted a license to practise medicine by the Third Medical Society of the State of Vermont and some months later entered the Army as Surgeon's-Mate In the War of 1812 he was at the capture of York and finally in the battle of Plattsburgh, where he was highly complimented for his bravery under fire

Soon after the War he resigned from the Army and commenced the practice of his profession in Plattsburgh, keeping a store at the same time along with two physicians successively until he reentered the Army as Post-Surgeon in 1819 when his practice was left to his cousin, Samuel Beaumont During this period of his practice in Plattsburgh, the following amusing advertisement appeared in the Republican, which was the town's newspaper

"The person who took a small glass Sand Box from the office of Doct Beaumont is requested to return it, and save their reputation as it is well ascertained who the offender is"

Unfortunately, we are not subsequently informed if the thief saved his reputation

Three years later a great opportunity came to him at Fort Mackinac, for a young French Canadian, Alexis St Martin, was shot in the stomach at close range in the store of the American Fur Company Beaumont was called to attend him, and, fortunately, under Beaumont's unemitting care, the patient was saved, but

recovered with a permanent hole in his stomach Through this hole in St Martin's stomach, Beaumont was able to make four series of experiments upon the physiology of digestion, but these were only accomplished under considerable difficulty for the patient was an elusive, drunken old reprobate Finally, in 1833, Beaumont published the results of these four series of experiments in a book entitled, "Experiments and Observations on the Gastric Juice and the Physiology of Digestion" It was published by Frederick P Allen of Plattsburgh and reissued the following year by Lally Wait and Company in Boston Fourteen years later his cousin, Samuel Beaumont, edited a second edition of this book which consisted merely of many minor corrections Later an English and German edition appeared, and still later, when the International Congress of Physiologists met in Boston in 1929, it was again republished by the American committee as they considered it represented America's foremost contribution to physiology A copy at that time was given to each of the delegates along with a medal on which the profile of Beaumont was depicted The book in its first edition was sold at \$2 00 a copy, but now has increased in value so that it is worth from \$50 00 upwards The closest research of modern times has added only a little to the work done by him as represented in this book

Finally, in 1839, Beaumont resigned from the Army and entered into private practice in St. Louis, where in his last thirteen years he enjoyed a most extensive and lucrative private practice His letters home, which still survive, are addressed mostly to his parents or specifically to his father They all show an intense devotion to his family In 1814, he writes a tender letter of sympathy to his mother on account of his father's death, and advises his brother Abel to look after the farm, thinking with a little more experience, the advice of others and good health he should be competent to look after it He seems to have been teaching school at that time In 1815 he writes to his brother Abel "Should I get my pay soon and conclude not to remain in service I shall be in Connecticut before many months" In a letter he wrote Abel in regard to quitting his teaching to superintend and carry on the old farm in Lebanon he writes "I am convinced that I shall, before many years, exchange my present profession of physics and surgery for that of agriculture which I am very fond of and grow more and more so as I advance in life" Subsequently, Abel seems to have studied medicine and to have gone to New York to practice, where he died a few years later On April 22, 1835, Beaumont writes to his brothers and sisters from Plattsburgh that he expects to be permanently located in St Louis at least for several years, and adds "if you and the girls

should feel a mutual migratory spirit and your circumstances and situations will warrant a removal from your native soil to be transplanted in the far west, I will be looking out for you." In March, 1853 he fell on some ice-covered stone steps when returning home from a professional call, and, although his injuries at the time seemed slight, he never entirely recovered from them. Later he developed a carbuncle on his neck, and died on April 25 1853. His remains rest in the beautiful Bellefontaine Cemetery in St. Louis beside those of his wife whom he married as a widow—Mrs Deborah Green—in 1821. She survived him seventeen years.

Dr Samuel D Gross, a distinguished surgeon in Philadelphia, has given us the following sketch of Beaumont in his reminiscences: "I found Dr Beaumont an agreeable gentleman, suave and interesting in conversation with great enthusiasm for his profession, and admiration for its successful cultivators. The only thing that marred the pleasure of this and other interviews was his deafness, which compelled him to use an ear trumpet, and the listener to raise his voice to a fatiguing pitch. Dr Beaumont

was a man of small stature and delicate frame, with a darkish, sallow complexion, imparting to him a somewhat unhealthy appearance. He was at the time fifty-seven years of age, and looked old. An active life, attended with the many exposures incident to an army career, had made serious inroads upon a constitution never strong and robust."

Beaumont's genius surmounted his lack of a college education, his lack of a medical school training, his lack of a hospital experience, and gave to the world a name which will be long remembered in medical annals, for he blazed a path in the physiology of digestion which has now become a broad highway. He really belongs to the world, for his fame from these achievements in the physiology of digestion has made him a world known figure, but we in Connecticut more especially claim him as this is the land of his birth. You have set at naught the old adage that a prophet is not without honor save in his own country, by perpetuating Beaumont's memory in this highway. It will cause his name to be made known here even to coming generations.

HEALTH PROTECTION EXPENDITURE

Health protection for the public of the United States is disposed of with the expenditure of only 50 cents annually per person in tax money compared with the annual average expenditure of \$4.52 per person for police protection and \$3.32 per person for fire protection.

This is but one item in a pamphlet "Health Facts" just off the press published by The National Health Council as part of the material for the Health Today and Tomorrow campaign recently launched and planned for the winter and spring months. Already more than 400 cities have enlisted in the campaign through their state or city health officers who are taking the initiative in most of those localities. The climax of the campaign is to be in general an open Town Meeting held after a thorough community wide health inquiry has been made to discover public health needs in that locality.

Most of the statistics contained in "Health Facts" furnish a basis of comparison of local health conditions with immediately attainable health goals. Among other striking statements made in this pamphlet the following are a few which show the need for greater appropriations for community health work from both public and private sources.

We are graduating as many persons from the community into nervous and mental hospitals as we are sending out into the community each year from nurseries and universities. More than fifty per cent of all hospital cases in this country are those of some form of mental illness. The present annual average of mental cases recovered or improved is about forty per cent.

Another statement. Relief funds make little ap-

preciable addition to health services for the needy. Social Security Act appropriations when they become available for public health work, will not be large enough to make up for the depression shrinkage in regular health department appropriations since 1929.

Under the heading "What Voluntary Health Agencies Do" we read in this pamphlet that voluntary hospitals with about half as many beds as government hospitals accommodate about seventy per cent of the admissions in any one year.

Through health education campaigns financed privately the diphtheria case rate (in one urban campaign) was reduced from 19, for every 100,000 population to twenty-four.

Forty-eight per cent of the nurses available for community services are paid from private funds. On the other hand the public health nursing service is the largest single item among public health expenditures—about one-third to one-half of the tax funds for public health goes to pay for public health nurses. Yet the total number of nurses now serving the country amounts to only one-third of the number needed in communities. Public health nursing organizations have suffered a ten per cent reduction in income while the volume of free service has had to be increased.

"Health Can Be Measured" and "Health Can Be Purchased" are headings of two other sections of the pamphlet. This is a limited edition, and it is already apparent that a second printing will be necessary. To cover the cost, a nominal charge is made of twenty cents for a single copy and fifteen cents a copy in lots of 100 or more ordered from The National Health Council, 50 West 50th Street, New York City.

CASE RECORDS of the MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

FOUNDED BY RICHARD C CABOT, M D

TRACY B MALLORY, M.D., *Editor*

CASE 21491

PRESENTATION OF CASE

A sixty year old unmarried white American female was admitted complaining of shortness of breath and a lump in the neck.

About ten months prior to admission the patient first noted that activities which she had previously carried on without difficulty now produced shortness of breath and fatigue. This gradually increased in severity so that climbing two flights of stairs forced her to rest because of breathlessness. When excited she had always had some fluttering palpitation, which had not increased during the present illness. Seven months before entry she noticed that her memory was becoming poor. She had occasional dizziness while standing and looking upward. Three months before admission she first noticed a swelling in her neck which became progressively larger. Shortly afterward her friends noticed that her voice was becoming hoarse, and when she swallowed food it "did not go down straight." Occasionally deglutition was accompanied by a tight dry feeling in her throat. There had been no weight loss.

One sister died of carcinoma, another of tuberculosis. One brother died of a probable general paresis. Her father died of cirrhosis of the liver, her mother of carcinoma of the skin.

Physical examination showed a well-developed and nourished elderly woman who appeared to be quite comfortable. The skin was warm and moist. The eyes were symmetrically prominent and there was definite lid lag. There was an asymmetrical nodular enlargement of the thyroid and a bruit was audible over the gland. There was slight tremor of the extended fingers. The heart was enlarged to the left. The sounds were regular and of good quality but there was a split first sound at the apex which was heard faintly at the aortic area. The systolic blood pressure vacillated between 170 and 205 but the diastolic remained constantly at about 110. The lungs were clear.

The temperature was 99.8°, the pulse 88. The respirations were 20.

Examination of the urine was negative except for 6 to 8 white blood cells per high power field. A urinary concentration test showed a specific gravity between 1.012 and 1.015. The blood showed a red cell count of 4,800,000, with a hemoglobin of 70 per cent. The white cell count was 5,500, 72 per cent polymorphonuclears. Stool examinations were negative. The nonprotein nitrogen of the blood was 32 milligrams per 100 cubic centimeters. An intravenous phenolsulphonephthalein test showed 40 per cent excretion of the dye in one hour. An initial basal metabolic rate was plus one. Subsequent tests ranged between minus 5 and minus 14, with a single reading of minus 22.

X-ray examination showed that the lung fields were clear. The diaphragm and heart shadows were normal. There was no substernal thyroid or tracheal compression.

Eight days after admission operation was performed.

DIFFERENTIAL DIAGNOSIS

DR JACOB LERMAN. The first two symptoms, shortness of breath and a lump in the neck, immediately suggest a diagnosis. A person with a lump in his neck who is short of breath is more often than not thyrotoxic.

However, I do not see any mention here of any other toxic symptoms, i.e., their presence or absence, except weight loss. We must assume that they were sought and found to be absent. The prominent symptoms apparently were those of pressure,—difficulty in swallowing, and tight sensation in her throat.

There are, apparently, two members of the family who have had carcinoma. That would suggest a possibility that the lump in the neck might be malignant.

We place a good deal of emphasis on a warm moist skin in a differential diagnosis. In general a cold clammy skin will practically rule out hyperthyroidism from a clinical standpoint. A warm moist skin can only be said to be consistent with hyperthyroidism.

There are two very important physical findings suggesting the diagnosis of thyrotoxicosis. We have a goiter plus eye signs. No mention is made here of a stare. I feel that a stare is a very important eye sign, certainly as important as prominence or lid lag.

I should like to see more description of the thyroid. All we know is that it was a lumpy goiter but no mention is made of the consistency or the character of the gland. Consistency is very important in differential diagnosis and also gives one a clue as to the possibility of treatment. If this gland were particularly hard, we would suspect that she had had iodine medication previously. This would help us in diagnosis. A bruit is also very important in differential diagnosis here. In general one may say that almost ninety per cent of hyperthyroid

patients have a bruit. In some instances where the diagnosis of hyperthyroidism is not made in spite of a bruit, the gland is found to be hyperplastic. Consequently we pay a good deal of attention to a bruit in a thyroid gland.

"The heart was enlarged to the left." That does not mean hypertrophy because percussion is not infrequently erroneous in toxic goiter. It is common for the examiner to over-percuss perhaps by two centimeters when the heart is overactive. I should not be surprised if the heart were found to be of normal size by x-ray.

Obviously there is some fixation of the specific gravity and that is consistent with an arteriosclerotic kidney.

"An intravenous phenolsulphonphthalein test showed 40 per cent excretion of the dye in one hour." Thus the assumption that we are dealing with an arteriosclerotic kidney is probably correct.

The initial basal metabolic rate was plus one. I am assuming that the examiner did not find any history of iodine treatment because that would change the entire picture. Up to the point where the metabolic rate is introduced the history and physical examination seem to represent a clear cut picture of toxic goiter with some symptoms of pressure. A metabolism of plus one could be consistent with hyperthyroidism. We have seen several patients who have had metabolisms ranging between zero and plus ten with very few symptoms and signs except goiter who nevertheless made a characteristic response to iodine, proving that they had hyperthyroidism. I assume no iodine was given here. The unusual feature here is the spontaneous reduction of the metabolism to a low level. Even so I am forced to make a diagnosis of hyperthyroidism in the past in a patient whose thyroid probably underwent spontaneous involution. One might speak of it as an extension phenomenon and thus account for the low metabolism.

In the presence of a bruit I shall predict that the surgeon found hyperplastic tissue. This has occurred on several occasions when we did not suspect it and the bruit was the only clue to it. I remember one patient in particular, a young girl who had a metabolism of minus twenty. We thought she had simple colloid goiter but the surgeon at operation found an obviously hyperplastic gland. The metabolism after operation varied little from the one before operation. It is possible for a hyperthyroid gland to undergo involuntary changes to the point of complete atrophy and exhaustion and produce myxedema. Recently we saw a case of this sort and Dr. Hurxthal believes he has seen six or eight cases of myxedema following hyperthyroidism. Consequently, we may suspect that this patient is on the road to myxedema.

X RAY INTERPRETATION

DR. GEORGE W. HOLMES. These films are taken at seven foot distance, not during quiet breathing but at full inspiration and the heart shadow is somewhat smaller than during quiet breathing. I think it is fair to say it is within normal limits. There is nothing unusual in the lung fields. We might wish that the exposure was a little greater so that we could see the trachea in the anteroposterior view. In the lateral we see it more distinctly and certainly it is not narrowed unless we interpret this small indentation as narrowing. We can see the tumor mass in front of the trachea and there is some increase in the distance between the spine and the trachea suggesting that the tumor extends completely around the trachea. In these films the tumor seems to be rather small and homogeneous, certainly one would not suspect it to be a particularly nodular tumor. The spine shows hypertrophic changes which are very common and have no bearing on the diagnosis.

DR. J. H. MEANS. Would you say the distance between the posterior wall of the trachea and the posterior wall of the spine is about twice the normal thickness? I was looking at one on the ward this morning that looked about half the width of that.

DR. HOLMES. There must be considerable variation in the normal and it may be increased by rotation. I think it would be safer to say that it is greater than normal.

DIFFERENTIAL DIAGNOSIS CONTINUED

DR. LERMAN. I think the clinical diagnosis is that of goiter, probably toxic in the past, without any clear cut toxicity at present. We may say it is a gland undergoing involution. But I shall predict that the pathologist will find hyperplasia in spite of that, merely on the basis of the presence of a bruit. There is hypertension and probably moderate arteriosclerotic heart and kidney disease.

CLINICAL DISCUSSION

DR. MEANS. I think when Dr. Mallory produces a case that seems to be somewhat obvious there is usually a joker in it somewhere. I think we have a right to know whether she did or did not get iodine because the reaction to it is important in diagnosis as Dr. Lerman brought out. If she had had for instance a metabolic rate of minus five and got iodine and it dropped to minus twenty two, I should say that was good evidence she probably had thyrotoxicosis. If the fall happened spontaneously it would put a different complexion on the problem.

DR. TRAUB B. MALLORY. We certainly had no intention of being mysterious about it. She had none.

DR. MEANS. That means that twenty two is

a natural basal level and it is hard, therefore, to say she was thyrotoxic. I think Dr Lerman is correct in saying she may have been in the past and now is on the road to myxedema. That would be a logical interpretation.

I have been trying to guess why the operation was done. Was it done because of pressure symptoms or because she was thyrotoxic? Was it done because they thought it would be good for her heart? Or because they believed the lesion was malignant? The chances are very strongly against its being malignant if she had truly had Graves' disease, because they do not go together for some mysterious reason that we do not understand. I should think there was no strong indication for operation here on the basis of existing thyrotoxicosis. If that is the reason I think they were rather radical because an old woman of this sort might be carried on iodine the rest of her life and not have to submit to surgical treatment. Pressure may have been a perfectly good indication. Whether one should operate for pressure would depend on the severity of the symptoms and how they were progressing. The fear of malignancy would be another good ground. I fancy they may have operated for pressure.

DR MALLORY: Dr Cope, will you explain the indication for operation?

DR OLIVER COPE: We did operate largely for the pressure symptoms. Dr Lerman has come more or less to the same diagnosis that I think Dr Hertz and I did. There is one thing that is not quite fair about the description of the goiter, often the descriptions in the records are somewhat erroneous. The goiter was symmetrical and not nodular. At operation it certainly was bilaterally symmetrical. Perhaps it would be best for me to describe what I found at operation. The goiter was symmetrical and it was not in the least adherent to the surrounding tissues. Except for the color it had the granular uneven lobular appearance of a hyperplastic gland which had been given iodine. The cut surface was similarly granular. On gross appearance it was typical of an iodimized hyperplastic gland except for one important exception, it had not the pinkish color of a true hyperplasia but was very obviously white. The gland contained very little blood and the cut surface exuded a large and unusual amount of lymph and serum. The enlargement was sufficient to have given definite pressure symptoms. We did think of it as a gland that had been previously hyperplastic with hyperthyroidism that had gradually become exhausted. Hypertension and toxicity were not the indications for operation. The indications were mechanical.

PREOPERATIVE DIAGNOSIS

Toxic nodular goiter

DR JACOB LERMAN'S DIAGNOSES

Nodular goiter—toxic in the past
Involution and hyperplasia
Hypertension
Arteriosclerosis, cardiac and renal

PATHOLOGIC DIAGNOSIS

Chronic thyroiditis, Hashimoto's struma

PATHOLOGIC DISCUSSION

DR MALLORY: The gross appearance of the resected part of the gland has already been described very well by Dr Cope, and the microscopic appearance explains its peculiarities. It was a typical Hashimoto's struma, one of these peculiar cases of chronic thyroiditis in which the entire thyroid gland is filled with lymphocytes which are arranged in the form of hyperplastic follicles. In a thyroid lesion of this type perhaps three quarters of the entire gland will be made up of lymph follicles.

The origin of this type of thyroiditis and even its outcome are, I think, still complete mysteries. No single individual has ever seen very many cases and consequently it is difficult to piece together the whole clinical picture. I think this case is a very interesting one in that it presents, as Dr Lerman has brought out very clearly, so many suggestions of a preceding hyperthyroidism. In the average case of exophthalmic goiter a very considerable amount of lymphoid infiltration is always present and it would seem possible from the histologic point of view to interpret these lesions as an extreme grade of the same type of pathology that one sees in exophthalmic goiter. We were not able to find any hyperplasia in the persisting remnants of thyroid tissue, however, nor have I ever been able to prove persisting hyperplasia in any of the other cases of Hashimoto's struma I have seen.

DR MEANS: Were there any follicles left?

DR MALLORY: You mean acini of thyroid tissue? Yes, a moderate number.

DR MEANS: What kind of cells?

DR MALLORY: Low cuboidal.

DR MEANS: With a good deal of colloid?

DR MALLORY: A fair amount, yes.

DR MEANS: Hashimoto's form of thyroiditis rarely can be diagnosed clinically. It may present pressure symptoms or myxedema. I remember a case years ago that Dr Brewster did two operations on that histologically was fairly typical of Hashimoto's struma. We did not know about Hashimoto's work at that time but it was later decided that that was what it was. There was no history of hyperthyroidism prior to the development of myxedema symptoms in that case.

Dr Mallory has suggested that Hashimoto's struma may be the end result of the lymph-hyperplasia that is a part of the histologic

picture in thyrotoxicosis that phase of the picture which Dr. Warthin has stressed as being very important. I find it difficult to accept the theory because there has not been any antecedent story suggesting Graves' disease in most of our cases of Hashimoto's struma.

DR. MALLORY: I should agree.

DR. HOLMES: From the histology of these tumors you would expect it to disappear under radiation.

DR. HAMPTON: I had a patient, Dr. Holmes, with such a tumor that was treated by x-ray and it did disappear promptly but it left a fibrous band around the trachea that produced marked dyspnea and cyanosis. I wonder if the trachea was actually inflamed in this case, whether there is a tracheitis with this.

DR. MALLORY: I do not know.

DR. COPE: The interesting thing was that inflammation of the surrounding tissues was conspicuous by its absence.

CASE 21492

PRESENTATION OF CASE

A forty-four year old divorced American woman entered complaining of right lower quadrant pain.

Six months before entry the patient felt a sharp pain in the right lower quadrant just medial to the anterior superior spine. This pain lasted about five minutes and slowly went away leaving a dull nagging ache. Since the onset of this illness she had at least a dozen similar attacks of pain in the same region radiating upward and also down toward the vagina. The attacks of pain increased in length and a physician told her that they were due to a kidney stone. At about this same time she noticed some vaginal bleeding between her periods, which was very slight but enough to require the wearing of a pad. It occurred several times and did not bear any relation to the menstrual cycle.

Twenty years before entry she had an attack of right lower quadrant pain and was told that she had appendicitis. Operation was advised but she refused. Another similar incident occurred twelve years before entry.

Her family history is non-contributory.

She had been married nineteen years before entry and had separated from her husband eleven years later. Her husband and three children were living and well. Eight months ago she had a thyroid operation.

Physical examination showed a well-developed obese woman in no acute distress. The heart and lungs were negative. The abdomen was obese. There was slight tenderness in the right lower quadrant. No masses were felt. Pelvic examination showed a lacerated and relaxed perineum. There was a moderate yellow

ish white, vaginal discharge. The cervix was large, boggy, lacerated, eroded and showed a large os with numerous nabothian cysts. The body of the uterus was moderately enlarged, irregular and showed prominence of the right anterior wall. The fundus was moderately retroverted. A rectal examination confirmed the above findings.

The temperature was 98.2°, the pulse 72. The respirations were 18.

Examination of the urine was negative. Examination of the blood showed a white cell count of 6,200 and a hemoglobin of 80 per cent.

On the day following admission operation was performed. The convalescence was uneventful and she was discharged on the sixteenth post-operative day.

DIFFERENTIAL DIAGNOSIS

DR. LANGDON PARSONS: "Six months before entry the patient felt a sharp pain in the right lower quadrant just medial to the anterior superior spine. This pain lasted about five minutes and slowly went away leaving a dull nagging ache. Since the onset of this illness she had at least a dozen similar attacks of pain in the same region radiating upward and also down toward the vagina." The fact that twelve attacks had occurred in the past six months would tend to rule out the possibility of a ruptured follicle or corpora hemorrhagica which on occasion give rise to sudden sharp abdominal pain. The attacks together with the radiation of the pain suggest a uterine stone as they did to the physician who sent her to the hospital. In terminal hydronephrosis is a possibility.

"The attacks of pain increased in length and at about the same time she noticed some vaginal bleeding between her periods which was very slight but enough to require the wearing of a pad. It occurred several times and did not bear any relation to the menstrual cycle." This is a very significant fact and cannot readily be overlooked for intermenstrual bleeding cannot be ignored. Some people have a slight pink staining at about the mid interval of the cycle at the time of ovulation due to hyperemia of the endometrium but the continuous bleeding in this instance seemed to have no relation to the period. Through repeated trauma, either postcoital or donching, bleeding might occur from an endometrial polyp, eroded or cancerous cervix.

Cancer of the fundus or adenocarcinoma of the body of the uterus occurring before the menopause is not uncommon and manifests itself chiefly as bleeding rather than discharge. Usually there is an increased amount of bleeding at the time of the regular periods which are usually not otherwise altered. Menorrhagia is frequently accompanied by a slight blood trickling between the periods. Pain however is commonly a late manifestation of the disease.

Cancer of the fundus is so frequently regarded as a post-menopausal disease that it is well to consider that it may occur during the normal menstrual life. An attempt to treat such a patient as a functional bleeding problem without a diagnostic curettage may result in disaster. This pitfall is further enhanced by the failure to find much in the way of gross pathology on physical examination. Not enough information is offered in the history to suggest a possible endocrine disorder. Therefore it must be assumed that we are dealing with an organic lesion. Moreover, the majority of symptoms tend to point to the uterus or adnexa as the source of the pathology. Arbitrarily then disease of the urinary tract or appendix has been excluded despite the fact that similar attacks of pain were noted twelve and twenty years ago with operation advised then.

"Eight months ago she had a thyroid operation." Myxedema will produce menorrhagia but we have no information about her periods other than the factor of intermenstrual bleeding.

Pelvic examination showed a lacerated and relaxed perineum consistent with the trauma of repeated childbirth.

There was a moderate yellowish white vaginal discharge appearing from a large, boggy, lacerated and eroded cervix full of numerous nabothian cysts, which is the typical picture of a chronic endocervicitis showing cystic dilatation of the glands on cut section and rarely the site of a carcinoma of the cervix.

"Examination of the urine was negative. Examination of the blood showed a white cell count of 6,200 and a hemoglobin of 80 per cent." Certainly there is little to suggest an acute inflammatory process and we may definitely rule out disease of the appendix or urinary tract.

Let us consider the pelvic findings in view of the history of six months of intermittent right lower quadrant pain gradually increasing in length associated with intermenstrual "spotting."

The presence of nabothian cysts in a chronically infected cervix together with its appearance would seem to rule out cancer of the cervix as a cause of bleeding. The entire description of the feeling of the pelvis would be consistent with pelvic inflammation associated with a fibroid uterus. The uterus is enlarged and irregular as well as retroverted. There is right lower quadrant abdominal tenderness as well as a prominence of the right anterior wall of the uterus consistent with an enlarged hydrosalpinx or tubo-ovarian mass. The pain might readily be explained on a twisting of such a hydrosalpinx. The retroversion of the uterus would be consistent. Pelvic inflammation of long standing later giving rise to symptoms may be present with little in the way of a systemic

reaction. Carcinoma of the tube seems unlikely and the character of the discharge is usually watery or bloody in gushes.

A fibroid uterus alone might explain the symptoms. The uterus is enlarged and irregular. The leiomyomata may then be regarded as diffuse. A partial twist of a pedunculated fibroid would explain the pain, while the bleeding may well be due either to a polyp or submucous fibroid. There appears a definite relationship of a fibroid uterus to endometrial hyperplasia which is to be expected if both are considered as the end result of estrin activity.

Though no adnexal tumor can be palpated, a twisted ovarian cyst is a possibility. Torsion which relieved itself would explain the intermittent character of the pain as well as its gradual progression. Slight bleeding accompanies ovarian irritation. Little is noted in the systemic reaction and we must assume that the torsion never was severe enough to interfere with the blood supply.

Diffuse adenomyoma or endometrioma of the uterus would be consistent with the physical examination. More information concerning the amount of bleeding at the time of the period would be helpful. The uterus is diffusely enlarged particularly on the right anterior wall. This may be due to an endometrioma at the cornual junction or may be in the wall itself. The association with fibroids is not uncommon. Frequently a uterus with diffuse endometrioma is mistaken for a fibroid uterus. In most instances some degree of retroversion is present. No suggestion of cysts is found in the broad ligaments. My feeling is that we are dealing with the diffuse nodular type of endometrioma rather than the more common chocolate cyst variety.

PREOPERATIVE DIAGNOSIS

Fibroid uterus

DR. LANGDON PARSONS' DIAGNOSES

Diffuse endometrioma of the uterus

Torsion in hydrosalpinx?

Carcinoma or adenoacanthoma of the fundus?

PATHOLOGIC DIAGNOSES

Endometriosis of the uterus

Chronic endocervicitis

Healed appendix

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY. The preoperative diagnosis of the surgeon who operated on this patient was that of multiple fibroids of the uterus. Under ether the vaginal examination confirmed the previous findings. The curettage showed apparently normal endometrium. The cervix was very large and boggy and the vaginal wall was so short that he felt that a complete

hysterectomy from above would be difficult. He therefore, amputated the cervix from below, then went in above and removed the remainder of it along with the tubes and ovaries. An incidental finding was that the gallbladder contained stones.

Examination of the uterus in the pathology laboratory showed only slight enlargement, but on the posterior surface were some small soft hemispherical projections about one centimeter in diameter. On section these appeared honey combed with minute cavities. There was, however, no hemorrhage or tarry discoloration. The tubes and ovaries were negative.

Microscopic examination showed the presence

of the endometrial type of glands and characteristic endometrial stroma deep in the wall of the uterus and particularly in the localized nodules. Uterine endometriosis of this type is not uncommon and in my experience is much less apt to show the typical tarry appearance that one expects to find in the ovarian lesions or in peritoneal implants. Whether the menstrual reaction and hemorrhage fails to take place in them or whether the hemorrhage occurs but is effectively disposed of is not yet clear. Probably the most important feature in the diagnosis of endometriosis is that the surgeon should constantly bear it in mind as a possibility in any pelvic lesion.

PROGRESS IN MEDICINE

IF one raises the question as to the progress of medicine, say in the past hundred years, or in the past thousand years, one is met with a vast array of facts as to cause and course of disease, the structure and the function of the human body, the influence of heredity and environment, the interrelations of the body and the mind. Then too there is the increase in the average length of life, the practical elimination of certain diseases, the justifiable hope that certain other diseases may be caused to disappear from civilized communities. It requires libraries to house the books which tell us of new knowledge and from this point of view the progress has been almost marvelous.

There are other tests of progress, however, and other points of view from which we may regard medicine. Does it rank higher as a profession than formerly? Does the physician realize more fully than ever the high ideals of his art? Is he held in higher honor and regard? Does he deserve to be? Is the physician more than ever a highly respected member of the community? Perhaps to these questions a pre-

cise answer cannot be given. The highest ideals of the profession seem to be no higher and no lower than they were at the early times of which we have records. There is the same devotion to the welfare of the patient, the same consecration to the relief of suffering. Also, apparently from early times until now there have been unworthy physicians.

If we ask for some more nearly absolute test of progress we are appalled at the magnitude of the patent medicine business, and the prosperity of those who prey upon human weakness and credulity in matters of health and disease. To the physician it seems that people are more gullible in matters of health than in anything else, and no less gullible now than in the Middle Ages. Today is a day of scientific nomenclature: electrons sell big.

That idea of buying and selling is picturesque. Though often inaccurate and inadequate as used in common parlance, it is sometimes devastating. "The doctor sold himself" is distressingly true, on occasion. But in another slightly different sense is it not true that the doctors have not sold themselves to the people? The profession has not sold itself to the public.

We may reject this crude phrasing of an unpalatable idea. We do not like to think that it is a true indication of the way in which the medical profession is regarded. However, actions speak louder than words and the historian of medicine, weighing carefully what he says and estimating the progress of medicine, declares "the reader must not forget, however, that only a minority of the sick seek the aid of a physician."¹ Only a minority of the sick seek the aid of a physician! What a challenge to the medical profession!

PEDIATRIC PSYCHIATRY

THE practitioner of medicine, and particularly the pediatrician, seems in need of some defence against an idea gaining in prevalence that the pediatrician should be his own psychiatrist. The newer psychology and the possibilities of mental hygiene have been gaining on us by leaps and bounds, and it is time that certain limits be defined before the child's doctor, who has, after all, certain important functions to perform, gets bogged down in a quagmire of behavioristic difficulties.

No one will admit more readily than the psychiatrist, that burly little brother in the medical family, the difficulties of his specialty and the arduous training which a proficiency in it requires. There has been an unfortunate tend-

ency, however on the part of psychiatry, to criticize pediatrics for failing in those very functions which psychiatry has earmarked for its own and to forget that pediatrics has its own very definite obligations to discharge.

Brennemann a few years ago, in his tolerant way, directed attention to the menace of psychiatry in pediatrics and perhaps at that time fired a shot which is still heard around the psychiatric world and may be responsible for the unimadversions on pediatrics which are occasionally heard today. As a matter of fact he was not implying that the pediatrician should embrace psychiatry, nor preach upon the pre-erives of the psychiatrist, but that common sense might at times be less dangerous than a meddling psychoiatry untempered by this ameliorating influence. Any well trained psychiatrist will agree with this statement.

The pediatrician who wishes to do his own job well, and who wishes to be left alone to do it has found an able supporter in Crothers. According to his expressed belief, "The present situation in regard to mental hygiene activities of pediatricians is thoroughly absurd. A great deal of the difficulty is that there is a general assumption that there is a 'whole child' or rather a series of such children for whom the pediatrician is responsible. Every one seems to think in controversial moments, that the whole child should be supervised by some single expert. In ordinary life no sane person makes any such assumption. The distribution of the control of the child between different persons and the abolition of control by adults for a great share of the time are the routine procedure of all sensible parents.

"The simpler method is to try to find out ways in which one can develop a specific pediatric art of medicine. I think that all pediatricians have accepted the idea of growth and development and they have also accepted responsibility for the supervision of well children. In addition, they have undertaken to give prompt and adequate service to sick children. Nothing can be safely added to pediatrics which renders the practitioner unavailable for the care of sick children no matter how desirable the new technique or procedure may be."

The fact is that the organization of an active pediatric practice precludes the possibility of mixing a formal psychiatric practice with it. As Crothers further says, "The meticulous keeping of the time-consuming appointments is one of the difficult things to arrange. For this reason alone the prolonged interviews of the conventional psychoanalytic schools are almost impossible."

A common sense psychology the pediatrician should be able to employ in his daily work and he should be able to recognize those difficulties for which outside help is needed. Psy-

chiatry, to do its part, must supply a personnel capable of assuming its share of the mutual burden without adding financial ruin to the patient's other disabilities.

POSTPARTUM PULMONARY COMPLICATIONS

The most important pulmonary complications following childbirth are insufflation of gastric contents, pneumonia, embolism, and atelectasis

Intratracheal insufflation of gastric contents either during labor under hypnotic drugs or more commonly during delivery under anesthesia is a serious complication which may lead to immediate death or provide the cause for pneumonia or lung abscess Frequently food is consumed before the onset of labor and due to the retarded emptying time of the stomach during labor a large proportion of the gastric contents may be retained In some hospitals patients are allowed solid or semi-solid food during labor Therefore, the average obstetric patient differs markedly in her preparation for anesthesia from that of the average surgical case Obstetrical anesthesia is all too often administered by an inexperienced anesthetist who is unable to cope with the vomiting patient properly

The medical attendant cannot prevent the patient from taking food at home but he can advise her against this once labor begins and can see to it that she does not have food during labor, especially if he anticipates using analgesic drugs or anesthesia If the patient has had food shortly before delivery is anticipated and inhalation anesthesia is necessary, gastric lavage is a feasible method of preventing this complication The writer knows of two deaths on the delivery table from aspiration of gastric contents which have occurred in one large institution during a two-year period Tracheotomy, inverting the patient, or mechanical intratracheal aspiration was of no avail On autopsy in each instance, the trachea, bronchi and bronchioles were filled with aspirated gastric material It is obvious why the various methods of resuscitation failed In less dramatic instances where smaller amounts of material are aspirated we find the principal causes of various degrees of atelectasis, pneumonia,

and occasionally lung abscess The most effective treatment is prophylactic and consists in preparing the patient for anesthesia in so far as we are able and in securing the most expert administration of anesthetics

Pneumonia in the puerperium is not a common complication It may be present or incipient during labor and later be recognized A fairly large proportion of cases follow operative deliveries with difficult anesthesia This type especially is likely to show the characteristics of bronchopneumonia but the process may be localized to one or more definite lobes Symptoms are complicated by the patient's reaction to the delivery and the signs in the early stages are not clear cut The clinical signs with the aid of portable x-ray are generally adequate for diagnosis Immediate sputum typing is important In the Type I group the immediate administration of serum frequently gives excellent results Otherwise the treatment is supportive with sedation and oxygen therapy as needed

Pulmonary embolism is the most common cause of sudden death in the parturient and puerperal patient It occasionally occurs in pregnancy During or immediately following delivery, embolism is most commonly associated with rheumatic heart disease, difficult vaginal deliveries, vaginal manipulation in placenta praevia, difficult anesthesia and cesarian section Embolism in this group usually occurs during the delivery or in the first six hours postpartum All degrees occur from those in which the only clinical evidence is a few localized râles in the chest with slight sudden elevation of pulse and respiration to those in which the patient suddenly becomes cyanotic and expires in a few minutes The prognosis is in direct proportion to the severity of the case The mortality in massive puerperal embolism is quoted by various authors at seventy per cent.

Later in the puerperium the chief source of pulmonary embolism is pelvic thrombosis and thrombophlebitis Many of these patients show no clinical evidence of the thrombosis and the occurrence of embolism is unpredictable In those instances in which thrombophlebitis is known to exist, our best prophylaxis consists in keeping the patient in bed for at least one week after the temperature and pulse have reached normal levels

The treatment consists in sedation by morphia and, in the serious group, the use of the oxygen tent Pulmonary embolectomy is still in the experimental stage and is available in few large institutions To date it has carried a high mortality

Postpartum pulmonary atelectasis either of slight or massive variety undoubtedly occurs more frequently than is generally considered It plays a rôle preliminary to the occurrence of pneumonia in many instances In the massive variety the extensive involvement of the affected

Comments and questions by subscribers are solicited and will be discussed by members of the Section

lung and the retraction of the heart to the affected side are pathognomonic. If uncomplicated the prognosis in this condition is excellent. From the standpoint of differential diagnosis its recognition is important. The treatment consists of O_2 inhalations or in turning the patient from side to side several times during the day until reinflation is established.

THIRD ANNUAL POSTGRADUATE MEDICAL EXTENSION COURSE

The following sessions have been arranged by the Committee for the week beginning December 8

Barnstable

Sunday December 8 at 4 00 P.M., at the Cape Cod Hospital Hyannis. Subject Kidney and Bladder Diseases, B (Surgical) Prostatism and Related Diseases Cystitis and Pyelitis Instructor S. B. Kelley J. I. B. Vall Chairman

Bristol South (Fall River Section)

Monday December 9 at 4 00 P.M., at the Stevens Clinic of the Union Hospital Fall River Subject Diseases of the Liver Hepatitis and Painless Jaundice Problems in Diagnosis and Treatment. Instructors C. M. Jones and L. S. McKiltrick Eugene A. McCarthy Sob-Chairman.

Essex North

Friday December 13 at 4 00 P.M., at the Hotel Bartlett, 95 Main Street, Haverhill. Subject Pediatrics The Neonatal State and Its Diseases Medical and Surgical Aspects Instructors L. W. Hill and T. H. Lanman. Francis W. Anthony Chairman.

Essex South

Tuesday December 10 at 4 00 P.M., in the Nurses Home of the Salem Hospital Salem Subject Pediatrics Abdominal Disease in Childhood Medical and Surgical Aspects Instructors S. H. Clifford and J. W. Chamberlain. Walter G. Philpen, Chairman

Hampden

Thursday December 12 at 4 00 P. M., at the Academy of Medicine Professional Building 20 Maple Street, Springfield and at 8 00 P.M., at the Holyoke City Hospital Holyoke Subject Dermatology Ten Common Skin Diseases—Diagnosis and Treatment. (1) Impetigo Contagiosa (2) Scabies (3) Acne Vulgaris (4) Psoriasis and Seborrheic Dermatitis, (5) Epidermophytosis (6) Herpes Simplex and Zoster (7) Eczema (8) Erythema Multiforme (9) Verruca Vulgaris and (10) Dermatitis Medicamentosa and Dermatitis Venenata. Instructor E. L. Oliver George L. Schadt and George D. Hendersonsoo Chairmen

Hampshire

Wednesday December 11 at 4 15 P.M. in the Nurses' Home of the Cooley Dickinson Hospital Northampton. Subject Kidney and Bladder Diseases B (Medical) Chronic Nephritis. Cardiorenal Disease The Use of Diuretics Instructor W. R. Ohler Robert B. Brigham Chairman.

Middlesex South

Tuesday December 10 at 4 15 P.M. at the Cambridge Hospital, Cambridge Subject Ophthalmology and Otolaryngology (a) Two Major Hazards in Diagnosis of Diseases of the Eye Ear Nose and Throat as Seen in General Practice (b) Special Treatment in Acute Medical and Traumatic Diseases of Eye Emergencies Arising in the Treatment of the Ear Nose and Throat. Instructors P. A. Chandler and C. T. Porter Edmund H. Robbins, Chairman.

Norfolk South

Monday December 9 at 8 30 P.M., at the Quincy City Hospital, Quincy Subject Kidney and Bladder Diseases, A (Surgical) Hematuria Its Significance in Surgical Diseases of Kidney and Bladder Instructor Richard Chute. David L. Belding Chairman

Plymouth

Tuesday December 10 at 4 00 P.M., at the Brookton Hospital, Brockton. Subject Review of the Principle of Dietetics Instructors W. P. Murphy and John Talbot. W. H. Pulsifer Chairman.

Worcester North

Friday December 13 at 4 00 P.M., at the Bank Hospital, Fitchburg Subject Lung Diseases (a) Significance of Symptoms and Signs in Chronic Lung Disease Tuberculosis Bronchiectasis etc. (b) The Value of Surgery in Above Disease Problems Instructors T. L. Badger and R. H. Overholt. Edward A. Adams Chairman.

BOSTON MEDICAL LIBRARY

HENRY BENCE JONES, M.D., F.R.S 1813-1873

HENRY BENCE JONES is probably best known to clinicians as the discoverer of a variety of proteins, occurring in the urine, which is commonly designated as 'Bence-Jones Bodies'. This was but one of several important discoveries of a chemical nature which he made, for he may be accounted a pioneer among physicians of the nineteenth century in bringing to bear the results of chemical research upon the clinical aspects of disease. He was born at Thornton Hall, England, on the 31st of December 1813. When he was twelve he was entered at Harrow where he received a classical training, and at eighteen was matriculated at Trinity

College, Cambridge From this university he received, in succession, an A.B., in 1836, an A.M. in 1842, an M.B. in 1845 and an M.D. in 1849. He "walked the wards" of St. Georges Hospital as a part of his medical training. During that time he was carrying on special work in chemistry with Thomas Graham at University College. In 1841 he visited Giessen where he continued his chemical studies under Liebig. He became a licentiate in 1842 and a fellow in 1849 of the Royal College of Physicians, and subsequently was for several years its senior Censor. In 1846 he was elected to the Royal Society and from 1860 to nearly the end of his life he was secretary of the Royal Institute.

From 1846 until 1860 he was Assistant Surgeon, and later surgeon, to St. Georges Hospital. His celebrity as a physician is indicated by the names of some of the distinguished men of England to whom he ministered in that capacity, viz., Thomas Huxley, Herbert Spencer and Charles Darwin, to mention only three.

In the catalogue of the Royal Society are recorded the titles of thirty-four articles from his pen. That he utilized his chemical researches in a practical way may be inferred from the titles of some of his papers, viz., "Gravel, Calculus and Gout, the Application of Liebig's Physiology to these Diseases," 1842; "On Animal Electricity, An Abstract of the Discoveries of Du-Bois Raymond," 1852; "Animal Chemistry in its Application to Stomach and Renal Diseases," 1850; "Lectures Upon Some of the Applications of Chemistry and Mechanics to Pathology and Therapeutics," 1867; "Croonian Lectures on Matter and Force," 1868. Michael Faraday was a close friend of his and a two volume Life of Faraday, written by Jones, attests the great admiration he entertained for him.

His death took place in London, April 30, 1873. His wife, who was a cousin, and a daughter of the second Earl of Gosford, and a large family survived him.

There are few recorded instances of men who have achieved distinction in the clinical field whose success there seems so definitely grounded upon their own achievements in the realms of pure science. This is the more striking in Jones' case because his practice and research were carried on simultaneously and it was only when compelled by physical warnings of a serious cardiac lesion that he curtailed his clinical work, he was able to continue his scientific studies almost to the end. There is scarcely one of his published communications that does not indicate a desire to correlate scientific truth with diagnostic and therapeutic usage, in a practical way. He enjoyed a large acquaintance among the pure scientists, notably with Latham, Graham, Fownes, Liebig, Tyndal, Huxley, Du-Bois Raymond, Kühne, Brücke, Ludwig, Faraday, Helmholtz and Grove.

Among the distinguished practitioners of his day he was not quite so widely recognized. He was honored by membership in numerous scientific and philanthropic societies. His temperament was one that made friends and provoked enmities. His enthusiasm for his work made him a stimulating and inspiring teacher, adored by youth, to whom he was always kindly disposed and helpful, but his intolerance of authority and opposition brought him into conflict with fellow-workers at times, though he was never unwilling to acknowledge that he was in the wrong when it could be demonstrated. The later years of his life were occupied to a considerable extent by his duties as secretary of the Royal Institute where he was the one responsible for selecting outstanding lectures, both in science and literature. He also devoted a good deal of time to devising, while he was a member of a Royal Commission, measures to control a serious epidemic among cattle that had appeared in England in 1865.

It would be difficult to find a better demonstration of the value of a scientific training in physics and chemistry to the practical requirements of a physician than is exemplified in the life of Henry Bence Jones.

MISCELLANY

VISITING OFFICIALS OF THE AMERICAN MEDICAL ASSOCIATION

Dr. James S. McLester, President, and Dr. J. Tate Mason, President-Elect of the American Medical Association, made a flying visit to Boston, November 27, as arranged in the program to visit the several constituent medical societies of the National Association.

Dr. Roger I. Lee, a Trustee of the American Medical Association, entertained the visitors at a Somerset Club luncheon, and Dr. Mongan, President, and Dr. Begg, Secretary of the Massachusetts Medical Society, arranged a reception and banquet at the Harvard Club, to which the officers of the State Society, and the District Societies and coordinated medical interests were invited. Both Dr. McLester and Dr. Mason entertained the assembly until a late hour by recitals covering the history of the American Medical Association with full descriptions of all its activities as carried on by the large number of bureaus, heads of departments, and the scientific sections.

These eminent leaders of the profession held the interest of the audience by the clear presentation of facts and the compelling logic of the principles of the national body.

After the address of Dr. McLester, a film was run off which made it possible for the company to visualize the work of each department with reproduc-

tions of photographs of the founders of the Association and many of the present officials.

The most urgent appeal in the addresses was for coordination of the whole medical profession in promoting the best possible care of the illnesses of the people and the maintenance of the sacred functions of the doctor in his relation to his patient.

It was clearly explained that the recent concentration of attention of certain Federal plans on the problems of the medical profession brought us to the brink of a disaster which although dispelled for the time being demands of the profession concentration on the plans and purposes of certain government officials and in order to prevent lay control of medical service there must be developed unanimity of purpose and action by the medical profession.

The speakers made it plain that the House of Delegates intends to carry out the will of the profession but that there must be shown to this representative body exactly the character of these common sentiments. To that end each component society must concentrate on the medical problems before the country and send well informed delegates to the executive body of the Association.

The speakers urged those in attendance to go on to their local societies and instruct the individual members in the important medical problems before the nation.

Dr Charles E Mongan President of the Massachusetts Medical Society presided and gracefully introduced the speakers

A FAREWELL DINNER FOR MR. FRANK KIERNAN

On the evening of November 25 the friends of Mr Frank Kiernan assembled at the Hotel Statler to express their appreciation of the work done by him in Massachusetts for the past ten years and to wish him success in the new position which he is about to assume as Director of the New York Tuberculosis and Health Association

Mr Kiernan came to Massachusetts in 1925 to serve the Massachusetts League as its Executive Secretary His remarkable energy and interest in public health work led to responsible positions with other organizations as shown by his coincident appointment to the position of Secretary of the Massachusetts Society for Social Hygiene Secretary and Treasurer of the Massachusetts Central Health Council and President of the New England Tuberculosis Association. He filled all of these positions with remarkable success and officers of these organizations responded to introductions by the Reverend Walter F Greenman who acted as master of ceremonies and paid cordial tribute to the services rendered by Mr Kiernan His resignations from these positions were accepted with regret in order to facilitate Mr Kiernan's promotion to a larger field of usefulness

The especially appropriate addresses were delivered by Dr Frederick T Lord, President of the League Dr E. Granville Craibtree President of the

Social Hygiene Society Dr Henry D Chadwick, State Commissioner of Public Health Dr Charles F Willinsky Deputy Commissioner of Health of Boston and Miss Hazel Newton, representing the publicity division of the Boston Council of Social Agencies

In his response to the felicitations of the several speakers Mr Kiernan spoke eloquently of the cordial relations which he has enjoyed with the people of Massachusetts during the past ten years and assured the company of his continued interest in the public health policies of Massachusetts

THE REAPPOINTMENT OF DR. DURRETT

Dr J J Durrett of New York has been reappointed Chief of the Drug Division of the Food and Drug Administration. Dr Durrett will take charge of the work early in January

Dr Durrett returns to his former post after an absence of a little more than four years. During that period he was engaged in commercial work and was associated with E R. Squibb & Sons of New York City He originally entered the service of the Food and Drug Administration in May 1928 and resigned in August, 1931

Before entering the service, Dr Durrett had four teen years experience in the practice of medicine as a city health officer, and as a surgeon in the Public Health Service He holds BS M.S. and Ph.D. (Graduate in Pharmacy) degrees from the University of Alabama and the M.D. degree from Harvard University

As Chief of the Drug Division Dr Durrett will be in control of the work involved in the enforcement of those provisions of the Federal Food and Drugs Act which apply to drugs, medicines and veterinary preparations.

AN HONOR TO DR. ALICE HAMILTON

A luncheon in honor of Dr Alice Hamilton was given at the Women's Educational and Industrial Union, November 21 1935 by the Consumers League of Massachusetts branch of the National Consumers League of which she is vice-president.

Dr Richard Cabot presided and in his address deplored the fact that Harvard had not adequately recognized women leaders in the professions

Dr Hamilton is the first woman professor at Harvard University and has been recognized as an outstanding authority in industrial hygiene. She has recently been appointed adviser on industrial problems for the United States Department of Labor

RECOGNITION OF THE TEACHING SERVICE OF DR. J. B. AYER

A dinner was given to Dr James Bourne Ayer on Tuesday November 26 1935 at the Tavern Club Boston to celebrate the first twenty five years of his teaching in the Harvard Medical School About sixty guests attended the dinner all of whom are members of the Department of Diseases

of the Nervous System, Harvard Medical School, or of the associated departments of neurosurgery, anatomy, physiology, psychology and medicine Dr C Macfie Campbell acted as toastmaster and brief speeches were made by Drs James H Means, W Jason Mixter, George Walton, Merrill Moore, and Henry R Viets Amusing skits on the neurology of the past, depicting scenes in the lives of Magendie, Quincke and Gowers, were presented under the direction of Dr Stanley Cobb and Dr Tracy J Putnam Dr Ayer spoke briefly in regard to the developments in neurology during the last twenty-five years In this period of time the department has expanded from one with three or four men to a large group, represented by the following men, who were present at the dinner A few men active in neurology were unable to attend.

TUBERCULOSIS—A CHALLENGE TO YOUTH*

By LOUISE STRACHAN

*Director Child Health Education,
National Tuberculosis Association*

"He who has health has hope, and he who has hope has everything," runs an old Arabian proverb Hope is characteristic of youth, and health has long been regarded as one of youth's prerogatives Yet for countless ages tuberculosis has been reaping

a rich harvest in the field of youth That it existed in the days of Egypt's greatness is proved by the evidence found in recently unearthed mummies Tutankhamen, whose tomb in the Valley of the Kings was excavated in 1922, and whose age at death was not more than eighteen, appears to have died of tuberculosis The disease has never been a respecter of persons prince and pauper, poet and peasant, one and all have suffered its ravages

Tuberculosis seemed an invincible foe, and indeed it was until the genius of Koch discovered the cause of the disease—a tiny rod shaped germ known as the tubercle bacillus This happened but half a century ago, in 1882, and since that time, when a real offensive was launched against this ancient enemy of mankind, the number of lives lost because of tuberculosis has steadily decreased The tubercle bacillus is on the run! We know more about him today than has ever been known before in the history of the world We know enough to abolish the disease and the question is not "Can we?" but "Will we?"

Here lies the challenge to youth The fight can not be won without the support of the high school and college students, for in their group, between ages fifteen and twenty-four, tuberculosis still triumphs in its old rôle of "Captain of the Men of Death" Most young people possess courage—it is twin to hope—and will face facts The cold hard fact of the matter is that tuberculosis causes more deaths among young people, between fifteen and twenty four, than any other disease What are they going to do about it? If they do nothing, how can the fight be won?

What can they do about it? First, learn the facts Tuberculosis is preventable It is curable It is not hereditary It is a communicable disease spread only by close contact with a person whose sputum is filled with tubercle bacilli Secondly, know the weapons with which the disease is being fought the tuberculin test, a harmless skin test which reveals the presence of infection, the x-ray, which shows the degree of infection and disease, the sanatorium, and the surgical methods of treatment. Also learn the importance of the practice of good daily health habits, which help prevent the disease from developing There's a reason for adequate rest, well balanced meals, fresh air, and exercise!

How can this be done? The National Tuberculosis Association and its affiliated associations are hard at work on this problem of youth The tuberculin testing of high school and college students is spreading rapidly in all sections of the country and the interest and support of high school and college officials in this work is indicative of their recognition of its importance The first national conference on college hygiene, held at Syracuse University in 1931, laid down specific recommendations for the inauguration and conduct of an adequate tuberculosis program among college students, which includes not only tuberculin testing and xraying, but also routine instruction in the personal and community aspects of the disease This conference,

*Published to promote the success of the Seal Sale for 1935

sponsored by the American Student Health Association and the National Health Council was initiated by the National Tuberculosis Association and its Proceedings were published by the same organization. Now plans are under way for another conference to be held in 1936 to review the recommendations of the Syracuse meeting and strengthen and improve them in the light of five years' experience. The National Tuberculosis Association is closely associated with this undertaking also.

In the high school field much headway is being made. Field trips to local clinics and sanatoria arranged by tuberculosis associations for high school students are being successfully carried on with the whole-hearted support of school authorities. The lively interest shown by the students and the battles of questions that have been turned upon the leaders of the expeditions prove once again that "youth will face facts" and is eager to know the why and the wherefore of things. Viewing the tubercle bacillus under a microscope is a thrilling experience and the student who has done so is likely to become a missionary in the cause of spreading the facts about tuberculosis. A friendly talk with the superintendent of the local sanatorium and a visit with him to the x-ray room will familiarize the young adolescent with the weapons used in the fight against this preventable disease and dispel any lurking fears he may be harboring. It is indeed curious how many otherwise intelligent adults still possess an unreasoning fear of tuberculosis. It is of course a "hangover" from the old days when a diagnosis of tuberculosis meant tragedy.

Will youth accept this challenge? Will high school and college students lend a hand to speed the fight, win the victory and place tuberculosis in the limbo of ancient and forgotten diseases that have plagued humanity? The campaign is financed by the annual sale of tuberculosis Christmas Seals, a penny each, so everyone may have a share. Buy and use these Christmas Seals. They are messengers of health and hope and happiness. They tell of the courage and faith which has insured the success of the fight thus far. But besides sharing in the purchase of these little stickers learn the facts about tuberculosis and help your local state and national tuberculosis associations in their efforts to spread the truth about this preventable curable communicable disease.

CORRESPONDENCE

COMPULSORY SICKNESS INSURANCE

November 26 1935

Editor *New England Journal of Medicine*

Regarding the stand of the State Society against Compulsory Sickness Insurance for low income groups

The principle of insurance is sound. It is better for the cost of illness to be spread over a lifetime than for it all to come when a person is sick and unable to work.

It is stated that physicians give a hundred million dollars worth of service to the clinics, free each year. Besides this there is a vast amount of medical service outside the clinics that is never paid for. Why so bitterly oppose a system of insurance that would pay physicians for these services?

Yours very truly

MILMAN PEARL, M.D.

Brookfield Mass

A CORRECTION

Editor *New England Journal of Medicine*,

In my paper on "Myxedema Heart: Report of a Case" (*New Eng J Med* 213 918 1935) an error was made in the interpretation of the published electrocardiogram dated December 5 1934. Because of the slight irregularity and the marked artifact in Lead I it was wrongly interpreted as being auricular fibrillation. Because of this the paragraph in the discussion referring to auricular fibrillation does not apply.

Sincerely yours,

JULIAN O GALT

313 Commonwealth Avenue Boston Mass

THE PROBLEM OF CRACKED NIPPLES

November 22 1935

Editor *New England Journal of Medicine*

Many physicians and nurses and even some obstetricians fail to appreciate the true significance of cracked nipples. Many still adhere to the futile application of mild astringents during pregnancy and to such palliative measures during the puerperium as demulcents, styptic nipple shields, or the breast pump. They assume the cause to be the innate delicacy of the tissue of the nipples or the unusual vigor of the jaws of the nursing infant.

In my personal experience of more than twenty five years the actual cause of such fissures of more than transitory duration has invariably been found to be trauma from suckling due to insufficient or deficient lactal secretion. There has been a concomitant restlessness or excessive crying of the baby with a tendency to lose weight or at least not to gain. Rational therapy obviously should be directed to augmenting the supply of milk with complementary feedings.

Sore nipples therefore should be recognized as a cue in the demand for partial or total weaning of the nursing babe.

Yours truly

G W HAIGH, M.D.

Worcester Mass

VOMITING OF PREGNANCY

Editor *New England Journal of Medicine*

I was much interested in reading the article on "Vomiting of Pregnancy" which appeared in The *New England Journal of Medicine* in a recent issue.

213: 235 (Oct. 3) 1935

It seems to me that he is on the right track and that his ideas concerning its treatment will eventually be accepted

For the past four years I have been interested in this condition and was led to the same conclusions as regards treatment, but by a different method of approach

For the last ten years I have been experimenting with auscultation of the abdomen and, in a number of functional and pathological conditions, have noted the presence of exaggerated peristalsis such as nervous indigestion, acute alcoholism, cyclic vomiting of children, and the early vomiting of pregnancy. I am not concerned here with vomiting in the later months of pregnancy

There is a normal peristaltic rate and an abnormal. The normal rate varies from five to ten faint tinkles per minute, the truth of which any physician can satisfy himself if he will listen to the abdomens of thirty or forty healthy young adults. The normal rate seems to be remarkably constant.

When there is some abnormal stimulation of the sympathetic nervous system the peristaltic rate increases. The rate varies from fifteen sounds per minute to a continuous gurgle. The quality of the sounds changes also. The normal high pitched tinkle is replaced by a harsh low pitched gurgle. Occasionally the sounds are so loud that it is not necessary to use a stethoscope to hear them.

Occasionally, in cases of acute indigestion, seasickness, and in severe cases of vomiting of pregnancy, spasm is also present and may be so intense as to prohibit peristalsis altogether which temporarily prevents any sounds being heard. In many cases of very acute indigestion the writer has noted this condition, and after the administration of 1/50 of a grain of atropine has noted the presence of active peristalsis. It may prove to be the case that vomiting does not occur until there is a certain amount of spasm. In this condition atropine seems to be more effective than phenobarbital although both are necessary.

During the last four years the writer has collected a series of twenty cases of vomiting in early pregnancy. All but two of them were mild or of moderate severity and all responded quickly to phenobarbital given by mouth. In a few cases where vomiting prohibited its oral administration, sodium luminal was given intramuscularly. In these cases the response to treatment was immediate and surprisingly effective.

About a year ago two severe cases were admitted into the North Country Community Hospital in Glen Cove, Long Island. They entered at nearly the same time. One of them had been able to retain practically nothing in her stomach for a period of three weeks and had lost twenty pounds in weight. The other had been vomiting continuously for about two weeks and had lost fifteen pounds in weight. Both had been under severe mental strain, their husbands being without work. Both had negative physical examinations except for the presence of acetone in the urine and very active peristalsis.

These patients had been in the hospital for several days before I came on service, and had been treated in the usual manner with fluids and glucose which had resulted in very little improvement.

The first day they were given five grains of sodium luminal intramuscularly in divided doses, and three doses of atropine sulphate 1/100 of a grain. The second day they were given four grains of sodium luminal and two doses of atropine. No other treatment was given. In both cases the vomiting ceased within forty-eight hours, and both were able to retain some nourishment on the second day of the treatment. For the next three or four days, phenobarbital (grains ½) was given every four hours. In neither case was there a return of the vomiting. The patients remained in the hospital a few days and in two weeks both had nearly regained their normal weight.

This is only a small series of cases and I am in no position to judge whether the condition of hypermotility and its response to phenobarbital would hold true in a much larger series, but other physicians have told me that they have had success with this treatment.

Very truly yours,

NEIL C STEVENS, M.D.

Walpole, N. H.

SUPRARENAL CORTEX IN THE TREATMENT OF VOMITING OF PREGNANCY

Editor, *New England Journal of Medicine*,

In the October 31, 1935 issue of *The New England Journal of Medicine*, under the editorial section of Obstetrics and Gynecology, is a treatise on "The Treatment of Vomiting of Pregnancy."

In the discussion of therapy for this condition many types have been included. Nowhere, however, is there any mention of Suprarenal Cortex (Armour's).

This, I believe, is a serious omission because the condition may lead to therapeutic abortion, which is absolutely forbidden in some religions, or may lead to a profound mental shock to those parents who desire children of their own. Therefore, any form of therapy which has already been shown to be of some value, particularly in preventing abortion, is worthy of trial and certainly worthy of being included in a treatise of this sort.

Suprarenal Cortex (Armour's), given either intravenously or orally (the latter after vomiting has subsided), has already proved to be of marked benefit in some cases in our hands. Our preliminary report (by Dr Joel M. Melick and myself) appeared in the *Journal of Obstetrics and Gynecology*, Volume 29, page 602, April, 1935. Since that time more than fifty cases have been so treated, some being of mild degree, others moderate and still others who would be classed as hyperemesis gravidarum. In the first group there have been three failures and in the latter two groups, in no instances have we had a single failure. The group collected to date is admittedly inadequate for a critical analysis of the results, yet this number is sufficient to bring this therapy out

of the realms of philosophical probabilities. Certainly it should be given a trial when other measures fail. We have had no untoward effects from the suprarenal cortex itself in any of our cases. I am in hearty accord with the discussion that brings to light the possible complications of avitaminosis and dehydration.

It may be well at this time to stress the fact that we have used only Armour's products in this form of therapy. It is a well known fact that the strength and the hormone itself changes depending upon the method of extraction. No two manufacturers extract the whole gland exactly alike. It is therefore suggested at the present time that the Armour product be used exclusively until it is fully determined experimentally whether other manufacturers' products may be used in the same way.

If I did not fully appreciate the extreme importance of any efficacious therapy in this condition I would not ask you to bring this matter to the attention of your readers, but fully believing in this, I hope that you will have the kindness to supplement the treatise already printed with that expressed above.

Sincerely yours

WILLIAM FREEMAN M.D.

P. O. Box 489 Worcester Mass

November 14, 1935

OFFICIAL ACTION OF THE BOARD OF REGISTRATION IN MEDICINE

State House Boston

New England Journal of Medicine

This is to inform you that at a meeting of the Board of Registration in Medicine held November 15 1935 the Board voted to revoke the license of Dr John F. Cummings, of Brockton for conviction in court on a charge of abortion.

Yours very truly

STEPHEN RUSHMORE, M.D., Secretary

RECENT DEATHS

SOUTER — WILLIAM NORWOOD SOUTER, M.D. of Portsmouth (New Castle) New Hampshire died at his home, November 24 1935 after a long illness.

He was formerly a practitioner in Boston and held positions on the teaching staff of the Harvard Medical School and the Massachusetts Eye and Ear Infirmary.

Dr Souter was born in Virginia in 1861 and graduated from the University of Maryland School of Medicine and College of Physicians and Surgeons of Baltimore in 1886. His practice had been restricted to ophthalmology.

His widow Mrs Mary L. (Benton) Souter nee son Louis and a daughter Helen, survive him.

COY — SETH WILLARD COY M.D., of 34 Princeton Street East Boston, died at the Winthrop Hospital November 28 1935 the result of being struck by an automobile.

Dr Coy was born in Boston in 1868 and after being educated in the public schools of this city attended the Boston University Medical School and graduated therefrom in 1889. He was a member of the East Boston Medical Society and the Balbec Masonic Lodge.

His widow Mrs. Grace Coy and two sons Ralph Coy and Edward Coy survive him.

*Recurrence.

of the realms of philosophical probabilities. Certainly it should be given a trial when other measures fail. We have had no untoward effects from the suprarenal cortex itself, in any of our cases. I am in hearty accord with the dissection that brings to light the possible complications ofavitaminosis and dehydration.

It may be well at this time to stress the fact that we have used only Armour's products in this form of therapy. It is a well known fact that the strength and the hormone itself changes depending upon the method of extraction. No two manufacturers extract the whole gland exactly alike. It is therefore suggested at the present time that the Armour product be used exclusively until it is fully determined, experimentally whether other manufacturers' products may be used in the same way.

If I did not fully appreciate the extreme importance of any efficacious therapy in this condition, I would not ask you to bring this matter to the attention of your readers but fully believing in this, I hope that you will have the kindness to supplement the treatise already printed with that expressed above.

Sincerely yours

WILLIAM FREEMAN M.D.

REPORT AND NOTICES OF MEETINGS

THE CAPE COD HEALTH BUREAU ASSOCIATION

At the fall meeting of the Cape Cod Health Bureau Association in Hyannis on November 15, members of the health departments of most of the towns of Barnstable County assembled for a business session and to listen to an address by Dr Joseph E Barrett, Assistant Commissioner of the State Department of Mental Diseases. The President, Dr G E T Ward of Orleans, was in the chair, and the business session included records by the Secretary, Mr C R Bassett of Yarmouth, and a review of health conditions in the county the past six months by Dr A P Goff, County Health Officer.

Dr Barrett first defined the department which he represented, and then outlined some of the principal phases of its work. It is not, as many suppose, a branch of the Department of Public Health, but is independent, with only one other state department exceeding it in magnitude.

In 1863 there was established the State Board of Charity, which in general cared for health matters, hospitals, penal institutions, etc., and charities. Then there was constituted a Board of Health, Lunacy and Charity, later the Board of Health was separated, and still later Lunacy became Mental Diseases. In 1919 the various boards were legally named "departments." Massachusetts was the first state in the Union to establish a Department of Mental Diseases. The Divisions of the Department include those caring for medicine, mental hygiene, statistics and finance. There are sixteen hospitals maintained by the Department, and in addition there is the prison for the criminal insane at Bridgewater, which, when the new hospital for it at Norfolk shall have been established, will be given over to its care.

Dr Barrett stated that of the one million hospital beds in the country more than half are for the mentally ill. In Massachusetts, besides the sixteen State institutions, there are two Federal hospitals and twenty-nine licensed private ones. Of the 29,000 known mental patients in the State, 26,000 are in the hospitals, 21,000 insane and 5,000 feeble minded. The mentally ill number about one in 162 of the population. The cost of the sixteen institutions in 1934 was \$9,700,000, or about \$6.00 per week per person. Of the State dollar expended, about fifteen

cents goes for the mentally ill. In 1934, 6,824 persons were admitted to the hospitals, with the discharges in the same period, about half as many. The death rate is naturally high, for many are physically weak at time of entrance, while there are many elderly individuals. The number of feeble-minded in the State is about 90,000, listed partly through school clinics. So far as the schools are concerned the law requires the town authorities to provide a special school for them if there are as many as ten backward children in a district.

Clinics form a special feature of the program of the Department, and these include outpatient clinics as well as those at the hospitals, and number in all above one hundred. Social workers have the opportunity to discover the feeble-minded, and do good service in this matter. "There are some who think that all such cases should be hospitalized," said Dr Barrett, "but in fact, all do not need this. Early training may be effective, and many are reclaimed through this means." The general problem had best be attacked from the community side, and the clinics are valuable in this. One evidence of their agency is thought to be in the decreasing readmission rate, the statistics of other states showing in general an increase in this rate.

Following the address the gathering became a round table for the intimate discussion of many questions suggested by the address, which had local interest to the assembled health workers.

NEW ENGLAND DERMATOLOGICAL SOCIETY

The next meeting of the New England Dermatological Society will be held on Wednesday, December 11, 3 P.M., at the Boston City Hospital.

J HARPER BLAISDELL, M.D., *Secretary*

THE SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the office of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, December 17, 1935, at 12 noon. The speaker will be Arthur K Paine, M.D., F.A.C.S., Surgeon in Chief, Boston Dispensary, Consulting Obstetrician, Beth Israel Hospital, Chief of Staff, Evangeline Booth Hospital, Professor at Tufts College Medical School, and Assistant Professor at Harvard Medical School. His subject will be "Progress in Obstetrics." The usual luncheon will be served, and all physicians are cordially invited to attend this meeting.

WILLIAM HARVEY SOCIETY

The next meeting of the William Harvey Society will be held Friday, December 13, in the Auditorium of the Beth Israel Hospital, Boston, at 8.00 P.M.

PROGRAM

Speaker Dr Martin H Dawson, Assistant Professor of Medicine, Columbia University

Subject "Rheumatoid and Osteo-Arthritis"

Chairman Dr Nathan Sidel, Assistant Professor of Medicine, Tufts College Medical School

NEW ENGLAND PHYSICAL THERAPY SOCIETY

MEETING AT THE RING SANATORIUM AND HOSPITAL

The New England Physical Therapy Society will meet on Wednesday evening December 18 as guests of the Ring Sanatorium and Hospital Arlington Heights.

The address of the evening will be presented by Clifton T Perkins M.D. Assistant Superintendent of the Worcester State Hospital. The discussion will be opened by Winfred Overholser M.D., Commissioner of the Massachusetts Department of Mental Diseases.

A buffet supper will be served at 6:30. The meeting will open at 8.

BOSTON FLOATING HOSPITAL

MONTHLY STAFF MEETING

The next meeting of the Boston Floating Hospital will be held Friday 12 noon to 1 P.M. December 13 in the Board Room Boston Floating Hospital.

PROGRAM

Presentation of a Clinical Pathological Picture of Chronic Nephritis or Essential Hypertension in a Ten-Year Old Child.

Discussion by Allan Botter M.D., Children's Hospital and Soma Weiss M.D., Boston City Hospital.

ELIZABETH W. BARSON M.D. *Physician in-Chief*

PROGRAM OF THE SPRINGFIELD MEDICAL ASSOCIATION

In connection with the celebration of the three hundredth anniversary of the founding of the city of Springfield Massachusetts in or about May 1936 the Springfield Medical Association has arranged a program of meetings which will cover the important matters of medical history of that city.

Three meetings have already been held. At that of September 30 Dr. George L. Schadt presented a paper on "Medical Societies in and about Springfield, 1636-1936". At the meeting on October 28 two papers were presented, one by Dr. Robert A. Kilduffe on "High Lights in the History of Hospitals" and the other by Dr. Eugene Walker entitled "A Brief History of Springfield's Hospitals". At the meeting of November 25 Dr. Garry de N. Hough read a paper on "Medicine in Springfield 1636-1850".

The rest of the program follows:

December 16

Medicine in Springfield 1850-1900 — Dr. Frederick S. Hopkins.

January 27

Medicine in Springfield 1900-1936 — Dr. Lawrence D. Chapin.

February 24

Medicine in Massachusetts and New England from Cow Path to State Road — Dr. Reginald Fitz, Boston Mass.

March 30

The Development of Surgical Practice in Springfield — Dr. John M. Birnie.

April 27

The Development of Non-Surgical Specialties — Dr. Allen S. Johnson.

The Development of Surgical Specialties — Dr. Eugene W. Beauchamp.

May 18

The Development of Medicine in the United States 1636-1936 — Dr. Henry E. Sigerist. The Johns Hopkins University Institute of the History of Medicine. Baltimore Maryland.

The membership of the Springfield Medical Association is limited to fifty physicians. It was organized January 29 1905 and reorganized May 29 1908. The officers are as follows:

President, George L. Schadt. Vice-President, Garry de N. Hough. Secretary and Treasurer, Daniel R. Wheeler. Executive Committee, F. S. Hopkins, F. H. Baehr, J. P. Derby.

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held in the Peter Bent Brigham Hospital Amphitheatre (Shattuck Street Entrance) Tuesday evening December 10 at 8:15 P.M.

PROGRAM

Presentation of Cases.

Types of Syncope, Their Mechanism and Treatment. By Soma Weiss, M.D.

Medical students and physicians are cordially invited to attend.

MARSHALL N. FULTON M.D., *Secretary*

BOOK REVIEW

Free Medical Care (Socialized Medicine) E. C. Buehler 360 pp New York Noble & Noble, Publishers, Inc \$2.00

This book is the second of this author's series of books edited for the purpose of furnishing material for debaters

In the first part it summarizes conditions as they are in regard to medical service and presents some of the problems which exist This is done in a clear and fair manner

There then follows a splendid bibliography of the articles on this subject that have been published from 1929 to the Spring of 1935

The second half of the book consists in a reproduction of an appreciable number of leading articles mentioned in the bibliography These articles include those in favor of and those opposed to socialized medicine

Finally it gives a summary of the various experiments already being tried out in various parts of this country along these lines

At the end the recommendations of the majority and the minority on the Committee on the Costs of Medical Care are added and the recent votes of the American Medical Association, American College of Surgeons and the American Dental Association on these problems

It is an excellent reference book to any one wishing to become familiar with the various points of view on this complicated subject The author does not add any personal opinions

NEW ENGLAND SURGICAL SOCIETY

DIAPHRAGMATIC HERNIA IN CHILDREN WITH A REPORT OF THIRTEEN OPERATIVE CASES*

BY PHILEMON E. TRUESDALE, M.D.†

OPERATIONS undertaken for the cure of diaphragmatic hernia occurring in children are rare despite numerous reports to the contrary. A thorough search of the literature emanating from New England has revealed no operative cases other than those published by the author. Perhaps such operations have been done but not reported. We have authentic information about one child in New England who survived and three in New York State who died after operation.

Vannesson in 1912 reported thirty four cases of congenital diaphragmatic hernia in the new born (all discovered at autopsy) and stated that the prognosis was very grave and treatment nil. In 1914 Broca, Professor of Surgery Faculté de Médecine, Paris, described the condition accurately. He stated that nearly all of the cases were discovered at autopsy. Among the few patients operated upon for intestinal obstruction, strangulation of the bowel was the condition usually found. The mortality associated with operative interference in these cases was ninety per cent. In 1917 Holt described a case of diaphragmatic hernia in a child sixteen months old who died of pneumonia at the age of three and one half years. In conclusion the author stated that the hernia was not amenable to treatment. Many books on pediatrics such as those published by Ehrenfest, 1922, Cutler 1923, and Haynes, 1928 failed to mention the subject. Hess, 1922, and Lucas, 1927, devoted little space to this topic. In Abt's work on pediatrics, Richter made the statement that congenital large hernias, present from birth offer little opportunity for surgical treatment. In 1926 Morse in a one page discussion of diaphragmatic hernia came to the following conclusion:

"Hernia of the diaphragm is a very uncommon condition. The chance of closing the defect in the diaphragm is very small but there is a chance. Operate and give the baby what chance there is, unless

the defect by x ray is shown to be very large. In any case the chance for life is small."

Graffith and Mitchell in 1927 devoted two paragraphs to the subject with the following comment:

"The condition is uncommon in children. There is no treatment possible except an operative procedure if incarceration occurs, and this is not likely to be of any avail."

Bolling in 1928 made the following statement:

"In 1925 Hedblom was able to find only 22 cases in patients under twelve in whom operation had been carried out. In the non obstructed cases thoracotomy affords greater opportunity for closure of the hernial orifice."

He cited the case of Dr McLean's, a baby one year old treated medically.

In 1929 Kelley expressed the following opinion:

"One should operate only if there are distressing symptoms. The hernia may be inoperable because of the size of the defect. The hernial mass may be too large to fit the thorax. If such is the case and structures become strangulated, the constriction should be relieved and steps taken to prevent recurrence, and no further attempt should be made to reduce or close the hernia opening."

As late as 1934 Trémolières affirmed that the great congenital diaphragmatic hernias were not in the surgical domain. He warned surgeons to attempt only those cases in which the hernial orifice could be easily closed. Often in these congenital cases, he continued, the torn edges of the diaphragm are so thin and friable that suturing is illusory and even with good tissue recurrence is the rule. He believed that treatment should be a palliative therapy except in the traumatic cases and in those in which volvulus, strangulation or perforation exists and demands immediate surgical intervention.

Read by title at the Annual Meeting of the New England Surgical Society at Manchester, N. H., September 7, 1935.

Greenwald and Steiner in their report of eighty-two cases of congenital diaphragmatic hernia in children (1912-1928) found that forty-seven cases were diagnosed at autopsy, in four the method was not stated, probably discovered at autopsy. Intravital diagnosis was made in twenty-seven cases, six clinically and twenty-one at routine x-ray examination. In addition to those mentioned by Greenwald and Steiner the following authors have reported cases found at autopsy: Anosoff (2 cases), Barford, Barney and Evans (2 cases), Becker, Benda, Blumenfeld, del Carril, Cautley, Chapman, Crumbie, de Brum, Dérome, Dodds, Dunne, Falcone, Giangioffe, Gilford, (2 cases), Grénet, Guy, Harper (2 cases), Holt, Hume, Jacobs (4 cases), Karl, Kleine, Larson, Liepmann, Longaker, Lull, Massot, McLannahan, Metcalf, von Mikulicz-Radecki, Monks, Newberger, Oliphant, Palicz, Pistocchi, Putschar, Quénu, Rawes, Reichard, Reviglio, Salomon, Sighinolfi, Smith, Stenzel, Vichard, Williams, H. O., Williams, P. F., and Zamorani.

Other reports in which the condition was discovered by routine x-ray examination have appeared by the following authors: Abercrombie, Ager, Bradley, Brown, Brun, Cabitto (2 cases), del Carril, Connors, Conybeare, de Elzalde, Epstein (3 cases), Greenway, Guastanian and Antonelli, Guastanian and Estiu, Haroen, Healy, Jansen, Jenkinson, Kinney, Klebs, Lamarque, Lauenstein (2 cases), Menville, Morrison, Nalbant, Nobécourt, Pancoast, Paterson, Philips, Rivarola, Roberts, Rossi, Schisler, Schonfeld, Sennels, Stimson, de los Terreros, Thursfield, Trémolières, Tuscherer, van Gelder, and Viallet. All but seven of these patients, ranging in age from one week to fifteen years, were alive at the time the articles were written. Klebs' patient lived six years with the left diaphragm entirely absent. De Elzalde's patient died at the age of four months. He stated that his patient did not do well from birth, but that even when operation is done under favorable conditions, only forty-one per cent of the patients survive. In Jenkinson's case the condition was found by chance when rib resection was done for empyema.

The following authors report cases in which the condition was diagnosed correctly clinically: Ankerhold-Hellner, Barrett and Wheaton, Bonzango, Donovan (3 cases), Fischer, Hunter, Johansen, LeWald, Peter and Pokorny, Philippi, Trillat and Belly (2 cases). In nine cases the diagnosis was confirmed by autopsy. Ankerhold-Hellner's patient died at the age of five weeks as surgical intervention was being considered. In Hunter's case the infant's heart was kept beating for an hour, the left lung was one fourth the normal size and had two lobes. The right lung had three rudimentary lobes. Only the rudiments of the left half of the diaphragm were present indicating incomplete fusion in embryonic life. The appendix was high

in the epigastrium, the stomach unrotated in the chest and the ascending and transverse colon in the left thorax. Trillat and Belly's two cases were in female infants who died shortly after birth. These two cases were encountered in 2,180 deliveries.

In Philippi's and Fischer's cases the parents would not consent to operation. LeWald interpreted his case as congenital short esophagus and thoracic stomach, no defect was seen in the diaphragm at the time of operation and the stomach could not be returned to the abdomen because of the very short esophagus.

October, 1931, we published a series of twelve operative cases of diaphragmatic hernia from our clinic, nine of which were in children. Each was without a sac, false hernia or *hernia spuria*. Figure 2 shows the usual sites of herniation in

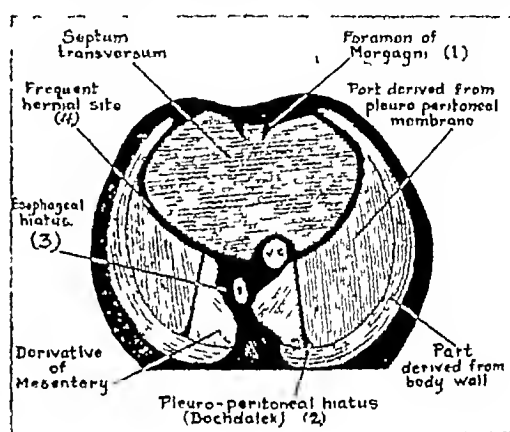

FIG 2

the diaphragm. None of the apertures in children were at the esophageal hiatus, a common site of hernia, site 3. Three were through the foramen of Bochdalek, site 2. In all the rest of the cases operated upon, including the four to be reported, the tear extended laterally to the periphery of the diaphragm in the weak area in the dome corresponding with the point of fusion between the pleuroperitoneal membranes and the septum transversum, site 4. In one of these cases there was a second tear at the foramen of Morgagni, site 1. In the traumatic cases, we have assumed that a congenital origin pre-existed because of the thinness of the diaphragmatic musculature at the site of the tear; the sluggish response to the faradic current indicating trophic disturbance in this area, and the presence of other congenital malformation such as harelip. Thus congenital malformation of the diaphragm was doubtless an antecedent of the traumatic injury. As Quénu remarked in 1920, it is very rare for a normal diaphragm to sustain injury even in cases of serious trauma.

Herewith follow the reports from our clinic of four additional operative cases of congenital diaphragmatic hernia in children.

CASE X. A. J. McH., No 33626. This patient was a girl ten years old born May 11, 1924 in normal labor. Soon after birth, symptoms of labored breath

ing cyanosis, and altered digestion occurred. At the age of two and one-half years her ailment was diagnosed as pulmonary tuberculosis. She was sent to Denver Colorado with her mother. X-ray examination at the Children's Hospital there revealed a diaphragmatic hernia with the entire stomach and loops of intestine in the left pleural cavity (See figure 3.) The examiners found no evidence of tuberculosis. Physicians stated that the hernia was so large and so involved that it could not be cured by operation and that she would remain in a precarious state.

Despite her handicaps however the patient continued to live the life of a cripple with constantly disturbed gastrointestinal respiratory and circulatory functions. She was subject to frequent attacks

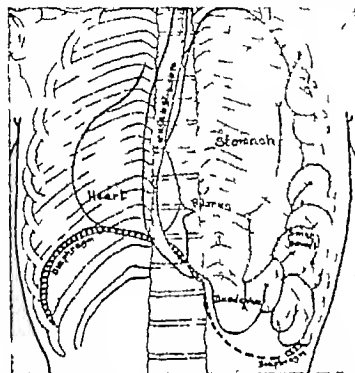

FIG. 3. Case X. Drawing made from x-ray film showing inverted stomach and loops of intestine in the left pleural cavity at 2 1/2 years.

of smothering cyanosis coughing and vomiting. Her physical activity was greatly limited because of the dyspnea, aggravated by the intake of food. During the past year these spells became more frequent and more severe. The attacks came on suddenly; they began with hiccoughing and coughing followed by choking, cyanosis and generalized convulsions. She would be in terrifying agony until relieved by hiccoughing and vomiting. Her mother stated that in several of these attacks during the past month the child had the appearance of impending death. Her diet was limited. She was able to take sparingly of fish, cereal, grape-jelly and ice cream. Water and most fluids however distressed her immediately. The two weeks before her arrival were spent at Carlson Hospital Omaha. There it was felt that her condition was so critical because of obstruction that, unless relieved by surgery she would succumb in one of her attacks.

Our physical examination revealed a poorly nourished pigeon-breasted pale slender girl. There was left border dullness at the sternum with location of heart sounds revealing a dextrocardia. The left chest was barrel-shaped hyperresonant, full of rumblings tinkles and peristaltic sounds. The abdomen thorax showed the rachitic rosary. The abdomen was markedly scaphoid. The body diameter at the umbilicus was twice that measured at the nipples. X-ray examination with barium meal and enema revealed an inverted stomach, all the small intestines two-thirds of the colon, cecum, and appendix to the left chest.

A proteic diet was employed for two weeks. Dur-

ing this period attacks of bowel obstruction occurred at about the same time each day lasting from one-half hour to two hours. They were relieved by frequent change of posture and massage of the abdomen. Enemata could not be tolerated.

Operation was done March 4 1935. Under gas-oxygen-ether positive-pressure anesthesia administered by Dr. A. H. Miller the thorax was opened by a semilunar incision beginning over the costal cartilages portion of the fifth rib sweeping downward and backward over the sixth and seventh ribs ending over the tubercles of the seventh and eighth ribs posteriorly. The sixth and seventh ribs were removed. The pleura was then opened and the flap thrown back on its base.

This opening exposed the contents of the left pleural cavity which consisted of the inverted stomach, omentum entire length of the small intestine the appendix ascending and transverse colon and the spleen. (See figure 4.)

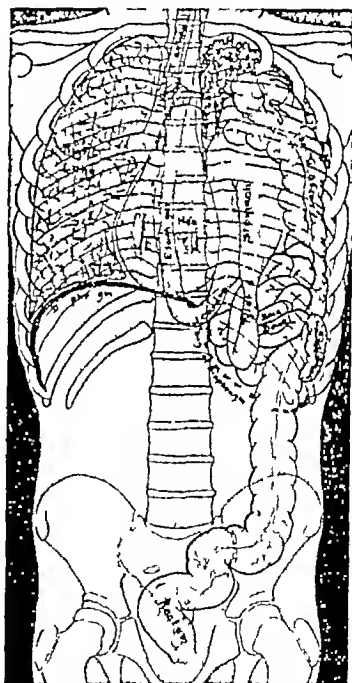

FIG. 4. Case X.

The stomach was only moderately distended up-side-down in position and occupying much of the apical and posterior portions of the left pleural cavity. The ileocecal region with the appendix was just below the clavicle. Much to our surprise the small bowel was well deflated and coiled to a comparatively small mass above the diaphragm which was found depressed below the level of the costal arch. The spleen lay in the costophrenic angle. The entire large omentum and all the large intestine ex-

cept the descending colon were above the diaphragm. The liver edge could be discerned protruding through the aperture. The lung was an apparently rudimentary organ entirely collapsed.

More room was required to deal with the hernia, so the eighth and ninth ribs were removed. Here and there adhesive bands which attached the omentum and viscera to lung and pericardium were severed. The hernial opening was discovered to be transverse through the middle of the diaphragm about five inches in length and extending from the para esophageal musculature toward the left to the

were applied at intervals of about an inch. The thoracotomy wound was then closed with interrupted sutures of silkworm gut.

The patient's condition during the operation was not alarming at any time. The duodenal tube was passed and about one ounce of brownish fluid evacuated from the stomach. Hypodermoclysis of 800 cc. of saline was given. The following day the child took small amounts of water and milk by mouth. Temperature was 100.2° by rectum, pulse 140, respirations 24. Except for incisional pain, the general condition was satisfactory. During the early

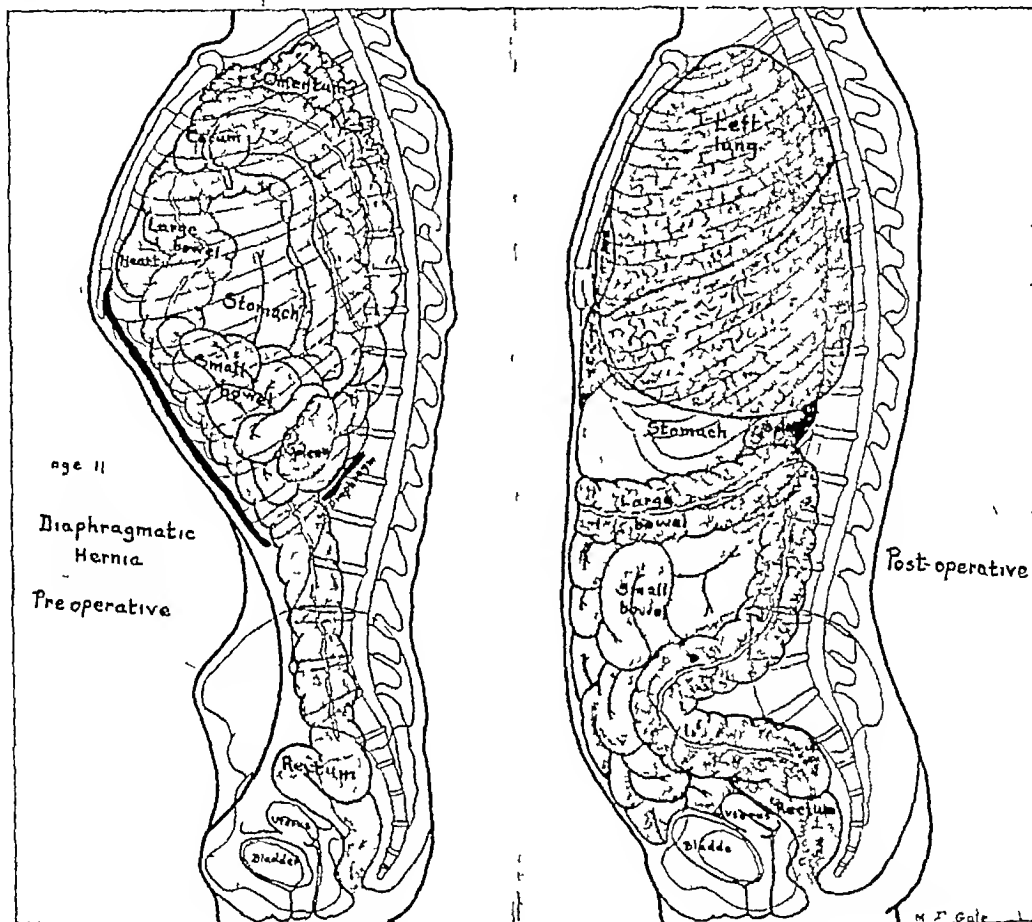

FIG 5 Case X. Profile view of organs and contour of the body before and after operation

periphery of the diaphragm. The structures in the aperture, particularly the spleen and intestines, were firmly adherent to the margin of the opening above and below. Separating and freeing these was most difficult and time-consuming, and the most dangerous part of the operation. When accomplished the edges of the aperture were grasped with Allis forceps, and the margins raised and spread apart. The operation of reduction was then begun.

First the spleen was severed from its attachments and passed downward through the opening, then the small intestines and omentum reduced. No little difficulty was met in replacing the colon and stomach. This step was finally accomplished by using a dry gauze sponge as a contiguous carrier. As the long narrow sponge was tucked downward through the hole, it carried the bowel with it. Eventually the colon and stomach were reduced in this manner. Finally the opening in the diaphragm was closed by a running suture of black silk (No. 7). Several interrupted sutures of the same material

morning of March 6 she vomited frequently for a period of five hours. The mother had been warned never to give the child an enema because at one time when given an enema at the hospital in Denver the child became deeply cyanosed, dyspneic, and nearly expired. Now an enema was clearly indicated, and we reasoned that if the hernia was reduced, the success of an enema was of vital significance. It was given and to the great surprise of mother and child, no trouble ensued. The result was satisfactory and this proved the turning-point in the convalescence. Vomiting ceased. At noon she drank six ounces of orange juice. The following day, March 7, the patient ate with relish a portion of macaroni and cheese. She soon showed marked improvement and commented eagerly on the appearance of her abdomen which was no longer scaphoid but rounded.

By March 10 the temperature was normal. The bowels continued to move well with enemata. March 26 x-ray examination showed an exudate in the

left chest and about 500 cc. of turbid fluid was aspirated. April 11 she was discharged recovered having gained twelve pounds during her convalescence. She now swims rides a bicycle, and other wise leads a strannous life. Before operation the patient measured four feet ten inches in height and weighed fifty-two pounds. By August 12 her weight was seventy-two pounds and she was two inches taller. Figure 5 shows position of organs before and after operation.

CASE XI J N No 33908 An intelligent, coöperative boy of thirteen years poorly nourished and underdeveloped was admitted March 30 1925 with the following history:

Except for frequent spells of "colic" this child seemed normal until the age of eleven months. At that time a severe cold with paroxysmal coughing was thought to be pertussis. At fourteen months he had severe attacks of vomiting which lasted for five days and nearly proved fatal. Relief was finally obtained by enemata. X-ray film then showed congestion of the left lung. A diaphragmatic hernia was not detected. From the age of eighteen months attacks of vomiting came on every two weeks with intense upper abdominal pain and belching of foul smelling gas. There was no cyanosis or dyspnea. When five years old the boy had a second attack of "pertussis". After one severe coughing spell he was very ill and vomited thereafter every night for six months. Roentgen rays taken in Los Angeles showed pneumothorax and collapsed left lung. When repeated shortly afterwards in Oakland the films showed the colon protruding through the diaphragm into the left pleural cavity. At the age of six, left phrenicotomy was done in Oakland California without subsequent improvement. In spite of his physical handicap however the boy managed to lead a fairly active life.

Our physical examination revealed no abnormalities of eyes teeth or throat. The right chest was clear and hreath and voice sounds normal. The left chest was somewhat dull over the entire middle and lower portions with breath sounds diminished over these areas. Intestinal gurglings and murmurings were audible throughout the left chest. The heart was markedly displaced to the right with left border and maximal beat at the sternal line. Sounds were regular of good quality with no murmurs. Over the left scapula was a small phrenicotomy scar.

The abdomen was soft somewhat distended and tympanitic on the left side as far as the pelvic brim. There were no masses, spasm nor tenderness. Extremities were negative.

Examination of the blood revealed a mild grade of anemia with 3 840 000 red cells 5900 leucocytes and 75 per cent hemoglobin.

X-ray examinations April 2 1935 showed the cardiac end of the stomach displaced laterally lying above a narrow shelf like portion of the diaphragm. The thoracic portion of the stomach was larger during inspiration. The stomach was atonic, markedly dilated, and nearly filled the abdomen. The gastro rugae were thickened and tortuous. At six hours there was an eighty per cent residue in the stomach. All the small intestine, two-thirds of the colon cecum and appendix filled the left chest. At twenty-four hours the stomach still contained a small residue of harlum.

Operation was done April 8 1935 the thorax was opened in the same manner as described in Case X. The seventh eighth, and ninth ribs were cut and the flap containing the ribs reflected upward. The ribs were not removed. The chest contained the

cardiac end of the greatly enlarged stomach, the major portion of the colon with cecum and appendix, all the small intestine and the spleen (figure 6). The defect in the diaphragm extended laterally from the aorta to the periphery. Adhesions around and beneath the opening in the diaphragm were freed with great effort.

The viscera were replaced with some difficulty. The aperture in the diaphragm was then sutured with silk and the operative wound closed with through and through mass sutures of silk worm gut.

Early postoperative progress was excellent with temperature nearly normal and bowel movements normal. On the third postoperative day 250 cc. of turbid fluid was aspirated from the left pleural

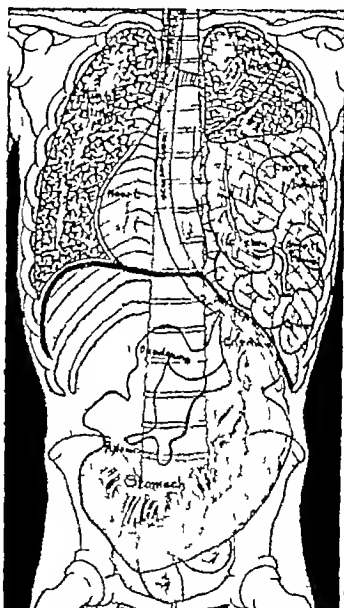

FIG 6

cavity. April 11 a chest tap yielded 250 cc. of blood-stained fluid. The following day a tube was inserted to facilitate drainage and a transfusion was given. The next two weeks the patient made steady progress. The chest was irrigated daily with chloramine. May 14 the patient complained of pain in the left shoulder. It was also noticed that the pulse rose to about 120 when the boy was active. To correct some degree of left scoliosis of the spine and relieve the pain in the left shoulder a plaster cast was applied May 29 with marked improvement in the patient's condition. The cast was removed June 11. The patient was discharged June 15 with a small sinus in the left chest still draining. August 1 the patient reported that he had gained ten pounds and was looking forward to entering school in California in September. Figure 7 shows the position of the organs after operation.

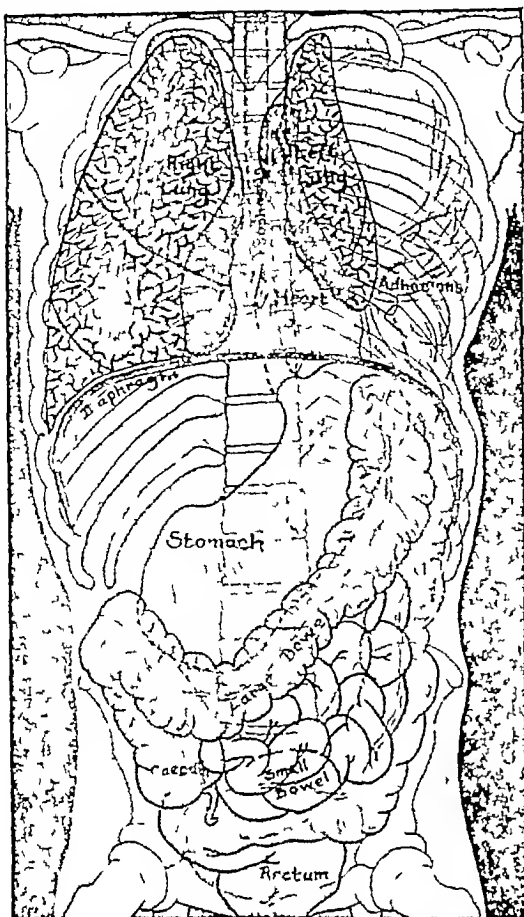

FIG 7 Case XI. A composite drawing from x-ray films taken after operation and showing small intestines and colon in their normal position below the diaphragm

CASE XII A boy, nine years old, the fourth child of normal parents. Delivery was by breech presentation. During infancy feeding the child was a difficult problem and cyanotic spells were frequent. When thirteen months old he was placed in a New

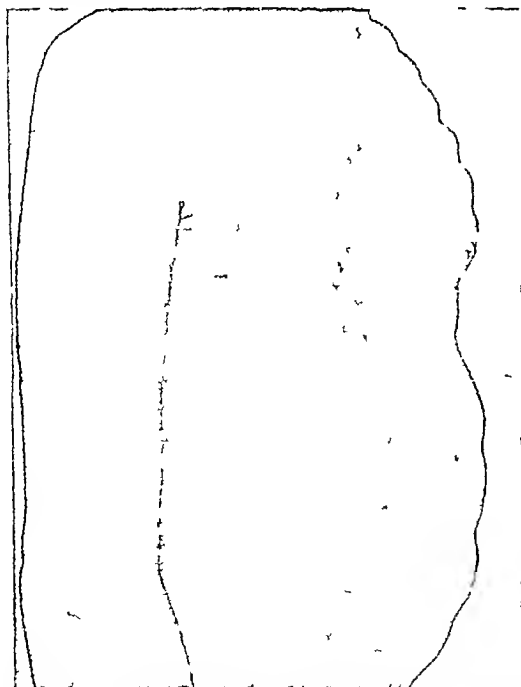

FIG 8 View of chest in Case XII showing depressed sternum.

York hospital for regulation of feeding. At this time x-ray examination revealed the small intestines in the left chest. Each night this child manifested thoracic distress relieved after vomiting. For four months prior to admission to our clinic April 5, 1935 these attacks had not recurred. The child played with his schoolmates and was an intelligent fourth grade pupil. Previous illnesses included rheumatic heart disease and the patient was reported to have had pneumonia three times. He complained of pains throughout his limbs and joints with intermittent rise of temperature.

Physical examination revealed a pale, slender boy of nine with choreiform movements. The tonsils were large and pitted. Blood pressure was 105/60.

The thorax was funnel shaped (Figure 8). The entire right chest was hyperresonant. The left chest was flat over the lower half with diminished breath and voice sounds. No peristaltic sounds were audible at the time of the examination. The apex of the heart lay to the right of the sternum. A violent cardiac impulse was seen in the right fourth interspace. The heart beat was vigorous, abnormally rapid, with a loud precordial systolic murmur. The electrocardiographic tracing revealed simple tachycardia and deep Q waves in leads 1 and 2 of uncertain significance.

A diagnosis was made of congenital diaphragmatic hernia with heart disease, rheumatic or congenital, and mitral stenosis. It was decided that the condition of the heart could withstand the operation for reduction and repair of the hernia, although the marked dextrocardia and funnel chest might present difficulty in the return of the heart to its normal position after reduction of the hernia.

A barium meal on April 8 revealed a portion of the stomach and all the small intestines in the left chest (See figure 9a). April 9 a barium enema showed all the colon proximal to the splenic flexure and appendix in the left chest (See figure 9b). At the base of the left chest laterally, there was an area which contained no loops of bowel and which was presumably occupied by the spleen.

April 13, 1935 operation was done by the thoracic route. The eighth rib was severed at each end, the flap thus made turned upward, and the ninth rib severed at one extremity. The heart was entirely to the right of the sternal indentation which formed an almost complete partition between the two sides of the chest. The rent in the diaphragm extended out to the midaxillary line, somewhat more posteriorly than in the two former cases. The large bowel was firmly adherent to the edge of the hiatus. The adhesions were very dense and tough, and had to be severed before the viscera could be replaced in the abdominal cavity. Part of the bowel could not be dissected free and was left attached to the underside of the diaphragm, the aperture being approximated above it. The rent was closed with a running suture of silk starting medially and continuing gradually toward the periphery. Near the outer edge several interrupted silk sutures were required to close the rent. The chest wall was closed with interrupted sutures of heavy silkworm gut. In the lateral sulcus of the diaphragm a small soft rubber tube was placed, secured to the parietal pleura with plain No 0 catgut and drawn out through a stab wound. Diathermic coagulation was used for all bleeders.

The patient reacted well immediately following the operation but increasing pallor was noticed, and the day after operation he was given a blood transfusion. Temperature was 101.6 degrees, pulse 130. Breathing was labored. Therefore he was placed in an oxygen tent with improvement in his condition, temperature between 100 and 101 degrees

and pulse 120. The following morning a chest tap yielded 400 cc. of dark bloody fluid. Auscultation revealed signs of pneumonia on the right side although x-ray examination showed no evidence of gross consolidation. There was a left hydropneumothorax, the fluid level being opposite the fifth interspace posteriorly. The mediastinum remained displaced with the right cardiac border in contact with the lateral wall of the chest. The patient was restless and dyspneic during the night of April 5. The following morning of the third postoperative day at about 5:00 a. m. he became cyanotic and expired.

A restricted postmortem examination through the incision revealed death due to asphyxia. The left

tained fluid. Both lungs showed marked congestion.

The lesson to be derived from this case lies in the recognition of the cause of the concealed hemorrhage which was an important factor in the cause of death. At first it was difficult to explain the presence of blood in the left pleural cavity. Upon minute inspection however two small veins were found open one in the costophrenic sulcus of the diaphragm and the other at the angle of the thoracotomy incision where the layers of the thoracic wall overlapped. Immediately after complete closure of the thoracotomy wound and artificial expansion of the left lung the negative pressure within the pleural cavity was artificially increased to or beyond the normal degree. The suction thus

FIG. 9. Case VII.

a. Roentgenogram after barium meal showing small intestinal loops in the left chest.

b. Roentgenogram after barium enema showing colon in left chest.

pleural cavity contained about 600 cc of blood stained fluid with a number of large clots. This blood apparently came from the lateral aspect of the diaphragm where it was cut for a short distance. The line of suture was intact and held firmly. The left lung was collapsed. The left pleural cavity extended beyond the midline, the heart being entirely on the right side with a considerable degree of torsion on the great vessels. The right ventricle was hypertrophied undoubtedly the result of pulmonary resistance. No valvular disease was demonstrable. The right lung and heart showed signs indicating asphyxia. Although much blood was lost most of which was replaced by transfusion, there was no recent copious hemorrhage to account for the rapid exit. Asphyxia was regarded as the most logical immediate cause of death aided by the left hemothorax. The right lung showed small areas of hemorrhage with

created probably kept the ends of these veins open and bleeding continued unimpeded in the free pleural cavity.

Inasmuch as no other source of bleeding could be detected it seems plausible to assume that, even from open ends of small vessels a sufficient amount of blood can be extracted by suction to jeopardize life. We suggest therefore exercise of the utmost care in obtaining complete hemostasis of all vessels communicating with the pleural cavity. Possibly the use of the diathermy instead of ligation of vessels may have been a factor in avoiding points of origin for bleeding.

CASE XIII. No. 34198. W. B. This patient was a boy eleven years old who had the appearance of a child of seven. He spoke haltingly and his mind seemed sluggish. His mother reported that his condition was normal until he was five years old. At

by a hit and run motorist, the tricycle was demolished and the handlebars were forced violently against his abdomen. He was taken to the Millard Fillmore Hospital, Buffalo, in a critical condition. For two months he complained of severe pain in his right chest. X-ray examination at this time showed a dark shadow in the right chest thought to be fluid. He suffered from dyspnea and difficulty in taking food. Two months later he was removed to the Children's Hospital where the diaphragmatic hernia was disclosed by x-ray examination. He remained there under observation for two years. His parents were informed that nothing could be done to cure the diaphragmatic hernia and that the in-

x-ray examination of the gastrointestinal tract with barium by mouth, showed the inverted stomach with its greater curvature at the level of the fourth rib and loops of small intestine in the left chest. (See figure 10a) May 11, the barium enema revealed the colon in the left chest, with constriction of the loops as they passed through the aperture in the diaphragm. (See figure 10b)

May 15, 1935 the hernia was repaired through a thoracotomy approach. Long sections of the eighth and ninth ribs were removed. In the left chest were the stomach, spleen, and most of the large and small intestines. The structures were adherent about the margin of an aperture which measured five-inches

FIG 10 Case XIII
a Roentgenogram after barium meal showing inverted stomach and intestines in the left chest.
b Roentgenogram after barium enema showing herniated colon in left chest

testines would probably become strangulated and cause death.

From this hospital the patient went to a convalescent home for six months and finally returned home in the care of his family physician, Dr. A. J. Ferris. The history is one of increasingly severe attacks of sudden epigastric pain with dyspnea, vomiting, sweating, and weakness. Spells occurred after eating and lasted for an interval varying from a few minutes to several hours. During the past year they occurred about once a week. The parents, desperate, decided to take the risk of an operation.

Physical examination revealed a poorly developed and poorly nourished boy of eleven. Blood pressure was 95/50. The percussion note was flat over the lower left chest and voice and breath sounds were diminished. The heart was considerably displaced to the right, sounds were slow, regular, and of good quality. Gurglings were audible in the left chest posteriorly. The abdomen was scaphoid. On May 10

in length. These adhesions were cut and all the abdominal viscera in the chest replaced below the diaphragm. The tear, extending from the pillar on the left side of the esophagus, to the perimeter of the diaphragm, was closed with a continuous silk suture. Several interrupted sutures of silk were then taken along the suture line to reinforce it and a small soft rubber drainage tube was secured to the dome of the diaphragm and brought out through the incision. The chest was closed in layers with a continuous suture of chromic catgut No. 1 to approximate the edges of the pleura. The fascia and muscle layers were then approximated with chromic gut. Several interrupted silkworm gut sutures were also taken and the skin closed with horse-hair.

The temperature rose to 103.8 degrees early on the morning of the second postoperative day, but soon dropped to 99.8 and the chart remained normal thereafter. The wound healed rapidly and in

nine days the patient was up and about eating regular house diet. X-ray examination June 4 1935 showed a small amount of fluid in the left chest. A chest tap however failed to obtain fluid. After discharge the boy's history was uneventful until June 17 about one month after operation. He complained of severe pain in the left chest. Four cc. of pus were drained from the wound and the pain quickly abated. Since that time his temperature has remained normal and the child is enjoying vacation at the seashore where he is quite cheerful and happy.

Contrary to the opinion now held by general practitioners and pediatricists that operation for congenital diaphragmatic hernia should not be undertaken before school age or until the child has reached adolescence or until symptoms of strangulation appear, we believe that operation should be done in the early weeks or months of life. The diaphragm, like any other muscular structure of the body, requires exercise for its development. Moreover, the activity of the normal diaphragm, like that of the heart, never ceases. Unlike other muscle structures of the body, it enjoys no rest periods, not even during sleep. Therefore when stalled by the contents of a hernia, symptoms of disturbed digestion, respiration, and circulation occur. As a consequence, we find these children underdeveloped and undernourished. A girl, aged four, now under observation at the hospital, gives a history of having gained only one pound in the last two years.

It is hoped that all cases operated upon will be reported. Case XII demonstrates that valuable lessons are often derived from careful investigation of the causes of failure.

The author wishes to acknowledge his indebtedness to members of the hospital staff who directly or indirectly have participated in the care of these patients or in the preparation of the written material and illustrations in this article. We are very much indebted to Dr. Albert H. Miller for a major service. He has originated and made practical application of a method of administering positive pressure anesthesia under gas-oxygen-ether without which our results could not have been achieved.

PASTEUR AND KOCH SHOWED THE WAY

Of these two, only Koch was a physician, Pasteur being a chemist. Pasteur showed that fermentation and putrefaction were due to the action of living microorganisms reproduced from similar preëxisting forms. This discovery marked the end of the belief in the theory that germs of disease can develop spontaneously from non-living matter. Based on this, it was possible for these pioneers and others to demonstrate the relation of a microorganism to a specific infectious disease in man and animal.

Soon after Pasteur's remarkable discoveries, enthusiastic but uncritical workers claimed to have discovered the causative germs of many prevalent diseases, among them the "germs" of smallpox, scarlet, cancer, etc. Fortunately, Koch formulated four postulates which he insisted must be met before a germ can be accepted as the essential cause of a disease.

First, said Koch, in order to prove that a certain microbe is a cause of a certain disease it must always be associated with the disease. Secondly, we must completely isolate this microbe from the diseased organism and grow it outside the body in a pure culture. Thirdly, when a healthy susceptible animal is inoculated with this pure culture, the germ must always produce the disease.

Fourthly, the germ should be recovered from the animal so infected, and grown in pure culture outside the body. It was the insistence on these postulates which permitted the establishment of bacteriology as a science.

The discoveries of these two men put public health on a scientific foundation. They gave a tremendous impetus to the study of germs and, together with others who followed, furnished exact knowledge concerning the causative agents of a number of important communicable diseases.

While many of the important theoretical contributions to the field of modern public health have come from England, France and Germany, many of them were first applied on a large scale in this country. Thus, antitoxin, while first produced in Europe, was perfected and applied in this country on a larger scale than anywhere else. The tubercle bacillus was discovered by Koch but the dramatization of this great discovery was made in America, so that Koch, on the occasion of his visit to the New York City Health Department in 1908 said, "Most of these bacteriological and serological discoveries have come from Germany. For my part I must admit with shame that we in Germany are years and years behind you in their practical application. You have done marvelous work." — *Neighborhood Health*, Vol 1, No 1 June-July, 1935

The Massachusetts Medical Society

SECTION OF TUBERCULOSIS

Ball Room Assembly, Hotel Stadler, Boston, June 5, 1935, 9 A.M.

PRESIDING

Donald S. King Boston Chairman
Olin S. Pettingill, Middleton Secretary

CHAIRMAN KING It is difficult to arrange every year an interesting program on one disease. In the past few years attention has been given to treatment, so this year we thought you would be interested in a symposium of Differential Diagnosis. As you will see we have had to call heavily on the roentgenologists but this is natural in view of the

fact that we are so dependent on the x-ray examination. Dr. Sosman has come from the Peter Bent Brigham Hospital to present the first subject, Differential Diagnosis of Pulmonary Tuberculosis and Carcinoma."

We will reserve discussion of the papers until the end of the Symposium and go on to the second paper on Differential Diagnosis of Pulmonary Tuberculosis and Abscess and Bronchiectasis.

Not submitted for publication.

BRONCHOSCOPY AND THE DIFFERENTIAL DIAGNOSIS OF TUBERCULOSIS, LUNG ABSCESS, AND BRONCHIECTASIS*

BY G. ARNOLD RICE, M.D.†

A CAREFUL history and physical examination together with x-ray and laboratory examinations will in a great many cases suffice to make a diagnosis of tuberculosis and lung abscess. Regarding bronchiectasis it is necessary also to add bronchography. Demonstration of bronchiectatic cavities is best made bronchoscopically, for to instill lipiodol supraglottically may be said to be a hit or miss method as it is necessary in many cases to remove pus, granulation tissue and debris through the bronchoscope before instilling the lipiodol to obtain a more complete and true picture of the situation. It may also be necessary to inspect the bronchi and bronchial openings for stenosis, tumor or foreign body and in some instances to obtain a specimen for examination.

Occasionally there are cases where usual methods of diagnosis are somewhat uncertain and bronchoscopy is of value in making a more definite diagnosis. The following cases are illustrations.

CASE 1. Male, forty-nine years of age. Nine months before this picture was taken the patient began to have cough but no hemoptysis, and expectoration was very little and consisted of white thin frothy material. He had progressive loss of weight and strength. For five weeks prior to our seeing him he was in a neighboring general hospital. Numerous sputum examinations showed no tubercle bacilli. The patient left against advice with no diagnosis made and came to us for diagnostic bronchoscopy. This was done. A curved flexible tip aspirator was inserted in the right upper lobe bronchus and a few cc. of pus were aspirated. Direct smear showed numerous tubercle bacilli.

CASE 2. This patient was admitted to Rutland State Sanatorium in extremely poor condition. After

study the staff at this institution decided that the patient had definite evidence of tuberculosis which at this time was not active and that she was suffering from something other than tuberculosis. Numerous sputum examinations showed no tubercle bacilli. In their opinion the clinical picture was more consistent with sepsis than tuberculosis. She was referred to us with a tentative diagnosis of bronchiectasis. Much pus was aspirated from the left lower lobe bronchi then the bronchiectatic cavities seen here were filled with lipiodol. This picture taken about six weeks later shows definite evidence of active tuberculosis and at this time the sputum was positive for tuberculosis. This is a case of tuberculosis and bronchiectasis occurring in the same individual and at the time she was admitted to Rutland State Sanatorium she was suffering from sepsis due to blocked drainage of bronchiectatic cavities and later active tuberculosis.

CASE 3. The patient, seven years of age, has had no cough. General physical condition below par. A lung specialist was consulted for examination prior to tonsillectomy. The patient is a contact case, for the mother died of pulmonary tuberculosis. X-ray of chest had been taken in Boston nine months ago and a shadow was seen in first film at the time and no diagnosis was made from the film. Referred to us for diagnostic bronchoscopy. Flexible tip aspirator was passed into the right middle lobe bronchus and about 20 cc. of thick foamy smelling pus was aspirated. Direct smear showed spirilla fusiform bacilli streptococci and staphylococci few gram negative diplococci and no tubercle bacilli. Guinea pig was inoculated. At this point evidence is strongly in favor of diagnosis of lung abscess. However two weeks later the guinea pig died and autopsy showed it to be riddled with tuberculosis. A second film taken the same day shows increased ventilation of lung area involved.

CASE 4. A patient twenty-two years of age normal weight 117 pounds had "the gripe" in September 1933 with high temperature for two weeks and at the end of this time the skin of her entire body was desquamated. She was admitted to a general hospital April 20, 1934. Six weeks prior to this time she presented typical symp-

*Read at the Annual Meeting of the Massachusetts Medical Society Section of Tuberculosis, June 5, 1935.

†Rice, G. Arnold—Bronchoscopist, Rutland State Sanatorium, Rutland, Mass. For record and address of author see "This Week's Issue," page 102.

toms of hyperthyroidism, with weight on admission ninety five pounds, basal metabolic rate plus 69 per cent, and the diagnosis of hyperthyroidism was made and she was put on Lugol's solution as preparation for thyroid operation. She was transferred to the surgical service on May 7, 1934 after giving consent to operation. On the same day, she began to run a temperature from normal, where it had remained since entering, to 101 degrees. Within three days the temperature was 105 degrees and she had developed cough. She remained very sick until the time of discharge, May 18, 1934. During this time, several x-rays were taken and no definite diagnosis was made by the roentgenologist. Two days prior to discharge she had a maculopapular pinkish rash, from ankles to neck, the consulting dermatologist was non-committal. White counts from May seventh to eighteenth ranged from 6,500 to 7,250, differential counts normal, Widal test negative, stools negative, urine normal, tests for undulant fever and typhus fever negative, negative throat smears, Wassermann and Kahn tests negative. Blood culture showed no growth. The patient was discharged against advice with diagnosis of hyperthyroidism and dermatitis of unknown origin.

She entered another hospital August 7, 1934 after having remained at home desperately sick since May 18. After a few days' stay in this hospital, where sputum examination was reported negative for tubercle bacilli and diagnosis of tuberculosis was made from interpretation of x-rays, she was discharged unimproved, diagnosis hyperthyroidism and pulmonary tuberculosis. Referred to Holden District Hospital August 17, 1934 by Dr. William B. Davidson of Worcester with tentative diagnosis of hyperthyroidism and lung abscess, right upper lobe, and request for diagnostic bronchoscopy. Weight 78 pounds, temperature 102°, pulse 130, patient extremely thin and emaciated. Flexible tip curved aspirator inserted in right upper lobe bronchus and about 20 cc thick, yellow foul smelling pus was aspirated. Direct smear showed organisms usually found in lung abscess and no tubercle bacilli. Guinea pig was inoculated. More bronchoscopies were done on September 1, 30, and Octo-

ber 10. She appeared to receive a tremendous benefit from these bronchoscopic aspirations. By November, 1934, she was symptom free and had gained sixteen pounds. Guinea pigs inoculated with material obtained directly from the bronchus after each bronchoscopy, revealed no lesions of tuberculosis. Patient continued to gain in weight and strength and examination of May 15, 1935 showed her to feel perfectly well. Weight 123 pounds, six pounds more than her usual weight prior to her illness, basal metabolic rate plus 15 per cent. Diagnosis—Lung abscess, hyperthyroidism possibly due to sepsis. First film taken day before first bronchoscopy and the second about seven weeks later.

CASE 5. Patient twenty one years of age had been an invalid for five years, much cough and profuse expectoration, four to five sputum boxes in twenty-four hours. Hemoptysis many times from few teaspoonfuls to twelve or fourteen ounces. Referred for diagnostic bronchoscopy. Plain film shows nothing definite. He had had some fifty sputum examinations, all negative for tubercle bacilli. Treated for tuberculosis in several localities. After aspirating about four ounces of thick, foul smelling pus, cavities seen in this film were filled with lipiodol. Several specimens taken directly from the cavities at different intervals through the bronchoscope failed to show tubercle bacilli in direct smear, and no lesions of tuberculosis were found in inoculated guinea pigs. Diagnosis Bronchiectasis.

CHAIRMAN KING. I am sure, as the program is proceeding you will realize there are difficulties in Differential Diagnosis, and I am glad that Dr. Lord is going to discuss this Symposium.

The third paper is by Dr. Zacks, on "Sillcosis"*. We have all encountered this problem of Differential Diagnosis.

I do not know how much Dr. Hampton knows about "Nontuberculous Fibrosis" today. Before he started to write this paper he thought he knew a good deal, but I understand that as the days have gone by he has become more and more discouraged. I shall be interested in knowing just what his present conclusions are.

*Not submitted for publication.

PROGRESSIVE IDIOPATHIC PULMONARY FIBROSIS ASSOCIATED WITH EMPHYSEMA*

BY AUBREY O. HAMPTON, M.D.†

AS the title of this paper indicates, we wish to discuss a series of cases of chronic pulmonary disease about which little is known. This presentation is a preliminary report of some work which your Chairman, Dr. Donald S. King, and I are pursuing. These cases are presented at this time because they are often misinterpreted as pulmonary tuberculosis. Various other clinical diagnoses are made such as asthma, bronchiectasis, heart disease, malignancy and pneumoconiosis. In view of the confusing nature of these pulmonary diseases under discussion we

will show only those cases which have had post-mortem examinations. Unfortunately, even a complete pathological examination does not allow accurate classification but most of the post-mortem findings are similar and are characterized by diffuse interstitial fibrosis, distortion and dilatation of the bronchi, diffuse emphysema and in the advanced cases emphysematous blebs.

The pulmonary changes seen at the routine x-ray examination which are due to idiopathic fibrosis are quite similar to those seen associated with tuberculosis. The chief difference is that usually tuberculosis is more localized and less likely to involve the entire lung fields. Fibrosis, however, may occur locally in both infra-

*Read at the Annual Meeting of the Massachusetts Medical Society Section of Tuberculosis June 5, 1935.

†Hampton, Aubrey O.—Assistant Roentgenologist, Massachusetts General Hospital. For record and address of author see "This Week's Issue" page 1202.

clavicular regions and as in the case of pneumoconiosis the upper lobes are quite commonly involved. Emphysematous blebs add to the confusion of the x ray picture in that they are often quite similar to the cavitation of tuberculosis. Pleural thickening and even pleural effusion are also common. The thin walled dilated bronchi and confluent emphysematous alveoli which occur often produce a diffuse honey-combed appearance on the radiograph. This picture is rarely seen in tuberculosis, and there are certain other helpful differential points in the roentgen examination which are obtained only by fluoroscopy and oblique and lateral radiographs. In brief they are tabulated as follows

in a hospital for several months. At about this time the patient became aware of marked palpitation on exertion. This was accompanied by a dull precordial ache and marked cyanosis on exertion. Six weeks before entering the hospital the patient's ankles began to swell. For some time the swelling was general but later a new type of swelling developed. The new type involved different parts of the body at various times such as the feet, legs, thighs, back, abdomen and face. These swellings came up rapidly over a period of several hours. The swelling was red, sensitive and there was also a tingling sensation. Accompanying this new form of swelling was a steady non-radiating gnawing moderately severe mid-epigastric pain. This pain was unrelieved by food or soda and there was no gas, nausea or vomiting or change in bowel habit. The patient was a semi-invalid for years and remained in bed for the past two months.

IDIOPATHIC FIBROSIS

1. Interstitial fibrosis usually diffuse but may begin in infracavicular regions
2. Progressive until death—3-30 years
3. "Honey-combed" appearance of entire lung
4. Emphysema diffuse with cavities in apices, bases and anterior lung tips
5. Cavities thin walled usually multiple and mold to each other. Adjacent lung tissue likely to be clear
6. Cavities usually not demonstrated in posterior anterior view of chest but strikingly plain in oblique and lateral views
7. Diaphragmatic outline and excursion usually abnormal. Rapid full downward excursion, slow shallow upward excursion. Heart, mediastinum, trachea and main bronchi may increase in size at sudden forced inspiration. Diaphragm symmetrical, high if fibrosis predominates, low if emphysema is most marked

PULMONARY TUBERCULOSIS

1. Fibrosis usually localized
2. X-ray shadows may become less marked or disappear
3. Rarely if ever "honey-combed"
4. Emphysema localized and cavities usually central or posterior
5. Walls of cavities usually relatively thick, do not "mold" and adjacent lung tissue dense.
6. Cavities best demonstrated in routine posterior-anterior views
7. Diaphragmatic outline may be abnormal but excursion usually fairly normal. Expiration and inspiration equal. No change in heart, trachea and mediastinum except shift to affected side. Position of diaphragm usually asymmetrical and varies, dependent upon the extent of the disease

The clinical aspects of idiopathic pulmonary fibrosis may best be presented by the detailed report of a case history of a typical example, but before we present this case it might be well to compare the radiographic and pathological findings in the twelve cases we have collected.

G. C. (10391). A fifty-one year old housewife admitted with complaint of bronchial asthma with wheezing and nocturnal dyspnea for twenty six years. The past history revealed that the patient had had rheumatic fever thirty years before which was not followed by any known sequelae. She had pneumonia in childhood and pleurisy at some indefinite time. The past history is otherwise irrelevant. At the age of fifteen twenty-six years before entry the patient began to have wheezing with difficult inspiration and expiration, dyspnea and nocturnal orthopnea. These symptoms persisted to the time of admission and gradually became more marked. The "asthma" was present the year around regardless of geographical location although it was worse at some times than at others. Morphine was begun at onset and was occasionally used for some years. At the time of admission it was being used daily in doses of $\frac{1}{2}$ grain with only partial relief.

Three years prior to entry the patient had frank hemoptysis on several occasions, severe night sweats, dyspnea and orthopnea, as well as persistent cough. A diagnosis of pulmonary tuberculosis with multiple abscesses was made and the patient was treated

The family marital social and occupational histories are noncontributory. A physical examination revealed a chronically ill and apparently worried middle-aged female. There was marked dyspnea and orthopnea. The lips were cyanotic. Cervical veins were distended, the liver was very large and tender and there was massive pitting edema of the legs. The chest findings were interpreted as extensive pathology compatible with advanced tuberculosis.

Laboratory Findings. There were no significant findings in the blood, urine or sputum. The red cell count was 5.3 millions and the leukocyte count was 13.5 thousands. Many sputum examinations at two hospitals were negative for tubercle bacilli or other specific organisms.

Postmortem Examination by Dr. Tracy B. Mallory. Pleural Cavity. Contains approximately 1 liter of straw-colored fluid. Both apices fairly adherent by means of thick fibrous bands to the parietal pleura. Left lung is fastened throughout its length in the axillary space by fibrous bands.

Lungs. Except for lower portion of right lower lobe the whole anterior surface of the right lung is made up of emphysematous bullous blebs of various sizes, the largest blebs measuring 5 cm in diameter. No blebs are seen in the left lung at this stage.

After removing the lungs from the chest the emphysematous blebs observed on the right are found to make up the middle portion of the upper and middle lobes, having covered the lateral portions when in situ. Small bullae are observed on the

(Slides were shown here)

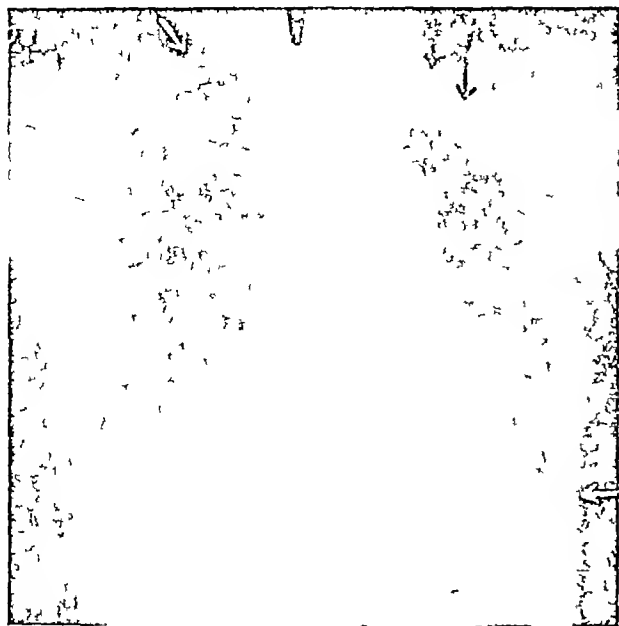

FIGURE 1a G C 10391 The posterior anterior view demonstrates cavities in left apex and infraclavicular region closely resembling tuberculosis. The large thin-walled cavities in the right apex and at the left base are more typical of emphysematous blebs. The heart is markedly enlarged and the mottling in both lung fields is due chiefly to fibrosis. There is some fluid at both bases.

FIGURE 1b G C. 10391 In the left oblique view numerous large blebs are demonstrated in the anterior margin of the right lung. These shadows are not seen in figure 1a because of their location and physical characteristics. The walls of these cavities are thin and mold to each other.

diaphragmatic surface of the left lung. Both upper lobes are moderately firm, grayish blue, and on cut section show moderate fibrosis with cavitation on the left side, the largest cavity measuring 1 cm in diameter. No cavities are present on the right side. All the interlobar spaces are obliterated by fibrous adhesions. The rest of the lung tissue is very slightly crepitant and dark grayish blue in color.

Microscopic Study of ninety sections from varying areas of all four lobes presents a very compli-

FIGURE 1c G C 10391 In the lateral view the substernal area is seen to be composed of numerous superimposed large and small blebs. The anteroposterior diameter of the chest is above normal.

cated picture. Emphysema with enlargement of alveolar sacs up to 2.3 mm is present in all lobes, but is most marked in the two upper lobes, where sacs 0.5 cm in diameter are numerous, and less marked in the right lower lobe. Also scattered throughout all lobes, approximately in proportion to the amount of emphysema, are focal scars, varying from 1 mm to 2.5 cm in diameter, the majority averaging 2.4 mm. With the elastic tissue stain it is evident that these consist of completely collapsed alveoli with collagenous obliteration of their lumina. A scar 2 mm in diameter shows the obliterated shadows of 40-50 alveoli, so that marked focal shrinkage of the pulmonary parenchyma must have occurred with corresponding "Raumverschiebungen" (Loeschke), and nowhere in the lungs are any lesions suggestive of tuberculosis found. In general, emphysematous dilatation of the alveoli is most marked in the immediate neighborhood of the areas of scar tissue. Throughout the lung there is no diminution in the elastic tissue, except in the walls of the largest scars. For the most part, even in definitely emphysematous alveoli, it appears increased rather than diminished.

The bronchi show a definite narrowing of their lumina. This is most marked in bronchi from 2.7 mm in external diameter, where the lumen is 35 per cent of the external diameter (normal 50 per cent). The bronchioles below 2 mm in diameter show no narrowing, and in fact, are frequently somewhat dilated. Only in one area in the left upper lobe is significant dilatation of larger bronchi noted. In these bronchi the muscle tissue is greatly diminished and in a few sections is almost totally absent. The muscularis of the remainder of the bronchi throughout all lobes is notably increased in thickness, running from two to three times normal and corresponding with the findings in paroxysmal asthmatic deaths. The bronchi down to 2 mm in diameter are for the most part free from exudate, though the bronchioles fairly uniformly contain mucus, and frequently large numbers of polymorphonuclear leukocytes and epithelial cells of the larger bronchi show only a low proportion of goblet cells, though the mucous glands of the submucous layer are unusually large, their ducts dilated, and a high percentage of cells active. However, the secretion within the cells and in the ducts is of a thin, apparently watery, consistency, quite different from the marked

ly basophilic secretion of the usual asthma case. The epithelial basement membrane is irregular in thickness for the most part showing only slight increase in width and moderate hyalinization but in some bronchi the thickening is of extremely marked degree. Eosinophilic infiltration is entirely lacking. Lymphocyte and plasma cell infiltration is present in relatively slight degree in the subepithelial tissues, more marked but still not intense in the stroma of the glands. A slight diffuse edema of the bronchial tissues is present. A marked brown pigmentation of the bronchial cartilage is noted. The arteries of all sizes show marked changes. In the larger elastic arteries atheromatous deposits are present, but relatively subordinated to a very marked fibrous intimal thickening which is rarely absent in any section and often is great enough to reduce the calibre of a vessel by fifty per cent. Leading

from the elastic arteries are arteries of muscular type typical of systemic vessels rather than of pulmonary ones in their well-developed muscularis. Finally the arterioles show a uniform thickening of their walls with intimal proliferation and some degree of hyalinization. The veins are not abnormal.

Heart Weighs 400 grams. There is marked hypertrophy in the right ventricle the wall measuring 14 mm. The left wall measures 10 mm.

CHAIRMAN KING: We have to arrange for a Nominating Committee and may I ask that the Committee sometime in the next half hour nominate the officers for the ensuing year.

The next paper which we have is entitled "Mycotic Infection of the Lungs in the Differential Diagnosis of Pulmonary Tuberculosis" by Dr. Bakst.

MYCOTIC INFECTION OF THE LUNGS IN THE DIFFERENTIAL DIAGNOSIS OF PULMONARY TUBERCULOSIS*

BY HENRY J. BAKST, M.D.†

DESPITE the fact that fungi have been recognized as organisms pathogenic to man since the latter half of the nineteenth century, their incident diseases form a general group of ill defined and poorly recognized clinical entities over which considerable confusion and controversy still exist. Much of the difficulty is unquestionably due to the ability of the various fungi to cause pathological changes which are practically indistinguishable from those of bacterial origin particularly tuberculosis. A fair portion of the responsibility, however, is also due to inadequate mycological study. It is to be expected that with the more widespread recognition of the importance of fungi as the causative factors of disease, sufficient interest will be awakened to necessitate the development of a more simplified groundwork for the support of clinical observation.

In the course of any confusing clinical investigation a return to fundamental principles of observation invariably results in a clarified view of what has previously been vague and complex. In our consideration of the pulmonary mycoses let us discard for a moment, the complex terminology, and widen our focus from a narrow view of the pulmonary pathology to a broad consideration of the patient as a whole. This will present a series of fundamental clinical pictures which we hope, will be of considerable aid in the differential diagnosis of pulmonary tuberculosis.

In order to differentiate these conditions on a clinically practical basis, a classification proposed by Watkins a few years ago is utilized. The fungi are divided into three groups. The first group consists of the filamentous forms,

the second is made up of the yeast like organisms, and the third represents the more complex types.

In the first group we have such organisms as actinomyces, colonistrepotrix, vibriothrix, cladothrix, leptothrix, and anaeromyces. Since this group has been demonstrated as being biologically related to the tubercle bacillus¹, it is not surprising that they should produce a disease which is practically indistinguishable from tuberculosis. This is particularly true of the streptothrix which stains with a variable degree of acid fastness and produces a disease picture which is essentially pulmonary in nature.

If we may accept pulmonary actinomycosis as the disease characteristic of the first group, a clear differentiation of it and pulmonary tuberculosis may be drawn.

Our patient may present the familiar picture of loss of weight, cough, hemoptysis, night sweats and fever. The mycotic infection, however, usually involves the basal or hilar portions of the lung.² Cavity formation is much less marked than in tuberculosis and abscess formation is a frequent finding. In its tendency to spread by contiguity, with marked fibrosis and disregard of anatomical boundaries, the process may at times resemble a neoplasm rather than tuberculosis.³ The lesion often spreads through the diaphragm and over 80 per cent of the cases show the presence of a sinus draining through the anterior chest wall. Persistent chest pain is almost an invariable symptom. More than half the cases have a cutaneous lesion, and the lymph nodes are rarely involved. A slight to moderate leukocytosis is frequently present.⁴ Definite proof of the otological factors of the disease process is obtained by microscopic examination of the pinhead sized yellow, or so-called sulphur gran-

*Read at the Annual Meeting of the Massachusetts Medical Society Section of Tuberculosis, June 5, 1933.

†Bakst, Henry J.—Junior Visiting Physician, Boston City Hospital. For record and address of author see "This Week's Issue," page 130.

ules, present in the sputum or pus. With actinomyces, a gram stain will demonstrate the presence of a tangled mass of blue threads surrounded by red clubbed ends⁵. A Ziehl-Neelsen stain, in the case of streptothrix, will reveal a loose network of filaments of variable acid-fastness sometimes presenting a granular appearance².

The yeast-like organisms included in the second group consist of those which reproduce by means of thaliospores, such as blastomycosis, torula, monilia, oidium and oospora, and those which reproduce by means of ascospores such as saccharomyces, willia, endomyces and coccidioides.

The characteristic features produced by the blastomycosis have been adequately described by Stober⁷ and Wilhelmj⁸. Their observations showed it to be a disease primarily affecting young adults subject to exposure, or employed in manual labor. The symptoms of loss of weight, cough, purulent (often bloody) sputum, and chest pain almost always date from a history of upper respiratory infection⁹. The outstanding features are those of pyemia with irregular fever, chills, and sweats⁸. The skin and subcutaneous tissues are often excessively undermined by large abscesses. Most important is the realization of the fact that 95 per cent of the cases show evidence of skin involvement which may vary from small pustules to large abscesses which break down to form chronic granulomatous lesions⁸. Bone and joint destruction has been found to occur in over two thirds of the cases, and may be expected to take place in almost any part of the skeletal system¹⁰. Over one third of the cases may show evidence of kidney involvement⁸. A blood examination will usually reveal the presence of a moderate leukocytosis⁹.

It is obvious that the diagnosis of blastomycosis should be considered⁷ in any patient presenting the triad of chronic pulmonary, bone, and skin lesions.

The addition of 10 per cent sodium hydroxide to the pus or sputum, examined freshly, will demonstrate the presence of yeast-like budding forms 10 to 30 micra in diameter with doubly-refractile contours¹¹.

Coccidioidal granuloma gives rise to a clinical picture practically identical with that of blastomycosis¹². It occurs primarily on the west coast¹³. The cutaneous lesions show a greater tendency toward ulceration, and more marked lymph node involvement occurs. The presence of suppurative orchitis is considered to be a diagnostic lesion by Cummins who reviewed the 200 deaths resulting from this disease between the years 1892 and 1929¹³. Since inoculated guinea pigs show early evidence of involvement, this predilection for testicular tissue provides a valuable diagnostic measure¹⁴.

Recently at the Boston City Hospital we

have had the opportunity to observe several cases of pulmonary infection associated with monilia¹⁵, a disease originally described by Castellani in his observations on "tea taster's cough" in Ceylon¹⁶. Unfortunately moniliasis has not, as yet, been generally accepted as a cause of primary pulmonary disease. This is probably due to the frequent occurrence of monilia as a secondary invader, and also, to a lack of adequate investigation of that group of cases of tuberculosis in whom the presence of acid-fast bacilli is never demonstrated. Because of the lack of an adequate number of reported cases, it is difficult to gather information which will allow differentiation of this disease and tuberculosis on a purely clinical basis. Aside from the fact that the pulmonary lesions occur, as a rule, at the base of the lung, and tend to leave the apices clear, little can be said to distinguish it from an acid-fast process. It is a diagnosis which must rest chiefly on the adequate demonstration of these organisms in the sputum, and the persistent absence of acid-fast bacilli, together with evidence of their pathogenicity.

The third group of mycoses consists of the more complex fungi such as aspergillus, penicillium, acremonia, mucor, rhizomucor, leichtheimia, sporotrichum and alcaidum. Here again we are dealing with a group which is probably most frequently found in the capacity of a secondary invader. Here also, we must depend on the demonstration of the organisms in the absence of acid-fast bacilli. A case followed in France for twenty-seven years with clinical tuberculosis, but with acid-fast bacilli absent from the sputum persistently showed the presence of aspergillus¹⁷. Another similar case, studied for ten years, showed the invariable presence of penicillium in the sputum¹⁸.

Therefore, to summarize briefly, we must recognize in distinguishing mycotic infections from tuberculosis, the necessity for a consideration of the patient as a whole. Confusion will invariably result from a point of view which is narrowly focussed on the presence of pulmonary pathology. The atypical location of the pulmonary lesion, a discharging sinus in the chest or neck, the concomitant presence of dermal or joint lesions should invariably lead to a suspicion of mycotic infection. Proof, however, must depend on the actual demonstration of the organisms in the sputum or pus.

CHAIRMAN KING. The final paper is by Dr Paul D White on "The Differential Diagnosis of Pulmonary Tuberculosis and Pulmonary Circulating Changes."

THE DIFFERENTIAL DIAGNOSIS OF PULMONARY TUBERCULOSIS AND PULMONARY CIRCULATORY CHANGES*

BY PAUL D WHITE, M.D.†

ON April 10 1934, a coal miner twenty five years old was admitted to the Heathfield Sanatorium in Scotland for observation. The history of the case presented by Drs. James Grant and John Miller of Ayr was as follows:

There had been excellent health until a cough developed in January three months earlier.

"Gradually some dyspnea on exertion became apparent in the following months but he was able to walk about. On April 3rd he suffered from acute hemoptysis of bright red blood and his medical attendant had his chest examined by x rays the following day and sent him with the film to the tuberculosis dispensary.

"The patient at examination on April 5th was a healthy looking vigorous adult with a slightly pale countenance. He was a little feverish the temperature being 98.9° F and the pulse rate 96. Apart from some crepitations in the left axilla, system examination revealed no abnormality. The skiagram of the chest showed rather a large heart shadow with increased density of lung shadow in the mid zone of the left lung. Sputum examination failed to reveal tubercle bacilli. The family history was good all near relatives being alive and well."

Under observation during the next few months he remained free of fever except for a few days in August when he showed dullness and pleural friction rub at the left lung base. For months he raised sputum daily at times blood-tinged. His heart increased in size and a systolic murmur appeared at the apex.

On August 28th the patient began to go downhill. He expectorated blood in the sputum, at first a tinge only but later copious quantities of bluish-red frothy blood. The skin and conjunctivae became jaundiced cyanosis was very evident, and the liver enlarged and was painful. The heart dullness was much enlarged in all directions the apex beat being scarcely perceptible and the cardiac sounds of very poor quality. A further x ray examination was made the following day. The film of the chest showed a colossal increase in size of the heart shadow and an upward bulging of the liver shadow.

Read at the Annual Meeting of the Massachusetts Medical Society Section of Tuberculosis, June 6 1935.

*White, Paul D.—Physician Massachusetts General Hospital, Boston. For record and address of author see "This Week's Issue," page 1202.

Two days later there was slight anasarca, and the blood pressure was 70/64. The urine revealed no abnormal constituents in solution or suspension a feature maintained throughout the Wassermann reaction was not done.

The patient began then to complain of stranguation and on account of a tentative diagnosis of pericardial effusion an attempt was made on September 2nd to perform paracentesis of the pericardium. No fluid was obtained but owing to the evident distress of the patient the attempt was not persisted in. Thereafter the patient became more dropsical cyanosed and breathless and died fairly suddenly on September 6th.

Postmortem examination revealed generalized edema, double hydrothorax, a small pericardial effusion of 6 to 8 ounces, no tuberculosis, extreme chronic venous congestion (brown in duration) of the lungs a somewhat enlarged liver with the characteristic nutmeg appearance of chronic congestion, and a markedly dilated heart with normal valves, but atheromatous occlusion of the anterior descending branch of the left coronary artery with a large fibrosed atrophied area (infarction) in the anterior apical portion of the left ventricular myocardium with partially organized laminated clot attached to it inside the ventricle.

Such a mistake in diagnosis should of course not be made. Fortunately such a mistake can not be made often because of the great rarity under the age of thirty years and even under the age of forty years of serious coronary disease with thrombosis followed by extensive myocardial infarction and left ventricular failure with pulmonary vascular congestion. Except for the age of the patient the clinical picture is, however, quite common, that is, pulmonary edema in acute or chronic form with or without the raising of blood, secondary to left ventricular failure due to coronary thrombosis. The more important points of differentiation from pulmonary tuberculosis are the following (1) a history, as a rule, of severe prolonged sub-

sternal pain, usually requiring morphine, at some time in the recent past, with or without a history of antecedent angina pectoris, (2) enlargement of the heart (the heart always becomes enlarged after coronary thrombosis before it fails), (3) a characteristically abnormal electrocardiogram pointing to recent coronary thrombosis—a very important sign, (4) x-ray evidence of engorgement of the blood vessels of the lung hiluses with or without engorgement of the smaller vessels extending radially toward the lung periphery, without more extensive involvement of the lung apices (there may be clouding due to pulmonary edema in severe acute attacks of left heart failure) and (5) the preponderance of moist râles at the lung bases if such râles are present—asthmatic breathing with scattered squeaks and groans may be present also when there is an associated cardiac asthma.

Pulmonary vascular congestion from failure of the left ventricle may complicate other types of heart disease besides that resulting from coronary artery obstruction. Most commonly hyperpiesia, or essential hypertension, is the factor behind left ventricular failure in most of the United States of America. The clues that differentiate such a cause of pulmonary edema and phthisis are (1) the history of a considerable degree of high blood pressure over a considerable length of time in a middle-aged or elderly person, (2) the story of dyspnea on effort for at least a few weeks, and frequently of attacks of paroxysmal dyspnea or cardiac asthma, especially at night, (3) the finding of cardiac enlargement, (4) the frequent finding of other special signs of left ventricular weakness, such as gallop rhythm, accentuation of the pulmonary second sound, and alternation of the pulse, (5) the x-ray picture of pulmonary vascular engorgement, and (6) the preponderance of moist râles at the lung bases, if there are any moist râles.

Other occasional causes of left ventricular strain and failure that may give rise to pulmonary vascular congestion are aortic valve disease (stenosis or regurgitation or both) whose presence is indicated by characteristic murmurs, luetic aortitis acting either by narrowing the mouths of the coronary arteries or by producing aortic regurgitation, and acute rheumatic myocarditis in childhood evident as an infectious process causing cardiac enlargement. Incidentally an interesting complication of a very severe acute rheumatic infection may be a hemorrhagic consolidation of the lung. Rarely "pure" mitral regurgitation and coarctation of the aorta may be important factors of strain.

There are three other cardiac conditions besides that of left ventricular failure that may simulate pulmonary tuberculosis in occasional cases. Usually the differential diagnosis is easy

and mistakes should be avoided without much difficulty in every case. These three conditions are mitral stenosis with hemoptysis, aortic aneurysm with pressure symptoms, especially cough, and congenital anomalies, particularly interauricular septal defect with marked dilatation of the pulmonary blood vessels.

Mitral stenosis should be easily distinguished by the finding of its characteristic apical mid-diastolic murmur with or without presystolic accentuation or thrill, but this murmur is often missed by a hasty or inexperienced observer who doesn't happen to listen exactly at the cardiac apex where the murmur is often localized. Useful aids in the rapid detection of the murmur are the use of the bell chest-piece of the stethoscope and auscultation with the patient supine or lying on the left side directly after exercise. Another helpful finding is the so-called mitral shape of the heart by x-ray.

Only rarely does the patient with mitral stenosis cough up blood and only very rarely any considerable amount of blood. When such an event occurs, however, there is a danger of confusion of the condition with phthisis, and first and last a considerable number of patients with mitral stenosis have been treated in sanatoria for tuberculosis. Infrequently phthisis and mitral stenosis occur together in the same case.

Aortic aneurysm may be easily missed without an x-ray. In most cases the Wassermann and Hinton reactions are positive and the subjects are usually men of middle age.

Wide open congenital auricular septal defects are fortunately rare. They give rise to great enlargement of the right heart chambers and massive engorgement of the lung hilus shadows which may be taken for enlarged glands or tumors.

Finally, a word is to be said concerning pulmonary vascular disease not necessarily associated with heart disease. The commonest is thrombosis or embolism with infarction, an acute lesion occurring as a rule as a complication of surgical convalescence or heart failure and difficult to confuse with pulmonary tuberculosis. Sudden chest pain or oppression or dyspnea, often a temporary state of shock, fever, leukocytosis, secondary dilatation of the right ventricle if the obstruction is extensive, pleurisy, and eventually signs of the pulmonary infarct by physical examination or x-ray distinguish pulmonary embolism or thrombosis in most cases. Rarely the thrombosis may be slow in its development, insidious, and difficult to diagnose, especially if it is a terminal event. In any case the blood spitting is only incidental.

A rare type of pulmonary vascular disease is endarteritis obliterans, of unknown cause, resulting eventually in enlargement of the pulmonary vessels and of the right heart chambers and

if extensive, cyanosis. It does not cause hemoptysis. The congestive heart failure if it supervenes is right ventricular, and not shown in the pulmonary circulation. Pulmonary arterial aneurysms are excessively rare and so far as I know have not been confused with phthisis.

Thus, in summary, there are rare cases of pulmonary vascular congestion due to left ventricular failure, of mitral stenosis with hemoptysis, and of aortic aneurysm with cough that

may on first glance be confused with pulmonary tuberculosis, but careful study should easily distinguish them in every case.

CHAIRMAN KING: Dr Lord has prepared a summary of this Symposium for you.

THE DIFFERENTIAL DIAGNOSIS OF
PULMONARY TUBERCULOSIS*

BY FREDERICK T. LORD, M.D.†

MUCH progress has been made in the diagnosis of pulmonary tuberculosis. This is due largely to the development of x-ray technique and a more complete understanding of the clinical aspects of the disease and of the conditions with which it may be confused. Occasional mistakes in diagnosis are inevitable, but their number may be reduced by complete investigation. In discussing the differential diagnosis I would emphasize the importance of the following considerations:

A family history of contact with tuberculosis or other opportunity for contagion may have an important bearing on the diagnosis in doubtful cases.

A past or present history of hemoptysis out of a clear sky is especially suggestive of pulmonary tuberculosis. Exceptions to the tuberculous origin of the bleeding in this group are for the most part due to malignant disease of the bronchi or lung. Though hemoptysis is common in patients with bronchiectasis, I have seen but one instance in which the bleeding was an initial symptom. Other rare causes are the rupture of tuberculous or anthracotic glands into the air passages, and syphilis of the trachea and bronchi. *Echinococcus* disease and *Distoma* *Rugieri* may also be responsible.

Primary pleurisy with or without an effusion is equal in significance to hemoptysis out of a clear sky in suggesting tuberculosis as a cause. In this group also malignant disease may be a cause of confusion. Primary endothelioma of the pleura is much less common than an apparently primary pleurisy arising by extension from a latent bronchial or pulmonary neoplasm. Examination after fixation and section of the sediment of the pleural fluid obtained after centrifuging may permit a diagnosis of malignant disease. Pulmonary infarction from latent thrombophlebitis may also cause an apparently primary pleurisy but its occurrence

after operation, delivery, or trauma, may serve to suggest this possibility.

Following occupational exposure to silicious dust the diagnosis of pneumoconiosis is not difficult, but tuberculosis develops sooner or later in a large proportion of the cases and recognition of the two diseases combined may be difficult or impossible.

The necessity for repeated examinations of the sputum for tubercle bacilli and other organisms is obvious. I would call attention to the diagnostic importance of the odor of specimens. Expectorated material with uncomplicated tuberculosis is without odor. In the presence of bronchiectasis there is a stale or musty odor in about half the cases. With lung abscess the odor is foul with few exceptions.

The use of tuberculin as a method of screening is of especial value in youth. The diagnostic importance of positive tests diminishes as age advances. The von Pirquet test is subject to an error of about ten per cent, and the test can be regarded as negative only when the intracutaneous method is used with increasing doses up to and including the injection of one milligram of tuberculin.

The leucocyte count has considerable value in differential diagnosis because of the usual absence of leucocytosis in uncomplicated tuberculosis and the abnormal elevation of the polymorphonuclear leucocytes with nontuberculous infection.

Careful attention to the clinical aspects is obviously of importance in differential diagnosis. Primary pulmonary tuberculosis is common in children but may also occur in adults. Diffuse or nodular primary lesions may be located anywhere in the lung and are associated with tracheobronchial glandular enlargement. The onset is insidious, the tuberculin test positive and leucocytosis absent. The outlook is good. There is no significant destruction of tissue. Resolution is slow leaving calcified areas and fibrosis. In this group the principal difficulty is the distinction of such lesion from acute broncho- and lobar pneumonia in which, how-

ADDRESS OF DR. DAVID L. EDSALL*

MY mind goes back more than twenty-five years to an evening when the Pathological Society of Philadelphia held a celebration of its fiftieth anniversary. After the dinner where there had been a number of excellent speeches, Dr. Abraham Jacoby sat with a group of us younger men who were very devoted to him, and spoke with warm approval of the speakers and their ease in after-dinner speaking. He said that all his life he had been afflicted with stage fright, but in the past two years it seemed to be disappearing. He was eighty-one at the time. I thought then what hard luck it was for me to look forward to over forty years of stage fright, but I am quite sure, even if I reach more than seventy-nine years, I should not be able to respond in a calm and adequate way to the kind things, the over-generous things, that I have heard said this afternoon and tonight.

My mind goes back also to twenty-three years ago when I came here. I had just gone through two attempts, in two different cities, at rather radical efforts at progress. Both were largely failures. It was, probably, in part due to mistakes but partly bad luck. I felt, however, very conscious of Napoleon's statement that any one who has been repeatedly unlucky is a poor person to put in charge of things because his previous experience destroys the morale of the organization he has charge of. When I came here I thought people might be suspicious of my personal capacity in carrying anything out when I had had such luck before. I also had in my thoughts the feeling I had always heard, as an outsider, that this was a cold and critical community and very unfriendly to outsiders. Indeed, one very distinguished person, when I was called here, advised me not to "put my head in the lion's mouth." I came and found totally contrary conditions to what I had expected. A year after I came here I was talking over things with a friend who had been in one of the earlier unsuccessful ventures. He asked me many questions and finally said, "With your previous experience you should keep pinching yourself to see if you are dreaming."

I often wondered what the reasons were for the relative ease in getting things accomplished here. I think there are two or three reasons that still stay in my mind as very conspicuous explanations of this. The first one, it seems to me, is exemplified by one of my experiences in practice. In a city where I had lived most of the people I saw who had neurasthenia had it, I thought, because they had no particular interest in anything and didn't take active part

in anything, with the result that they became bored and nervously broken down. When I saw people with similar trouble in Boston, it was because they were following an ideal with such insistence that they exhausted themselves in trying to reach what they were after. When I was in Peking—as it was called nine years ago—an able paper was published on the difference between the East and the West, by Hu Shih, the Chinese philosopher and publicist. He pointed out a variety of differences between the East and the West, and epitomized them by saying that the easterner was quite content to sit by the wayside and watch things go by, but the westerner was filled with a certain kind of discontent, what one of their poets has called a "divine discontent," which impelled him to go on and do better things than he had done before. I have had the feeling from the very beginning that one of the characteristics in this community is that element of divine discontent and the willingness to go on and do better things than had been done before. I found myself at once in an atmosphere where the President of the University, the Corporation of the University, the trustees of the hospitals, and especially the Massachusetts General where I was at work, and everyone else seemed to be striving to get things in better condition and still maintain the traditions that had made the institution what it was. I feel convinced that more than age and more than tradition, the present position of Harvard University, and the great influence that New England has had in the affairs of the nation, have been due to this attitude of divine discontent and the impulse to better things. I met no hostile opposition, except from the occasional "off-horse" that one finds in any organization, but I met much criticism—a nonpersonal, constructive criticism that was based upon dissatisfaction with imperfect things and a desire to make them better, with helpfulness in correcting them.

The other thing that impressed me very much, that many of you who live here may not see quite so clearly, is that in connection with educational, hospital or public affairs of any kind the outstandingly predominating element academically in this community is keenly interested in the one University. In almost all the organizations that I have knowledge of the controlling men are themselves Harvard men and are deeply interested in anything that may benefit Harvard. It has always seemed to me that this is one of the important assets of this University. In other places that I know anything about there is not that feeling. They may have one local university—they often have several—but the community itself is not intensely interested in one place and there are usually as many men there who are alumni of

*At a dinner held in his honor at the Harvard Club, Boston on October 23, 1935, upon his retirement as Dean of the Harvard Medical School and Harvard School of Public Health.

institutions elsewhere as of the local university. There are graduates not only of the local university but almost as many men who are graduates of Harvard, Yale, Princeton or other places, so that their academic interests and academic devotion are very mixed indeed.

Before I came here I had had some unhappy experiences with university administrative officers, university trustees and hospital trustees. I even dallied at times in my thoughts, for my amusement, with the idea that some time I might persuade a benefactor to give a large gift in order that there might be established a school for training university presidents and trustees and hospital trustees. I came to the conclusion that that idea wouldn't work here because it had been so well done already. The corporations that I had known before were bodies that seemed to me—university and hospital trustees both—to be chiefly swayed by the feeling that their job was censorship and restraint. The Corporation of Harvard University on the contrary, is thought by all the Faculty and especially by those of us who have, in administrative positions, had to make many hundreds of recommendations, to be a body that is there in order to encourage and help. The President that I served under most of the time I cannot speak of quite, I think, with calmness. I spent fifteen years serving with Mr. Lowell. Those fifteen years included, of course, many conferences and I never left any conference without a feeling that I had been helped, encouraged, and stimulated in a way that was one of the greatest gifts that I have had in all my active life. I remember well the day he told me he had the previous day given his resignation to the Corporation. I felt at that time as if I were academically orphaned. I think Mr. Lowell never knew when he first asked me to be Dean and I quite flatly refused, one strong reason for my refusal was that I had still that complex about university administrators and I was afraid that Mr. Lowell might be as arbitrary as some others I had known. At the end of fifteen years with him, the only arbitrary acts I knew of on his part were in two or three instances when disagreeable things had to be done and he insisted on doing them himself, because, he said, "Such things are part of the president's job and you have to live with those men." I thought seriously of resigning when Mr. Lowell told me he had resigned. It seemed fairer to the new President, whomever he might be, not to precipitate that extra confusion and I decided to wait two years. My two years are now up and I shall always feel very happy that I did not resign earlier, because the past two years with President Conant have been two very happy years of association with him. I have always had the comfortable feeling that Mr. Conant and I were brought up on the same bottle!

My confession of faith in medical education

has, I think, been quite simple. It has been apparently, one that is sympathized with by most of my colleagues, and comes down to three main things. The first is one that I think anybody would agree with, namely, that those who lead in any subject in a medical school or in any other part of a university must themselves be not only inspiring persons but they must be constantly adding to the progress of their subject. The second is that I think a medical school must grow continuously and intensively more deeply associated with the general university. Some of the older men present know the conditions when I entered Medicine, but the younger men may not see the importance of this point fully. The training in Medicine is one of the oldest trainings in the world, but it was long only a vocational training and often, in fact, almost a commercial training. Even when I entered a medical school which school was then the most influential in the country, it was true that the fees received from students ran the whole medical school and, in addition to that, it was still possible for the senior faculty to "cut a melon," so to speak, at the end of the year and divide the excess of the amounts that had been received from students and therefore increase their salaries by that bonus at the end of the year. That, I think, shows how far the change has gone. It shows how commercial the point of view was at that time and how far separated from the scholarly attitude of a general university faculty. I have heard much discussion for many years of the reasons why a medical school must be associated with a university. The usual reason given is that there is no chance of getting the money that is needed for the expensive methods of the present day without having the influence and prestige of a university behind any such efforts. There are far more important reasons than this. The practical reasons in education and research are quite obvious I think. The natural sciences have been the background upon which Medicine is built. They have become more and more essential. At the present time they are far more essential than ever before. The social sciences have always been of some degree of importance to Medicine. Psychology has long been important and no one can question that it is getting more and more important in the practice of Medicine. Economics has become so influential in Medicine that we have an Assistant Professor of Medical Economics in the Medical School, welcomed by the Faculty as being a very suitable thing. Sociology as it grows more forceful will be of essential importance. The Engineering School has become a blood brother of the School of Public Health and Public Health and Medicine are Siamese twins. The Business School already has had many associations with the Medical Faculty. I have no doubt that in a very few years there will be active and inter

ested cooperation between the Law School and the Medical School. Those are the practical aspects of it, but a larger aspect than that, I think, is that Medicine has become a scholarly pursuit in all its lines. It must exist in a scholarly atmosphere and not by itself if it is to progress adequately.

The other thing that seems to me to be so important, the third thing, is, what shall be done in regard to the superior student? I think everybody is agreed that an imperative duty in any medical school is to educate all students well and to turn them out to do an excellent job. But there is something more important almost than that. I think any faculty that is a good faculty may be depended upon to do that reasonably well, but the thing that is in my mind always is, what shall be done in regard to the exceptional man? Many years ago, long before any general restoration occurred there, I was in Williamsburg, Virginia, and while there went into the old Bruton Parish Church, which to me is, I think, the most moving place I was ever in in this country—to an American one of the most moving places in the world. They had, in restoring the pews, memorialized those great men who about the same time worshipped there. It is profoundly moving to see the names of George Washington, Thomas Jefferson, James Monroe, John Marshall, Patrick Henry, Edmund Randolph, and others only less great including, particularly, George Wythe the father of lawyers and especially the father of those two great adversaries Jefferson and Marshall, who had, each in his way, such profound influence on our country's great institutions. I question whether one could find anywhere such a galaxy of men of great influence gathered together at about the same time and at a very critical time. The Dean of William and Mary learned that I was there and insisted on my speaking to the students in chapel next morning. There is an old worn tablet in the floor of Bruton Parish Church chancel with the inscription, "Here lie two sweet infants" and after giving names and dates it ends with the simple plea, "God give us grace to follow them." I used that part of the inscription as my text in speaking to the students, thinking, of course, not of the "two sweet infants" but of those great men who had been there and who had initiated so much of the things we care most for in this country. Standing there on the slab that covers the remains of John Randolph in old William and Mary, where most of the men got such academic education as they had (George Washington's was three months in surveying) it was deeply moving to think of the profound effects of the vision, the courage and the powers of leadership of the men who had been there at that time. That gave me to think then, and gave me to think many times since, what a precious thing leadership is and

how far one may well go in attempting to find and develop those who seem to have the germs of leadership. We may all well feel very grateful to President Conant for making such determined efforts to go out and find leaders. But when you get them in your control as students they cannot be put into regular harness and regular routine with other students without great danger of blunting or killing their powers of leadership. Perhaps one of the things that I think is most feared by the conventional teacher is making experiments of this kind. I have seen repeatedly a start made to give great freedom to promising men and then because, in one or two cases, an individual did not do well with, that freedom it was given up with all the fine promising students. It is a gamble, but it is a gamble for very precious results and it is sad to think of a whole group of men, who have powers that are beyond those of ordinary men, being obliged to fall back into lock step with the whole flock because of one or two mistakes that have been made in the choice of men for such privileges. It is one of the responsibilities of the Medical School, or any other part of the University, to provide particular conditions for men who show signs of possible leadership, because of the great value they may prove to have. Since the Great War and since the awful destruction of intelligence that occurred then, it has seemed to me a peculiarly great responsibility, an almost solemn responsibility, to do what we can in this country where we have been relatively little touched by the loss of leaders, and especially during the present disturbed state of the world, to make the best conditions we can for those who may come to be leaders.

These are the things that I have had chiefly in my heart during the time that I have been Dean. I am not in the least desirous that my colleagues or my successor should feel any sentiment about carrying on details that have interested me. I trust that Dr. Burwell and my colleagues will not think that I hope my views will be followed after I have left my post. When a change occurs there must be a change or there will not be progress, but these great principles that I have spoken of are all things that I believe must be followed in order to accomplish the best that can be done. It is a happiness to think that with my successor and with my colleagues all this is in safe hands.

I have no regrets at giving up my work. I meet the relief from responsibility with great pleasure. I have great regrets in cutting the bonds with those I have worked with so long, but I shall have great happiness in one especial thing. When he was about to retire, Billroth who did so much for surgery, so much more than most of us do for any thing, was told by one of his friends that he should be very proud of his accomplishments. Billroth said he thought

little of them, but he did think often of the fact that scattered all over Germany and Austria were students of his, men who had made great names for themselves and men whom he had opportunity to help in some degree in their efforts toward their careers. I am happy to think that there are here in our own institution a large group of men that I have seen grow to leaders in their fields, and scattered over various parts of the country are others whose progress I have had opportunity to further and I shall

have the greatest pleasure in watching them go forward. I shall always look back with the most happy and most affectionate feelings toward the twenty three years that I have spent here and, perhaps, in many ways especially to the seventeen years I have spent in the Dean's work. I shall cherish particularly my association with President Lowell and recently with President Conant, and my intimate and affectionate association with many of my colleagues at the School.

NEW HAMPSHIRE MEDICAL SOCIETY

FACTORS IN THE MANAGEMENT OF CONSTIPATION*

BY FRED ELLSWORTH CLOW, M.D.†

"Do not fear to repeat what has already been said. Men need these things dinned into their ears many times and from all sides. The first rumor makes them prick up their ears the second registers and the third enters."—LAERTIUS

CONSTIPATION is the commonest single disorder suffered by human beings. Usually it is, like cough in pneumonia, a symptom. The great majority of women are thought to have it, often during the whole life, though in recent years loose clothing and more exercise have apparently decreased its incidence. As a symptom it appears in a very large percentage of histories taken at the bedside and in the office. It is essentially a delay in the evacuation of food residues, bacteria, which make up from thirty to eighty per cent of the stool (Bassler) dead epithelial cells, and chemical refuse. Reichman has described cases in which an evacuation of the bowel took place normally at two and three weeks' intervals. In deciding whether constipation does exist, an arbitrary thought has been that more than two or three days' delay constituted an abnormal state. Perfect health however, is not incompatible with these infrequent defecations, going even to the fifth and sixth days.

A definition of constipation then is not at all times so easy to compose. What to one patient is a normal condition is to the nervous health conscious, apprehensive individual a veritable Banquo's ghost. Where one is satisfied to eject a hard, irritating stool after a siege of straining another's life is utterly ruined unless the bowel be emptied at least twice each day of liquid and likewise irritating contents. To some the failure to defecate on two days a week is constipation, to others it is the failure to defecate at least each morning and night.

With constipation as in many other states, the greater the number and variety of the symp-

toms the less actual trouble the patient really has. It is always a comfort as well as a nuisance to the listener for the voluble subject to run off a list of discomforts ranging from falling hair to pain in the feet. Before he has proceeded far the doctor knows the answer. And fortunately it is often constipation, and nothing more.

In a survey for this paper more than fifty separate causes are found in the literature. It is of course, impossible to cover so vast a field, so this discussion will be limited to a few aspects of the symptom complex, the etiology of a considerable group of cases where the trouble is easily ascertained and relieved, the importance of constipation in certain types of people, the relief of the symptom as a part of the treatment of many diseases.

Medical literature is filled with the discussion of constipation, yet much of it is positively useless to the clinician. "Some writers only mention constipation in passing and dismiss the subject with a word or two about a change of diet while others are too elaborate in their discussion, leading one to infer that many, if not most cases of constipation need an exploratory laparotomy for their correct diagnosis and a major surgical operation for their cure" (Canick.)

Though it is a concomitant of many diseases, constipation is not especially characteristic of any disease. In the majority of cases it points to local disturbance of either the large intestine, rectum or anus, and it is usually functional rather than organic in origin. The relief of the symptom is not followed by cure in all people. The only result is a return to the purgative unless the patient is more than ordinarily persistent. And it is the persistent patient who is often the most difficult to relieve because of his "colon-consciousness." However probably nearly all methods of treatment partly psychic, partly physical, partly dietetic will bring lasting relief.

Customary though it is to distinguish degrees

*Read at the Annual Meeting of the New Hampshire Medical Society at Manchester N. H., May 7, 1929.
†Clow, Fred Ellsworth—Visiting Physician, Hecstus Hospital, Wolfeboro, New Hampshire. For record and address of author see "This Week's Issue," page 1292.

such as obstipation and constipation, types such as atonic and spastic, organic and functional, as though it were possible to use these classifications as bases for diagnosis and treatment, it is usually the case that one deals with a combination of etiological factors as well as physiological variations in the actions of the alimentary tract. Organic change may be functional stasis.

One can but be surprised at the number of people who over large periods have taken increasing amounts of purgatives without any cause ever being sought. It is often these patients who have rectal or anal constipation. Relief of the latter difficulty is easy, satisfactory and permanent.

To define the cause of stasis in any given case may be a trying problem. In some instances the complications of the condition are, in themselves, causes. One can never forget in the individual of almost any age the possibility of the most serious cause of all, neoplasm. The diagnosis, at a time when operation can be successful, may tax the knowledge of the most specialized. Benign stricture, too, offers its own difficulties. Lead poisoning even in these modern days cannot be entirely ignored.

Fecal colic may present the symptoms of intestinal obstruction, with severe cramp-like pains, even fever and pronounced leucocytosis. Enemata will rule out the more serious condition, but the patient may be severely prostrated with points of residual abdominal tenderness, remaining for several days, presumably caused by local peritonitis at the site of spasm. More interesting still are the cases of genuine obstruction possibly with ulceration of the gut, in an apparently normal colon, due to fecoliths.

The differentiation of atonic and spastic constipation, except in certain types of individuals, is impossible. The senile patient with flabby skeletal muscles and the person who lives a sedentary life, likewise the high-strung nervous individual who is constantly under tension, are fairly easy to classify. But types fade into each other, with the variation in the response to stimuli, with mental attitude, habits and diet.

As direct causes one must mention weakness of the bowel wall, partial obstruction, from whatever cause, and weakness of the nerve mechanism. The flabby abdominal muscles of the woman who has had pregnancies, the ineffective diaphragm of the old person with chronic emphysema, the general incompetence of the senile, the weak will of the easy going all contribute to the large group who must have some sort of laxative. Idiopathic dilatation of the colon, spasm of the musculature from irritation of harsh contents, and even the improper use of ill-adapted cathartic drugs may be features in the situation. Acute constipation of a troublesome type may occur as the result of psychic shock.

Anal constipation has been recognized for many years, in London, as a clinical entity. Frew has called attention to its significance in babies and small children and has described the characteristic greenish brown color of the stool which is practically always present. The story told by these patients, many of whom are beyond middle life, is that they have been constipated from childhood. Often the statement is volunteered that fecal matter comes to the anus but no reasonable amount of straining will expel it. Even a soft mushy stool presents difficulty. Unless the stool is of liquid consistency there is trouble. Enemata, or drastic purges, are used to produce practically every movement. Feces evidently stay for days in the rectum simply because the patient is unable to get the mass through the tight orifice.

The most important symptoms of constipation are those of a feeling of fullness and pressure with vague acute and subacute pains, or most significant, the cramp-like pains of partial obstruction, benign or malignant. The pain may be localized to regions of impaction or it may affect the region of the descending colon or the entire abdomen. The secondary disorders of a "liverish" condition, poor digestion, torpor, nausea and even vomiting may be very real indeed. Fecal accumulation most frequently occurs in the sigmoid, though the cecal region may be the site of a firm tumor that may be the cause of a mistaken diagnosis. One cannot ignore the attacks of diarrhea which may occur in constipation as a result of the irritation of an impaction in the rectum or higher in the canal.

"Biliousness" is a real entity as has been pointed out recently by workers at the Mayo Clinic. That "liverish" feeling that many people vividly describe, especially after a too great strain has been placed on the gastrointestinal apparatus through overindulgence in rich food, is a very real sensation. The shortest way to rid the patient of his accumulation of toxic products of faulty digestion and putrefactive residues is to use the duodenal tube promptly. Drainage of the bile ducts may well precede lavage using magnesium sulphate or hydrochloric acid. After the bile ducts have been emptied, using either pump suction or motor, through the tube is given a hypertonic solution of sodium sulphate, sodium chloride and sodium bicarbonate with phenolphthalein. The intestinal canal is cleared from pylorus to anus.

Constipation is a symptom, frequently, of cancer of the rectum, along with alternating diarrhea, or preceding diarrhea. The diagnosis of the latter condition depends upon remembering that it is always possible, and then looking for it. One can never forget that the replacement of constipation by diarrhea, particularly that type characterized by small frequent

painful stools, and an intolerant rectum, is an ominous sign

Blood in the stool unless it is red in color is more apt to arise from the small bowel. But every case of unexplained constipation should have repeated tests, though it must be remembered that occult blood may come from any part of the alimentary canal from mouth to anus. The difficulty of diagnosis of lesions of the large intestine where neoplasm is most frequent is considerable. Where the stool is deformed flat or ribbon like, especially with mucus, grey or brownish in color the difficulty is more often irritable colon.

The habits and diet are of first importance in the presence or absence of constipation. The patient who habitually ignores the signals from a full rectum is bound to be in more or less trouble. For the majority of people who have constipation two courses are apparently followed: the condition is allowed to drift, the victim being satisfied with a stool twice or even once a week, or various types of easily exhibited cathartics, of increasing strength, are habitually used. At some time or other most people use phenolphthalein in increasing doses.

Diet alone may be the cause of undue delay in the intestine. Concentrated carbohydrates and strained vegetables leave so little residue that peristaltic action is wanting. In the physiology of the intestinal movement it must not be forgotten that while bulk often governs movement, at the same time it may be a menace in that large boluses may be formed from such material as bran and cellulose which have been decidedly overpopularized as laxatives. The more the gut is angulated or narrowed the greater the potential dangers of this occurrence.

A fibroid in the true pelvis or a large prostate may be the offender. In certain cases of loss of tone of the rectum, and bladder, occurring particularly in organic lesions of the spinal cord a normal prostate may serve to block completely the anal canal. Unless the impaction is removed promptly and treatment directed to the rectum itself the condition of such patients becomes deplorable indeed. The prostate itself may be extruded in advance of the stool.

Certain precautions must always be observed in connection with the interpretation of constipation as a disease and as a symptom. Fecal masses in the cecal or sigmoid region are easily mistaken for neoplasms. No diagnosis of abdominal tumor is really safe until one is certain that both bladder and bowel are empty. The observation of visible peristalsis may be a pitfall, when the patient is thin and the abdominal musculature is flabby. Acute constipation can be the cause of intense suffering simulating to a marked degree a genuine acute emergency, and thus not only in children but in adults. The pain, shock and stomach disturbance have all the earmarks of a serious situation.

For a considerable period we have been teaching the laity the dangers of cathartics in the presence of abdominal pain. Many series of cases of perforative appendicitis with its grave mortality have been used to drive home this point. There is still room for more education in this direction. It has been the custom never to let slip an opportunity to tell those responsible for young people to use the enema bag freely, yet one is frequently astounded at the risks intelligent patients are constantly running.

The use of the stethoscope in abdominal examination should be as common as in auscultation of the chest. Unhappily it is not. Much information may be learned from listening to an abdomen that is in trouble, especially when the constipation is of recent development. The student should be familiar with the normal sound of gas and fluids in the gut. With radiographic evidence it may give the only physical signs to be elicited.

There are a few local results that appear to come directly from constipation. In some instances there is thinning of the gut wall, in others an actual thickening. What part delay plays in the beginnings of cancer is undetermined. Cancer occurs most frequently in men, while as Pennington has shown women are more apt to have constipation. The significance that should be attached to the development of constipation in one of normal habit previously is the most important feature. The person who complains of this, and especially of cramps due to an effort to get material past a narrow place demands the best diagnostic attention.

The reality of the somatic symptoms of absorption of material, due to delay in the bowel, has been seriously questioned. It has been shown that packing the rectum with cotton produces all the headache torpid feeling and abdominal discomfort coming usually from stasis. One can well believe that Munthe in "San Michele" tells the truth when he admits that in his manipulations of the wealthy Pomeranian women with "colitis" he was a hit of a quack.

The present-day diagnosis of "irritable" colon which seems so popular should be made with conservatism, especially if one believes that the "colon-conscious" person can get symptoms of everything to which flesh is heir. The best authorities are convinced that it is not an intestinal condition but rather a neurosis. In all the work on intestinal stasis there has been a paucity of evidence of production and absorption of toxins and pathogenic bacteria that would stand the cold evaluation of science. The evidence offered by surgical treatment which was used in the early days and which proved so disastrous for so many, should make us skeptical.

There is apparent agreement that the patho-

logical changes resulting from constipation concern themselves mostly with either thinning and dilatation of the colonic walls, from mechanical distention, or hypertrophy and spastic contraction of segments of the gut from prolonged efforts to force intestinal contents through. The interior of the colon is sometimes plastered with a uniform layer of feces from cecum to anus. Prolonged neglect on the part of an old person may lead to a solid packing of the entire large intestine, failure of peristalsis and death. Diarrhea may have occurred up to near the very end.

The notion of auto-intoxication from intestinal absorption has been with us a long time. Many disorders, even epilepsy, arthritis, hypertension and chronic Bright's disease have been attributed to this. Evidence is decidedly lacking that this is the fact. It would seem that more real benefit would have resulted to these people from the millions of "internal baths" that have left behind irritated colons in dejected patients. It is probably true that more systemic infections have arisen from too brisk catharsis than from microbe action in dry solid stools which notoriously contain a much smaller percentage of bacteria. There is no question that many patients are miserable when the rectum is full, and that relief is immediate once an evacuation takes place. But the relief is almost too sudden for any change in chemical intoxication.

The discussion of treatment centers about removal of the exciting cause almost more than in any other condition. For the majority of cases a cause can be assigned and with perseverance it can be removed. The therapy of the condition has already been indicated in the discussion of the etiology.

No case of constipation, in all honesty, should be treated without rectal examination. Why doctors shy at the insertion of the finger in the rectum is a mystery, for, as a prominent surgeon remarked "if one does not put a finger in the anus he is apt to put his foot in it."

Besides

- 1 The senile patient whose bowels are "just dead." For him only laxatives are of any use, and these mildest that will produce an effect.
- 2 The patient with fever must still get his calomel and salts.
- 3 The sedentary individual should be encouraged to walk in the open air, to "ride a bicycle" lying on his back after retiring, and to massage the abdomen, although this is never effective in the more resistant types of constipation. Even the leather covered "cannon ball" will make mighty little impression. And, as a rule, unless they are undesirably health-conscious most patients quickly tire of any regimen that requires much effort or time.

- 4 The uncooperative patient must have his pills and potions.

At present the market is flooded with combinations of paraffine oil and agar, usually with some real purgative as phenolphthalein or cascara. Apparently in the doses one can afford, the first two prove inefficient. The cost of such preparations puts them beyond the use of a good many people. In any consideration of the prolonged use of mineral oil two points should not be forgotten. This is the same oil that is admittedly the cause of epithelioma of the skin in textile workers. One may too, properly question the propriety of covering every particle of food in an envelope of undigestible fat, especially when we purposely omit lard and butter from the diet. What effects, if any, these obvious objections possess only the future can assess.

Milk of magnesia, cascara, and the almost forgotten compound licorice powder all have their uses, especially for temporary purposes. One or two glasses of hot water while dressing may stimulate the rectum to satisfactory evacuation. Arabian paste, easily prepared in the kitchen from prunes, figs, dates and senna leaves offers a mixture that can be used by every adult and the older children.

In many cases of functional indigestion the first thing to do is to stop all cathartic drugs. While some folks can stand drastic purgation without discomfort others are made utterly miserable with "gas and distress" by the mildest laxative.

- 5 For temporary use and I regret to say, too often permanently such laxatives as cascara and combinations of aloin and belladonna must be used.
- 6 Enemata are the safest and most effective ways of emptying the lower bowel. I know of no condition in which an enema of a pint of salt solution can do harm.
- 7 The treatment of anal constipation is simplicity itself. Examination discloses a firm narrow band encircling the anus, tight, tender and unyielding, just external to the pectinate line. Unless the rectum is investigated digitally the condition is sure to be missed. Gradual dilatation by bougies is not necessary or expedient for the obstruction is easily removed at one sitting, without division of the sphincter muscle. Apparently it does not recur. If fissure is present, as not infrequently happens from the repeated insults to the anal mucocutaneous lining, it is cured by the same operation which relieves the obstruction. Under general anesthesia the tight band is gradually and gently stretched, taking plenty of time for thor-

ough dilatation. Blood should not be produced. In many cases fissure of the anus is present with its sentinel pile. No anesthetic is needed in a baby for the stricture-like band is never so tense and spastic as in adults, so gentle dilatation with the index finger is not too painful.

In spite of all one says and does millions of people are still going to seek their relief at the drug counter. One cannot wholly blame them when the treatment of so apparently simple a condition is yet imperfectly understood. How a dose of castor oil produces its effect is still a mystery. On the one hand is the costly and elaborate investigation often followed by a radical operation. On the other is the box of pills or the bottle of patent medicine given without a thought by the harassed physician or by the suave counter prescribing druggist. Between them is the rational régime which relieves the condition but does lend itself to the present hurried mode of life. The patient deserves a sensible investigation of his difficulty.

Whether or not one believes in auto-intoxication, it is a fact that many persons suffering from a variety of conditions are relieved by transnodal lavage and a genuinely clean intestinal tract. It is conceded that there is such a condition as biliousness and that drainage of the bile ducts and emptying the bowels does not relieve it. Migraine may not be caused by absorption of noxious toxins from the bowel but many of its victims are relieved by a cathartic which possibly removes the allergic substances, and by the prolonged use of lavage in not a small percentage of cases are permanently relieved.

The use of belladonna and olive oil enemas, to be retained overnight, relieves the spastic lower colon and sigmoid. It always does away with the patient's discomfort when evacuation leaves him with a feeling that "there is still something left."

Such extensive operations as colectomy in vogue a few years ago, as the result of Lane's teaching, have fortunately been given up. The last state of the patient was far worse than the first. The concept of auto intoxication upon which these drastic measures were based has been disproved. It is generally accepted that bacteria do penetrate the intestinal wall, to be destroyed in the lymphatic protective mechanism and in the liver. In any event it appears that the loose stool is far more dangerous than the dry solid type. It would appear that advanced workers who have dared put their patients on a régime which produced firm hard stools at long intervals had at least done them no harm. (Burnett.)

There can be no question that constipation is a nearly universal symptom, that it possibly has deep consequences for the patient that it

may be of serious import in the history and physical examination. In spite of the fact that the majority of people will stick to the pill box or the greasy bottle, physicians should realize that the condition deserves serious study and efficient treatment. In many instances the cause is easily discovered and as easily remedied. The patient is always entitled to the best in evaluating this symptom as he is in dealing with other more spectacular manifestations of disease. We are certainly not discovering a new disease concept.

The tremendously successful exploitation of the people of this country by commercial interests through the sale of laxative drugs alone is an index of the frequency of the condition discussed. We should remember, however, that constipation is not particularly a disorder of civilization when it is noted that Hippocrates and the medical writers of China and Egypt seriously considered it. Hippocrates describes abdominal massage. The Talmud advises the use of water, in large quantities, and vegetables. In modern medical literature hardly a disorder has had more attention, yet the problem still plagues us. We are managing a situation that has plagued man from the dawn of his birth.

DISCUSSION

PRESIDENT LORD: I will call upon Dr. Richard W. Robinson of Laconia to discuss this paper.

DR. RICHARD W. ROBINSON: *Mr. President and Members of the New Hampshire Medical Society*—I wish first to compliment Dr. Clow upon his courage in reading a paper on this subject. I don't know of anybody who could have done it any better than he.

Of course the problem of constipation is so universal to all of us that it should demand interest, but the very commonness of it, I suppose explains why we so seldom hear it discussed at our meetings. Another reason is that being armed with a number of drugs and materials, many so largely advertised to us that give us the means of overcoming its most prominent symptom, we forget its importance.

Leaving out the mechanical obstructive types of constipation, the type of constipation that is produced by such metallic poisons as lead and those constipations that result from diseases of the central nervous system, I think as Dr. Clow has said that most of the remaining cases of constipation can be classified as neuroses, some perhaps purely as neuroses, but the majority of them as neuroses only if we consider as a neurosis all functional nerve disorders. I think that the largest number of constipated individuals owe their condition at first, to deliberate failure to respond to the calls of nature and later to the taking of cathartics in order to relieve themselves at a more convenient time. I feel sure that a great many indefinite abdominal complaints are due to an irritated colon from the constant use of drug cathartics, and that the relief of a great many patients depends on getting them off the cathartic habit. That, to me, is the most important problem of constipation.

I think it has been pointed out that a large percentage of individuals that come into the clinics in

the cities with a tentative diagnosis of chronic appendicitis, gall bladder diseases, and so on, those who have nothing particularly definite about their complaints, turn out to be patients who have habitually taken cathartics. They show tenderness that extends along the whole of the large bowel. This tenderness is present upon palpation, and these patients are certainly relieved by getting them away from drug cathartics.

I do not believe that there is any place in the treatment of constipation for any drug by mouth, with the exception of the occasional administration of pure bile or bile salts, and this only rarely. The mineral oils that we have always considered to be the least irritating of all of the substances used in the relief of these ordinary cases of constipation, I believe, have been shown to contain a sufficient amount of sulphur to be in itself definitely irritating to the colon.

Now, there are a great many ways that have been described in the literature of dealing with the type of patient that I am speaking of. I will not enter into any discussion of them, except to describe to you a routine which has proved satisfactory to me.

Of course, the most important thing is the establishment of a definite habit time of bowel movement. The normal time, the most propitious time, is shortly after breakfast in the morning. I have been, in the last few years, prescribing for these patients, the drinking of a pint of normal saline an hour before breakfast in the morning. That gets them up early, but it does not do them any harm, and then I have them go to stool, at a prescribed time, in conducive surroundings, trying to convince them that they must take the time and be mentally at rest. After a period of fifteen minutes of effort, if they are not able to move the bowels at first, I have them take a small enema of normal saline, simply to start the bowel movement along.

If their diet, by history, is deficient in cellulose and fruit sugars, I think it is important to give them a moderate amount of these. I don't think it is valuable to stuff them full of indigestible substances.

DR. LOUIS C. AGER. *Mr. President*—Perhaps I have a foolish habit of contradicting people, but it is at least useful in making us think. All physicians should read Henshaw Ward's book on "wretched thinking."

Back in the last century when I was studying medicine I heard a lot about ribbon stools and their diagnostic importance. Having a mechanical turn of mind I tried to visualize their formation, but I have never been able to see it. I was doing considerable autopsy work in my undergraduate days and studied the intestine with the problem in mind. Just stop and think. The feces in the large bowel are quite liquid under normal conditions. We know that there is almost no absorption of liquid in the small intestine. On the other hand with stasis the feces remain so long in the large bowel that they become hard and dry. The sigmoid pouch is much more voluminous than the upper bowel, and the muscular pressure during defecation is strenuous. If the stool is soft it must be moulded into a solid mass. The shape of the stool depends upon the size and shape of the anal orifice.

PRESIDENT LORD. Is there further discussion, gentlemen, of this paper of Dr. Clow's?

DR. FLANDERS. *Mr. President*—I would like to discuss this paper from the standpoint of the patient, and not as a doctor. I have discovered that a man can go two days without a movement of the bowels and not die. A few years ago, when we made the rounds in the hospital, the first thing we used to

ask the nurse was, "Did the patient's bowels move yesterday?" and if the answer was "No," we said, "My God! why haven't you done something about it?"

I think I have been through the whole regimen. I have had my gall bladder pumped out. I have swallowed eighteen inches of hose with a lead sinker on the end and have lain five hours on my side until I was as hysterical as a woman. When bile was not rising in sufficient quantities, the nurse obligingly drenched me with a solution of sulphate of magnesia. I certainly cannot recommend this procedure from the standpoint of the patient, nor can I commend it as a physician. I have eaten bales of hay, have drunk gallons of water and stuffed myself with vegetables until I stuck out like an alderman, but it did not help a great deal.

When I suspected that I might have an appendix, I did not dare to take any more cathartics, and that was a grievous condition. Just the other day I read that phenolphthalein is poisonous, so that is definitely out of the picture.

As for an enema it is difficult to get enough in to do any good. I have a vivid recollection of one case that was managed successfully. I once had a Negro patient who had a stoppage. He had lived in the woods all winter and eaten corn meal until he was unable to defecate.

I told his father to take him home and give him an enema. He asked, "What's dat, Boss?" I replied, "Make up a lot of hot soapsuds and get a lot into him. He will say he can't hold any more, but give him plenty." Later the father reported success, although the treatment was crude and unduly vigorous.

An enema may be good in an emergency, but just now I am very hazy as to the treatment of chronic constipation. I have tried everything except unwarranted extreme treatment, and I am still constipated.

MISCELLANY

PERSONALS

Dr. Richard W. Robinson of Laconia will be in New Haven the first three days of each week as a member of the "Urological Clinic" at the New Haven Hospital of Yale University. He will also be a part time instructor at the "Urological Clinic" of Yale Medical School. Dr. Robinson graduated from the School in 1920.

Dr. Charles F. Keeley of Claremont and Dr. Howard E. Thompson of Nashua have been made Fellows of the American College of Surgeons. They made the trip to San Francisco to receive their certificates of membership.

Dr. John L. Fromer of Bethlehem sailed recently on the SS. Manhattan for Cork, Ireland, where he will study at the Rotunda Hospital in Dublin, Irish Free State, until May.

NURSES

The State Board of Nurse Examiners held a routine business meeting Tuesday, October 8, at the office of the Commissioner of Education in Concord. The Board's membership comprises Miss Belle Valentine, R.N., of Concord, Miss Rosanna O'Donoghue, R.N., of Portsmouth, Chairman, Miss

Addie M Moore R.N. of Grasmere Miss Lonise Thompson, R.N., of Keene, and Sister Larivee R.N., of the Notre Dame Hospital in Manchester

The annual graduation exercises of the Elliot Community Hospital Training School Keene were held Thursday evening October 24 James A Hamilton Superintendent of the Mary Hitchcock Memorial Hospital at Hanover gave the graduation address.

Public Health and School Nurses from Sullivan and Cheshire Counties held their semiannual meeting at the Elliot Community Hospital October 18. Many suggestions were offered in connection with school health problems Miss Eva Fortier R.N., of Hinsdale presided at the session.

The commencement exercises for the school for nurses of the Laconia Hospital were held Friday October 26. An address was given by Marietta D Barnaby, R.N., Registrar of the Central Directory for Nurses Boston. Dr Clifton S Abbott President of the New Hampshire Medical Society presented the diplomas.

Health and Welfare provisions of the Social Security Act as they may affect New Hampshire were outlined and discussed at the forum for Graduate Nurses of the State conducted at Concord, November 15 by the State Board of Health. More than 100 nurses were in attendance. Dr Charles Duncan, Secretary of the Board was one of the principal speakers.

The Training School for Nurses at the Littleton Hospital was discontinued November 1. This is in line with the general trend in New Hampshire where student nurses are being concentrated in a few educational centers.

COUNTY MEETINGS

At the recent annual meeting of the Orafton County Medical Society held at Hanover the following officers were elected:

President Ralph G Perry Wells River Vt.
Vice-President Kenneth Churchill Lebanon.
Secretary-Treasurer Leslie K. Sycamore, Hanover
Censors Ralph E Miller Hanover John M Page Littleton Arthur W Burnham, Lebanon.
Member of Committee on Medical Jurisprudence Arthur T Downing Littleton.
Delegates Robert M Deming, Glencliff Leslie M McKinlay North Haverhill Leslie K. Sycamore Hanover

The Belknap County Medical Society held its monthly meeting at Plymouth, November 13. Dr Leslie K. Sycamore of Hanover spoke on "X Ray Examination and Gall Bladder Disease." Dr Raymond J Turley of Meredith presided at the meeting.

CLINICS

The State Cancer Commission is now maintaining clinics in eleven New Hampshire communities. Members of the Commission include Dr James W Jameson of Concord Dr George O Wilkins of Manchester Joseph W Epply of Manchester and John L. T Shaw of Chicheston.

The New Hampshire Tuberculosis Association held its eighteenth annual meeting at the Hotel Carpenter Manchester N. H. the latter part of October. The guest speaker was Dr Arthur J Strawn of Worcester Mass., who praised New Hampshire for its campaign against tuberculosis resulting in a death rate of but 35 per 100,000 population yearly the lowest in all of New England and ninth lowest in the United States. Dr Robert B Kerr of Manchester was reflected Executive Secretary.

A Maternal Health Center has recently been organized with offices at 1 South Street, Concord. Dr Ursula G Sanders of Concord is President.

HOSPITALS

The Margaret Pillsbury General Hospital at Concord is now equipped with a 100 per cent shock proof Theradex machine for use in the treatment of cancer. This makes it one of the first New England hospitals to have a complete shock-proof x ray equipment.

Under the will of the late Albert N Parlin the Elliot Community Hospital of Keene received a check for \$20,000 to be used to establish what is known as the Albert N Parlin Free Bed.

The Laconia Hospital is to be the recipient of \$3,000 under the will of Laura Weeks, late of Providence, R. I.

Through a gift of a \$10,000 x ray equipment by former Governor and Mrs. Huntley N Spanning the Frisbie Memorial Hospital of Rochester is to have an up-to-date x ray room installed.

COMPARISON OF DEATH RATES FROM TUBERCULOSIS IN THE NEW ENGLAND STATES IN 1934 (PULMONARY AND ALL FORMS)

State	Death Rate per 100,000 Population
New Hampshire	35.5
Maine	37.7
Connecticut	44.4
Rhode Island	44.4
Massachusetts	48.6
Vermont	52.6

CASE RECORDS of the MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

FOUNDED BY RICHARD C CABOT, M D

TRACY B MALLORY, M D, *Editor*

CASE 21501

PRESENTATION OF CASE

A sixty-one year old Nova Scotian teamster was admitted complaining of loss of weight and regurgitation of mucus

For about ten years at intervals the patient had regurgitated small amounts of mucoid material which seemed to come "from the back of his throat" This, however, afforded him no particular discomfort It was not accompanied by nausea and only recurred at scattered intervals About three years before entry it became somewhat more frequent, was associated with nausea, and the regurgitated material occasionally had a foul odor As before, it appeared to come from the back of the throat and the patient stated that he did not believe that it was actually vomited It was usually small in amount but as the frequency increased he eventually brought up as much as a quart daily The nausea became so troublesome that he curtailed his meals more and more During the month before entry he limited his diet to milk and ginger ale only At about this time he had a slight burning pain beneath the lower end of the sternum for a few days This was relieved by powders prescribed by his physician As a result of gradual loss of weight and strength he was compelled to cease working several weeks before admission At the time of admission he was unable to eat more than a spoonful of soft food at a time and the regurgitated material was now quite constantly foul smelling His weight, which had been 190 pounds ten years previously and 164 one year previously, was now only 135 pounds There was never any hematemesis or dysphagia Two weeks before admission an x-ray taken at another hospital showed a "pouch at the lower end of the esophagus"

He had suffered from hayfever occasionally until one year before admission His gallbladder had been removed thirteen years previously and a bilateral herniorrhaphy was done two years later

Physical examination showed a well-developed but poorly nourished man who appeared to have lost considerable weight recently There was complete edentia The neck was negative and the trachea was in the midline The heart and

lungs were normal The blood pressure was 130/75 The scars of the hernia repairs and cholecystectomy wound were well healed, but there was a recurrent inguinal hernia on the right side

The temperature, pulse and respirations were normal

Examination of the urine was negative The blood showed a red cell count of 4,700,000, with a hemoglobin of 80 per cent The white cell count was 4,600, 70 per cent polymorphonuclears Three stool examinations were negative There was no occult blood The nonprotein nitrogen of the blood was 24 milligrams A Hinton test was negative Gastric analysis showed a free hydrochloric acid of 0 to 50 and a total acid of 75 to 111

An x-ray following a barium meal exhibited gross irregularity of the lower esophagus and herniation of the fundus of the stomach through the esophageal hiatus The hernia, grossly irregular as a result of many filling defects, formed a tumor mass between the heart and the spine There was no obstruction to the passage of barium The stomach below the diaphragm, and the duodenum were negative A plain film of the chest showed clear lung fields and costophrenic angles The heart was not remarkable Within the shadow of the heart was a rounded shadow 10 centimeters in diameter

There was moderate improvement in the patient's ability to retain food On the thirteenth hospital day an exploratory laparotomy was performed but additional surgical intervention was deemed inadvisable The patient died on the following day

DIFFERENTIAL DIAGNOSIS

DR CHESTER M JONES As I started to read this I wondered whether we were not dealing with a diverticulum of the esophagus with retention of food which was later regurgitated As we read along, however, the picture becomes very unusual for a diverticulum without any complicating factor

Heartburn or burning pain under the sternum, for instance, I think would be distinctly unusual for simple diverticulum

"At the time of admission he was unable to eat more than a spoonful of soft food at a time and the regurgitated material was now quite constantly foul smelling" This, of course, indicated stasis

"His weight, which had been 190 pounds ten years previously and 164 one year previously, was now only 135 pounds" A very striking loss of weight and that, it seems to me, definitely rules out a diverticulum alone on which to base all his symptoms or as the basis of the loss of weight

From the story alone it seems to me that we have a right to consider two or three diagnoses

It is possible that he had an esophageal diverticulum, at the lower third of the esophagus, but this seems unlikely in view of the fact that he had so much stasis and because of the quality and character of the symptoms, and with such a striking loss of weight. The only other condition I know of that will give as much vomiting as that is either a diaphragmatic hernia, a fairly large one, with stasis in the hernia at times, or, of course, an obstruction lower down in the stomach itself. I think Dr Mosher is absolutely correct in saying that diaphragmatic hernia is very frequent and very commonly does not have symptoms. Occasionally they produce symptoms, however, but I think it is rather rare. The usual symptom is easy vomiting, especially when leaning forward with regurgitation through the cardia from a large gastric pouch above the diaphragm. There may be pain at times which sometimes simulates gall stones. It usually occurs at about the age of sixty, but I think it is extremely unusual for a patient with a simple diaphragmatic hernia no matter how large, to have vomiting of this degree and the terrific loss of weight that he had. I take it he was a laborer doing hard work who could not be bothered about anything except symptoms that were striking. I think this pouch seen by x ray was a pouch all right and that it represented a sacculization possibly from a diaphragmatic hernia, but with some complicating factor.

"He had suffered from hayfever occasionally until one year before admission. His gallbladder had been removed thirteen years previously and a bilateral herniorrhaphy was done two years later." I should say these facts were unfortunate from the patient's point of view but contribute nothing to the history.

"The neck was negative and the trachea was in the midline." This suggests that there was no mediastinal tumor which was displacing the trachea.

Aside from the emaciation, the physical examination does not help us at all in making a diagnosis. There was no evidence of herniation of the diaphragm with the stomach and colon above the diaphragm.

Following histamine there was a perfectly good secretion of normal gastric juice with nothing in it that was diagnostic. One thing I would like to know about the gastric analysis which is not given is the question of tube stasis. Was there a large amount, and how much was removed? It is possible the tube might have gone through the hernia and that there was no stasis where the stomach was explored with the tube.

I should like to comment on the x ray films. I should think we have the explanation here of the complicated factor in this diaphragmatic hernia which was the basis of loss of weight and illness. Most diaphragmatic hernias are not described in this way, as having many filling

defects in the portion of the stomach which is visible. Filling defects—unless associated with food stasis—should represent polyp or very striking gastritis with hypertrophy of the rugae with pseudopolypoid formation. I think polyps ought to be considered. Polyps themselves do not cause symptoms such as are described here unless there is a complicating factor. For that reason one would have to consider malignant degeneration of polyps which apparently were seen in this portion of the stomach above the diaphragm. There was no actual obstruction of the esophagus from the point of view of the roentgenologist but there must have been some pressure on the esophagus and some difficulty in the passage of solid food. The patient was existing on liquids and not taking sufficient calories in the liquid to maintain weight and strength. The shadow in the region of the heart might well be a tumor mass in the wall of the stomach in the upper portion of the diaphragmatic hernia.

I suppose that an attempt was made to explore this diaphragmatic hernia on the basis of there being a tumor there and in the hope that the tumor might be resected, certainly a very major operation and obviously it was more than this patient could stand.

I should think from the story and x ray report that one had the right to make a diagnosis of diaphragmatic hernia, that a portion of the stomach above the diaphragm developed polyps with malignant degeneration of some of them. The interesting thing is that there is no evidence of involvement of the stomach below the diaphragm. I think it occurs occasionally. With any diaphragmatic hernia, if there is fixation of the portion of the stomach above the diaphragm, one might develop quite striking gastritis. I think I have seen such cases. They do have some discomfort and pain and we do know there is a tendency in chronic gastritis with polypoid formation to have degeneration of the polyps with the development of malignancy. I think that is what occurred here, above the diaphragm, and not in the portion of the stomach below the diaphragm.

X RAY INTERPRETATION

DR. RICHARD SCHATZKI: The examiner (I did not examine the patient myself) saw the barium run along this mass which is visible just above the diaphragm. It is irregular and has the appearance of an ulcerated tumor. The barium runs along the border of the mass much as the esophagus does along a large herniated stomach. Here you see the shadow described as lying behind the heart representing the same mass. There is perhaps one factor which is not quite consistent with a hernia, that is the fact that a well developed fundus seems to lie below the diaphragm.

I should like to say a few words in general in regard to diaphragmatic hernia which we are

discussing There are, in principle, two different types of hernia, the congenital type which has a short esophagus and is rather rare, the acquired type which is much more common, particularly in old people. In these cases the esophagus is pushed upward by the stomach or the herniated stomach lies alongside of the esophagus. We examined a number of old people and could demonstrate hernias in about three out of four cases when examined with particular care in regard to the question of herniation. Some of these patients received air insufflation of the colon in order to increase the abdominal pressure. These hernias in old people are apparently nothing but an increase of the normal movability of the esophagus and stomach in the hiatus.

May I use this opportunity to say a word about the differential diagnosis of varices and cancer of the esophagus by x-ray? One may get a wrong impression from the last case which was discussed here. The differential diagnosis in most cases is rather simple. In difficult cases demonstration of normal relief during peristalsis speaks in favor of varices and rules out cancer. Another test which may help is based on the fact that the size of varices can be changed by change of the intrathoracic pressure. There are, however, a few cases in which differential diagnosis is extremely difficult. The important fact which this case taught us was to call such a lesion cancer if there is difficulty in swallowing.

DR JONES May I ask one question in view of that? You showed me a case a year and a half ago which had a definite picture of occluding mass of varices in the esophagus. The patient had definite symptoms of obstruction.

DR SCHATZKI Yes, we first called it cancer, later saw the lesion extend over the whole esophagus and did not know what to call it. An enlarged spleen was discovered at that time. Liver test showed slightly impaired function. He died later and we did not get an autopsy. He had difficulty in swallowing up to his last day and I now think that he had cancer.

CLINICAL DISCUSSION

DR EDWARD D CHURCHILL The preliminary diagnosis was diaphragmatic hernia with carcinoma of the stomach. "Exploration in the region of the esophageal hiatus revealed a large, hard mass involving the cardiac end of the stomach and impacted in a diaphragmatic hernia. On gently running a finger alongside the mass an area of necrosis and pus was encountered in malignant tissue. Obviously a terminal case. Closed without drainage." Encountering a perforated carcinoma in that region spells the death of the patient and there is nothing more to be done about it.

CLINICAL DIAGNOSES

Carcinoma of the stomach
Diaphragmatic hernia

DR. CHESTER M JONES'S DIAGNOSES

Diaphragmatic hernia.
Polyps of the stomach
Malignant degeneration of the polyps

ANATOMIC DIAGNOSES

Leiomyosarcoma of the distal third of the esophagus with extension into and ulceration of the mediastinal lymph nodes
Dilatation of the esophageal hiatus of the diaphragm
Operative incision Exploratory laparotomy
Peritonitis, acute localized.
Hydrothorax, bilateral
Arteriosclerosis, slight coronary and aortic
Cholecystitis, chronic
Cholelithiasis
Operative scars Bilateral inguinal herniorrhaphy

PATHOLOGIC DISCUSSION

DR TRACY B MALLORY At autopsy a large tumor mass was found within the diaphragmatic hernia. It turned out to be not in the stomach but in the terminal portion of the esophagus, stopping absolutely short at the cardia, and the stomach was entirely free. The tumor had spread through the esophageal wall and involved a group of mediastinal lymph nodes on the anterior surface of the esophagus just behind the pericardium which were greatly enlarged to a mass six or seven centimeters in diameter. There was a small area of localized peritonitis in the immediate neighborhood of the operative exploration which is, of course, what would be expected from the findings at operation. The surprise in the case did not come until the microscopic sections of the tumor were examined. It turned out not to be a carcinoma but a leiomyosarcoma of the esophagus which is a quite rare tumor in this location, probably fifteen or so cases on record.

DR AUBREY O HAMPTON How polypoid was this mass? How much of the lumen of the esophagus was involved?

DR MALLORY Most of the mass was external to the esophagus rather than within it.

CASE 21502

PRESENTATION OF CASE

First Admission. A fifty-four year old white American female was admitted complaining of hoarseness.

One year before entry the patient noticed a swelling in her neck but was advised by her physician that it was of no significance. A few

months later she found that she was gaining weight and was advised to take thyroid tablets, which she did not do. She had been rather nervous during the year preceding admission, a fact which she attributed to familial difficulties. Four months before entry she had an attack of "grippe" which was associated with hoarseness. After the subsidence of the "grippe" the hoarseness persisted and attempts at lengthy conversation produced some breathlessness. There was a slight nonproductive cough during this time. She also had slight difficulty in swallowing which manifested itself as a "sensation of pressure" in the esophagus. There was no marked dysphagia. Her weight at the onset of her illness was 183 pounds. At the time of admission it was 193 pounds. The catamenia were still present and regular.

She had had diphtheria at the age of thirty-three and probably malaria at thirty-four.

Physical examination showed an obese apprehensive, middle-aged female in no acute physical distress. The eyes were normal. Oral hygiene was poor. The right lobe of the thyroid was slightly enlarged, hard and irregular and a small nodule about one centimeter in diameter was palpable in it. There was no tenderness. The thyroid seemed to extend on the right side subinternally. The heart action was rapid but was otherwise negative. The blood pressure was 240/120. The lungs were clear.

The temperature was 98.6°, the pulse 98. The respirations were 20.

Examination of the urine showed a specific gravity of 1.032, with a slight trace of albumin. The sediment contained 30 white blood cells and an occasional red blood cell but was otherwise negative. The basal metabolism rate was plus 10.

X-ray examination showed slight thickening of the soft tissues of the neck anterior to the trachea. The trachea was slightly displaced posteriorly with no appreciable flattening or lateral displacement. There was no visible mass in the chest. A slight mottling in the right first interspace was considered suggestive of an old healed tuberculosis.

Three days after admission an operation was performed and about half of the right lobe of the thyroid was removed. It was impossible to remove the entire lobe because of adherence and infiltration. Postoperatively the patient had very little reaction, convalesced well, and was discharged thirteen days after admission.

Second Admission, nine months later.

After leaving the hospital the patient felt well for about five months and then began to feel drowsy after breakfast. This sensation was relieved by a brief rest. A month later the mass in the right side of her neck again became evident but there was no dysphagia or dyspnea. She occasionally had a tickling sensation in her throat. One month before her readmission a second operation was done on her neck at another

hospital. She reentered this hospital for roentgen therapy.

Physical examination showed no essential change from that done at the previous admission.

She received two doses of x-ray and was discharged in two days.

Third Admission, one year and three months later.

Since her last admission she had felt quite well until three months before entry, when she became quite markedly fatigued while attending her sick children. About the same time, following exposure to a "draft", she developed pain in her right hip and a stiff neck. The pain in the hip was dull in character, persistent, and resulted in the necessity of using a cane. She received eight x-ray treatments which relieved this lameness. Shortly afterward, however, severe pain occurred in the left hip and she returned to the hospital for relief.

Physical examination was refused.

X-ray examination showed a moth-eaten destruction of the left pubis and bones in the left acetabular region with soft tissue thickening. There was also some periosteal bone destruction at the upper end of the right femur.

She was given local irradiation and was discharged two weeks after entry.

Fourth Admission three weeks later.

The patient returned at this time for further roentgen therapy. The x-ray examination showed slight distortion of the trachea as a result of a peritracheal soft tissue mass. A small defect was noted in the manubrium of the sternum. She was discharged three days later after receiving treatment.

Fifth Admission, three months later for further x-ray treatment.

Physical examination showed her to be fairly well developed and nonrashed and quite uncooperative. She complained of tenderness everywhere. The neck, pelvic girdle and left foot showed a brownish discoloration and thickening of the skin. There were several irregular firm masses on both sides of the neck moving with deglutition. The liver edge was felt three fingerbreadths beneath the costal margin upon deep inspiration. There was a slightly tender swelling of both ankles. There was no limitation of motion of the left hip but tenderness was elicited over the left ilium.

Examination of the blood showed a red cell count of 3,890,000, with a hemoglobin of 70 per cent. The white cell count was 5,600, 70 per cent polymorphonuclears, 11 lymphocytes, 14 monocytes and 5 eosinophils.

Sixth Admission, one month later.

Bence-Jones protein was not found in the urine.

X-ray showed a questionably active lesion below the right lesser trochanter. There was diminution of density in the bones and region of the right knee. There was a mass observed

at the end of the left second rib near the costochondral margin. The right side of the diaphragm appeared to be paralyzed, which was relieved after x-ray treatment.

She was discharged one week after reentry.

Seventh Admission, one and a half months later.

Since her last admission she had been having considerable pain across her chest and in the right knee and left ankle.

She refused to allow examination of her knee. A firm mass was present at the left costochondral junction. The heart was not enlarged but a soft systolic murmur was audible. Its location was not recorded. The blood pressure was 160/90. There was tenderness present over the right hip joint. The right knee and left ankle joints were swollen and tender. She received a series of x-ray treatments and was discharged in three weeks.

Final Admission, two months later.

Since her last admission she had been confined to bed most of the time because of marked weakness. The right knee was quite painful. There were also swellings in the left upper chest and axilla which were likewise painful.

Physical examination showed the patient to be mentally dull. The mass in the left anterior chest was larger than at the previous admission. There were no nodes in the axillae. Breath sounds were coarsened generally but the heart and lungs were otherwise unchanged. The spleen extended 2 centimeters beneath the costal margin with inspiration. There was a mass palpable on the medial aspect of the left heel.

Examination of the blood showed a white cell count of 5,300, 70 per cent polymorphonuclears, 1 lymphocyte and 29 per cent monocytes. An occasional stippled cell was observed.

She received further roentgen therapy and was discharged in two weeks. Following her return to her home she went progressively downhill and finally died four months later, three years and two months after the first entry.

DIFFERENTIAL DIAGNOSIS

DR ROBERT R. LINTON: "One year before entry the patient noticed a swelling in her neck but was advised by her physician that it was of no significance." A very questionable thing to tell a patient I should think.

"The catamenia was still present and regular." The last statement is entirely irrelevant as far as the story goes. It is unusual that it should have been regular and present at fifty-four.

From the present illness I should state that the important facts are she was admitted complaining of hoarseness, she had noticed a lump in her neck a year before and she had difficulty in swallowing. The first thing that comes to my mind, of course, is malignancy, and malignancy

most likely associated with the thyroid gland or with an aberrant thyroid. The tumor might also be in connection with the larynx or in close proximity to it. I do not think the fact that she had gained ten pounds during the last year is of great importance. Perhaps the only importance I would place is that with the disease I am thinking of I would not expect a great loss of weight early in the disease.

"The right lobe of the thyroid was slightly enlarged, hard and irregular, and a small nodule about one centimeter in diameter was palpable in it." This description would rather indicate that the lump the patient had noticed was in the thyroid, since it is the only mention of any lump that is made here. The description is a little difficult to understand, "hard and irregular, with a nodule one centimeter in diameter." One would rather expect a number of nodules would have been felt rather than simply one.

I should say that the laboratory data were essentially negative. The urine test I imagine was not a catheter specimen so that the sediment could be discredited.

From the description of the operative procedure here I should say there were two possibilities: one is carcinoma of the thyroid and the other is a thyroiditis, a Riedel struma. It is certainly obvious that whatever it was, it was impossible to remove it completely. It is very unusual to remove only half a lobe of the thyroid. I should say one usually removes at least three quarters, and possibly more. So we have the added fact that there was operative difficulty in removing what was attempted.

DR TRACY B. MALLORY: A point which is not put in there, Dr. Linton, but which I think you might as well know, is that the pathologic diagnosis at that time was chronic thyroiditis.

DR LINTON: That is interesting.

You cannot tell me what they did at the other hospital?

DR MARSHALL K. BARTLETT: I was present at that operation. It was equally unsuccessful. We attempted to remove the other lobe with about the same degree of failure.

DR LINTON: As you see she had a number of admissions following this second admission. The third was one year and three months later at which time she had developed pain in the right hip and a stiff neck and again received x-ray treatment and was discharged home. The x-ray examination at this time "showed a moth-eaten destruction of the left pubis and bones in the left acetabular region with soft tissue thickening and some periosteal bone destruction at the upper end of the right femur." That explains the pain in the right hip. She apparently had more pathology in the left than was not giving symptoms.

The brownish discoloration of the skin I interpret as being due most likely to x-ray therapy.

At the sixth admission apparently someone suspected multiple myeloma and a Bence-Jones protein was done which was negative.

No note of this neck is made at this admission but in this previous admission it showed a great many nodules which moved on deglutition.

This blood is not significant I think.

Perhaps Dr. Hampton will demonstrate this x rays at this time.

DR. AUBREY O. HAMPTON: I think the first pain she complained of was in the right hip. At that time we took this film of the pelvis. You can see here a moth-eaten bone destruction in the left pubis and periosteal elevation and subperiosteal destruction in the right femur. A little farther down the shaft in the right femur there is this extensive bone destruction which is fairly typical of malignancy.

This is a film of the pelvis after radiation and the bone destruction which was here has disappeared and now bone is present—a complete healing of that lesion. The femur responded likewise and there is no evidence of disease the second time. Here is a better film of the pelvis before treatment. It is very obviously destroyed.

The films of her chest which showed paralysis of the diaphragm are not here but I know that she had paralysis of the diaphragm on three different occasions and each time immediately after treatment over the neck or sternum the diaphragm would begin to move again—that is, within one week. I at no time saw a mass in this substernal area. She did have, however, destruction in the sternum, very indefinite, and I think in one or two ribs that I do not have here. Her os calcis showed a very unusual condition and was apparently involved also. There was a round area of bone destruction in its center and she had considerable pain in that heel and in her knee. We never were sure that she had bone destruction around the knee. The relief from pain by x ray was quite prompt but the recurrence was almost as prompt.

DR. LINTON: You have a skull plate?

DR. HAMPTON: I think we did at the time multiple myeloma was suspected, but the skull was negative.

I might also add that I saw and treated her many times and that she had at no time any palpable glands that I could find.

DR. LINTON: It seems obvious to me that the diagnosis is a carcinoma with metastases to the bone. The question is where did it arise? We have everything to point to the fact that it arose in the neck. We have a history of a lump the story of dysphagia, no difficulty in breathing, but difficulty in swallowing. We have two incomplete operations on the thyroid.

The breast is one of the common sites of carcinoma with metastases to bone and here we have no note of her breasts. They presumably

were normal. One of the other common conditions is carcinoma of the prostate. This patient being a female we can rule that out. Another condition is carcinoma of the thyroid. I think it is not unlikely that there may have been a small nodule of carcinomatous tissue which could have been missed either at the operation or in the specimen. It only needs to be a very small one. The metastatic distribution of the disease may overshadow the primary lesion so that it may be missed. I think I will stick to carcinoma of the thyroid with bone metastases.

DR. GEORGE W. HOLMES: May I make one suggestion? This tumor responded very well to radiation.

DR. LINTON: Then I should suspect papillary adenocarcinoma of the thyroid.

DR. HOLMES: They do not as a rule respond readily.

DR. LINTON: Then I suppose I will have to consider Hodgkin's disease.

DR. HAMPTON: I may have misled Dr. Linton. This response to the lymphoma dose of radiation was exceedingly prompt and the lesion would recur just as promptly in the same place.

DR. J. H. MEANS: There was a case that you probably remember that Dr. Mixer operated on, a very rapid fulminating type of thyroid malignancy which did respond to x ray very rapidly twice and then recurred in the mediastinum and was followed by very rapid death. Histologically there was a dispute among authorities as to what kind of tumor it was. I think Dr. Mallory rather favored carcinoma, but Dr. Allen Graham of Cleveland was here and called it a lymphoma. Dr. Hartwell I think was on the lymphoma side, but it was impossible to decide with finality what kind of tumor it was, apparently. It is interesting that Dr. Mallory and one other thought it was a carcinoma and yet it did respond very well to x ray so perhaps Dr. Linton is justified after all in his position. Thyroid tumors are unlike all others in the body anyway. They are very peculiar.

DR. HOLMES: We have had very few cases of metastases from tumor of the thyroid to bone and my experience, of course, is limited. Carcinomas from any part of the body may be fairly sensitive to radiation but as a general rule they are not.

Another point that is against carcinoma is the location of this metastasis in the heel. Carcinomas as a rule do not involve the bones of the hands or feet except when there is a pretty generalized distribution through the skeleton.

CLINICAL DIAGNOSIS

Lymphohistioma of the thyroid and bones.

DR. ROBERT R. LINTON'S DIAGNOSIS

Carcinoma of the thyroid with multiple metastases.

ANATOMIO DIAGNOSES

Lymphoblastoma of the thyroid, with metastases to the sternum, ribs, right femur and left os calcis and with extension to the mediastinum

Pathologic fractures of the right femur

Involvement of the right phrenic nerve with paralysis of the right diaphragm

Cholelithiasis

Endometrial polyp

Pseudomucinous cystadenoma of the left ovary

PATHOLOGIC DISCUSSION

DR. MALLORY The tumor in this case was exactly the same type that Dr Means has been describing in the other case. The original pathologic diagnosis was chronic thyroiditis and there is no question that he had an extensive and severe thyroiditis. When the tumor promptly recurred two months later, and Dr Miller operated again, it was then perfectly obvious that we were dealing with some form of malignancy. The sections removed at that time were very difficult to interpret and we finally called them lymphoma. Going back to the original section from the first operation we were then able to see what we had missed before, a very small area of pretty definite tumor in one corner of one section.

The patient finally was autopsied at home and we removed pieces of numerous tumors all over the body and put through numerous sections. I have been looking them over this morning and not in a single one of these tumors was I able to find a viable tumor cell. The last dose Dr Hampton gave her seemed to have killed off the cells as far as can be judged by the microscope or else one of those mysterious spontaneous degenerations of malignant tumors occurred.

So the postmortem gave us no additional his-

tologic information. The tumors we found scattered through a large number of bones and there was a very large recurrent mass in the lower portion of the neck running into the anterior mediastinum, infiltrating the manubrium and portions of the first two ribs. It grew posteriorly behind the pericardium, around the hilus of the lung, surrounding the phrenic nerve on the right very definitely. The lymph nodes throughout the body were negative and the spleen was negative. The distribution of this lesion is certainly not that of lymphoma. The majority of the metastases are apparently blood borne rather than lymphatic borne and the remainder of the tumor found is a local extension from the original mass.

There has always been a tremendous amount of argument over the classification of this particular group of tumors. There is one group of men who have done a good deal of special work on thyroid tumors who feel that every tumor in the thyroid is carcinoma whether it looks like carcinoma, fibrosarcoma or lymphosarcoma. This is one which they might cite in their favor. It certainly looks much more like lymphoma than carcinoma but in general its behavior is a little bit more like carcinoma. I still think lymphoma and fibrosarcoma may occur in the thyroid, however.

DR. LINTON To me there is one thing in which it did not seem like carcinoma of the thyroid. It did not have metastases to the lung.

DR. MALLORY Yes, you would expect metastases to the lung.

DR. LERMAN When I first saw the slides I thought it was chronic thyroiditis and with the recurrence it looked more like lymphoma. I sent a few to Dr. Allen Graham and he reported that it was a typical case of lymphosarcoma. He suggested the possibility of its having arisen from a Hashimoto struma. He has reported two cases and Smith one case, but the original sections do not suggest it.

ANNUAL REGISTRATION OF PHYSICIANS

A BILL providing for the annual registration of physicians has been filed recently with the Secretary of State by the Board of Registration in Medicine. The real intent of the bill is slightly different from the obvious purpose which appears on superficial examination, because of what seems to be an inverted order in the sections 4a and 4b. The real intent of the bill is to provide accurate and adequate information, easily accessible to all, as to which physicians the state now regards as qualified to practice medicine. Annual registration is only one of the elements necessary in fulfilling this intent.

At present there is at the State House an accurate list of all physicians whom the Board of Registration has licensed and has unlicensed, but this list refers only to these two acts. There is no way of knowing whether a person registered by the Board has died, or has moved to another state, no way of knowing whether

the certificate of any person registered by the Board is being misused, as in the case of impersonation of a deceased person to whom it was issued. There is no record of the whereabouts of the person registered if he has failed to record his certificate with the town clerk either originally or after moving to another town. Finally, although the list of registered physicians in the office of the Board is open to public inspection (by statute, only the copy of the list in the office of the Secretary of State is thus open) the securing of information by a person in a distant part of the state is time-consuming if one writes, and expensive if one telephones. Thus copies of the list should be more easily available, in all parts of the state, as in the office of every physician, every town clerk, every board of health, every drug store and every hospital. It is clear that a list meeting the requirements stated above and distributed widely throughout the state would be of very great advantage in protecting the citizens against unlicensed practitioners of medicine, because knowledge as to registration could be easily and almost immediately obtained.

What objection can there be to the making of such a list and to the wide distribution of copies? A possible objection might come from the medical profession who would have to pay the annual registration fee. They are now harassed enough by petty taxes for this and for that, among which the requirement of a certified check to pay the one dollar annual narcotic tax is one of the most annoying. Why should they have another charge imposed upon them?

The medical profession should consider first the possible advantage to the public, and then the possible advantage to themselves. Nothing more need be said as to the possible benefit to the public if results are obtained comparable with what was accomplished in the state of New York when it introduced annual registration of physicians. In the first year, one thousand unlicensed practitioners of medicine left New York to go to states without the annual registration. Undoubtedly Massachusetts received many. It has been estimated that in time a thousand would leave Massachusetts if the bill became law. This would be no small gain in protecting the public.

There might be economic gain for the physician. If the money now acquired by this thousand were to go to the medical profession it might not reach the figure of a million dollars, a low estimate of the income received by the quacks and charlatans, but it would certainly be more than the cost of annual registration.

There is another economic advantage for the physicians: the state will give them a certain amount of legitimate advertising, as in its opinion they are qualified practitioners. The opinion of the state may or may not be justified but it will be published and widely dis-

tributed throughout the state as an annual reminder

There is a possible objection Why should the ethical upright, honest, registered physician pay for the enforcement of the law against the quacks and charlatans and other unregistered persons? Well, the whole activity of the Board of Registration in Medicine is under the police power of the state The original registration fee is not merely to defray the cost of making out a certificate of registration It is to assist in the exercise of the police power of the state, and the costs of the annual lists, and of annual registration might be met by increasing the original fee for registration A more just allocation of these costs is to have a low fee for examination and original registration for the physician beginning to practice, and to distribute the continuing cost over the years of practice by an annual fee for annual registration as long as the physician remains in practice

The heart of the matter is that the state should register physicians, as it now does, keep a list, as it now does, and add to that a procedure for keeping the list accurate, complete and up-to-date and making it easily available to all interested persons by wide distribution throughout the Commonwealth

THE VALUE OF ARTIFICIAL MENOPAUSE IN CANCER OF THE BREAST

In recent years there has been a renewed interest in artificial menopause as an adjunct in the treatment of carcinoma of the breast Review of the work carried out by Beatson and

*A series of short selected articles by members of the Section is being published weekly
Comments and questions by subscribers are solicited and will be discussed by members of the Section

his followers early in the century discloses that they secured favorable temporary regressions in about a third of their cases of inoperable cancer of the breast as a result of bilateral oophorectomy. This procedure was rather widely used until the development of radiation therapy of fered a direct and more effective palliative attack on advanced lesions.

The original proposal of castration was based partly on the known relation between ovarian activity and growth of the breast, and partly on the apparently slower growing and less malignant characteristics of cancer in older women. New data have gradually accumulated in substantiation of these observations. Careful studies of end results of operations for cancer of the breast have shown that the percentage of cures in young women is less than in women who have passed the menopause, and that the grade of malignancy, as shown by histological study, tends to be higher in young women. Other studies have shown that there is a definitely increased likelihood of developing cancer in the remaining breast after removal of one breast for cancer. If pregnancy occurs this likelihood becomes almost a certainty and latent metastatic foci are stimulated to rapid and highly malignant growth.

From the laboratory have come experiments showing that oophorectomy prevents or decreases the incidence of spontaneous mammary cancer in susceptible strains of mice, and that transplantation of the ovary into young castrated males in some instances causes the development of spontaneous mammary cancer.

Radiation therapy has been used considerably to relieve pain due to bone metastases in the lumbar spine and pelvis and many patients treated in this way have experienced an artificial menopause. In this group of patients some very striking regressions of the malignant metastases have been observed even in areas of the body where no treatment was given. Stimulated by these observations radiologists have been inclined to bring about an artificial menopause as part of their treatment of inoperable and recurrent carcinoma of the breast. Thus a considerable group of cases has been accumulated, and results have been encouraging enough to warrant an extension of the method. Most of the cases have been treated too recently to permit statements as to the duration of the regressions which appear to occur in about a third of the women who are before the age of menopause.

Some clinics have been recommending artificial menopause by x radiation as a routine procedure in young women after operation for cancer of the breast. This seems justifiable on the grounds (1) that the per cent of cures is greater after the menopause (2) that a subsequent pregnancy carries a grave hazard of activating

latent metastases, or carcinoma of the remaining breast, (3) that since established metastases in some instances undergo regression after x ray artificial menopause, it is reasonable to infer that latent foci of metastatic disease will be inhibited or postponed in their development. The procedure is too recent to be evaluated in terms of the percentage of five-year cures, but the evidence on which it is based warrants its employment before end result studies are available.

**THIRD ANNUAL POSTGRADUATE MEDICAL
EXTENSION COURSE**

The following sessions have been arranged by the Committee for the week beginning December 15

Earnstable

Sunday December 15 at 4 00 P.M., at the Cape Cod Hospital Hyannis Subject Latest Developments in Endocrinology Instructors J. C. Amb and Oliver Cope J. L. B. Vall Chairman

Bristol South (Fall River Section)

Monday December 10 at 4 00 P.M., at the Stevens Clinic of the Union Hospital, Fall River Subject Diseases of the Liver Surgical Problems in Diagnosis of Acute Disease of Gall Bladder and Liver Instructors E. S. Emery and H. M. Cline Eugene A. McCarthy Sub-Chairman.

Essex South

Tuesday December 17 at 4 00 P.M. in the Nurses Home of the Salem Hospital Salem Subject Pediatrics The Neonatal State and Its Diseases Medical and Surgical Aspects Instructors J. L. Morse and P. J. Mahoney Walter G. Phippen Chairman.

Hampden

Thursday December 19 at 4 00 P.M., at the Academy of Medicine Professional Building 20 Maple Street, Springfield and 8 00 P.M. at the Holyoke City Hospital, Holyoke Subject Neurological Aids in the Diagnosis and Treatment of Disease from the Medical Viewpoint. Problems of History and Examination with Special Reference to (a) Neurosyphilis, Multiple Sclerosis and Other Degenerative Conditions. (b) Diseases with Acute Onset, such as Meningitis and Cerebral Accidents Instructor H. R. Viets George L. Schadt and George D. Henderson Chairmen.

Hampshire

Wednesday December 18 at 4 15 P.M., in the Nurses' Home of the Cooley Dickinson Hospital Northampton. Subject Kidney and Bladder Diseases B (Surgical) Prostatism and Related Diseases Cystitis and Pyelitis Instructor Richard Cline Robert B. Brigham, Chairman

Middlesex South

Tuesday December 17 at 4 15 P.M. at the Cambridge Hospital, Cambridge Subject Neurological Aids in the Diagnosis and Treatment of Disease from the Medical Viewpoint. Problems of History and Exam-

ination with Special Reference to (a) Neurosyphilis, Multiple Sclerosis and Other Degenerative Conditions (b) Diseases with Acute Onset, such as Meningitis and Cerebral Accidents Instructor Abraham Myerson Edmund H Robbins, Chairman

Norfolk South

Monday, December 16, at 8 30 P M, at the Quincy City Hospital, Quincy Subject Neurological Aids in the Diagnosis and Treatment of Disease from the Medical Viewpoint Problems of History and Examination with Special Reference to (a) Neurosyphilis, Multiple Sclerosis and Other Degenerative Conditions (b) Diseases with Acute Onset, such as Meningitis and Cerebral Accidents Instructor J B Ayer David L. Belding, Chairman

Plymouth

Tuesday, December 17, at 4 00 P M, at the Brockton Hospital, Brockton Subject Peripheral Diseases of Blood Vessels Instructors H F Root and R H. Smithwick W H Pulsifer, Chairman

A NEW COUNCILOR FOR NORFOLK DISTRICT

Dr S F Curran of Dorchester has been elected to fill the vacancy existing in the Council among those representing Norfolk District.

MASSACHUSETTS LEGISLATIVE NOTES

BILL FOR THE ANNUAL REGISTRATION OF PHYSICIANS

THE COMMONWEALTH OF MASSACHUSETTS

Board of Registration in Medicine,
State House, Boston

December 1, 1935

To the General Court of Massachusetts

In accordance with the provisions of section 33 of chapter 30 of the General Laws, a copy of the recommendations for legislation to be contained in the annual report of this Department (Pub Doc No 56), is herewith submitted, together with a draft of the bill embodying the legislation recommended. This draft has been submitted to council for the House of Representatives, as required by law.

Yours very truly,

STEPHEN RUSHMORE, M D, *Secretary,*
Board of Registration in Medicine

THE COMMONWEALTH OF MASSACHUSETTS
In the Year One Thousand Nine Hundred
and Thirty-Five

AN ACT to provide for the Annual Registration of Physicians and the Annual Publication of the List of Physicians duly registered.

Be it enacted by the Senate and House of Representatives in General Court assembled, and by the authority of the same, as follows

SECTION 1 Chapter one hundred and twelve of the General Laws, as appearing in the Tercentenary edition thereof, is hereby amended by inserting after section four the two following new sections —

SECTION 4A Every person registered by the board as a qualified physician, who is engaged in the practice of medicine within the commonwealth, shall annually in December renew his registration for the ensuing calendar year by payment of two dollars to the board and recording with the board his name, his registration number, his professional address, and such other information as the board may require, on blanks furnished by the board at the request of the physician and signed by him under the penalties of perjury, and thereupon the board shall issue to him a certificate showing that he is entitled to continue in the practice of medicine for the period covered by said renewal. Whoever, being duly registered under section two or corresponding sections of earlier laws, practices or attempts to practice medicine without complying with the requirements of this section, shall be punished by a fine of not less than five nor more than one hundred dollars.

SECTION 4B On the first day of March of each year, the board shall publish a list of the physicians who, in compliance with the provisions of section two or section 4A, as the case may be, are authorized by the board to engage in the practice of medicine in the commonwealth during the current calendar year, giving the name of each registrant, his registration number, his professional address, and such other information as the board may deem necessary, and shall send to each registrant a copy thereof.

RECOMMENDATIONS

I Providing for Annual Registration of Physicians and for Annual Publication of the List Thereof.

The statute now provides for the registration of qualified physicians and the keeping of a list of such registered persons which is open to public inspection in the office of the Secretary of State. In practice the information contained in the list is given out at the office of the Board as a matter of convenience to enquirers. No provision is made by the statute for keeping the list up to date and the Board, therefore, knows nothing about a physician after registration, except the town in which he records his certificate (statutory), unless complaint is made to the Board, or by chance his death is reported. He may have changed his place of residence and even left the State, or he may have died.

The Board, therefore, does not know who is actually practicing medicine in Massachusetts, and it is impossible for the law enforcing body to restrict practice to registered persons. The result is that there are probably a thousand unlicensed practitioners in the State, and it may well be that a considerable

number are practicing under licenses of deceased physicians

The providing of an accurate, complete and up-to-date list made easily available by wide distribution throughout the State will go far to eliminate unregistered practitioners of medicine from Massachusetts. Such a list is impossible without annual registration.

MISCELLANY

DR. H. P. MOSHER DELIVERS THE MUTTER LECTURE

On December 4 1935 Dr Harrie P Mosher delivered the Mutter Lecture at the College of Physicians of Philadelphia. The title was Histology and Pathology of the Esophagus with Clinical Applications.

MEDICAL AFFAIRS IN MAINE

Cancer Clinics. A well planned and supervised cancer clinic has now been in operation at the Maine General Hospital in Portland for the past three years. This hospital has an adequate x-ray apparatus and an ample supply of radium.

At the Central Maine General Hospital in Lewiston and at the Thayer Hospital in Waterville cancer clinics have been established with however a more limited supply of radium. In Bangor at the Eastern Maine General Hospital the radium supply is entirely privately owned.

At a recent meeting of the Council of the Maine Medical Association it was voted to hold the next Clinical Session of the Association in Waterville in October 1936. These annual clinical sessions have been extremely well attended and are very popular.

On November 21 1935 a combined meeting of the Kennebec County Medical Society and the Kennebec Valley Dental Association was held at the Elmwood Hotel in Waterville with a large attendance. A clinical session was held from 5 to 6 P.M., dinner at 6:30 P.M. and the scientific session at 7:30 P.M. The following papers were read and excited much valuable discussion:

"Relation of Dentistry to Medicine, by Dr Percy Butterfield D.D.S., Togus, Me.

"Blood Dyscrasias Manifest by Oral Lesions" by Dr Theodore Hardy Waterville, Me.

"Acute Oral Conditions" by Dr F. T. Hill Winterville, Me.

EDW. H. RISLEY M.D., Reporter

DR. ARTHUR BERK ADDRESSES A ROTARY CLUB

At a meeting of Rotary Clubs at Plymouth New Hampshire recently Dr Arthur Berk of Brookline Massachusetts with an office at 270 Commonwealth Avenue Boston delivered an address with the title "The Mind and Its Problem."

WPA GRANT FOR MIDDLESEX COUNTY SANATORIUM

The trustees of the Middlesex County Sanatorium at Waltham have been officially advised that the Federal Government has granted an appropriation of \$304,000 toward the enlargement of the Institution by one hundred and sixty beds.

Dr Samner H. Remick, Superintendent of the Sanatorium assisted the County Commissioners in filing with the Public Works Administration the necessary application for these funds in August. In September in furtherance of the project, Dr Remick accompanied by the Chairman of the Hospital Trustees Honorable Walter C. Wardwell of Cambridge and Frank Kiernan Executive Secretary of the Massachusetts Tuberculosis League went to Washington to interview Mr Harry L. Hopkins. Later when results did not seem to be forthcoming the same group visited Honorable David I. Walsh at his home in Clinton and laid the needs of the Hospital before the Senator. He was so impressed with the emergency situation which has arisen through long waiting lists and the increasing demands for hospital care by the patients in the cities and towns in the district, that he agreed to interview Honorable Harold Ickes, Secretary of the Interior and Public Works Administrator. A few days later the County Commissioners received word that the appropriation had been granted.

The Middlesex County Commissioners secured legislation in the 1935 General Court enabling them to raise funds to meet the Federal grant. It secured for the building of the addition to the Sanatorium. As soon as word was received from Washington Dr Remick and his associates proceeded to the humdrum of arranging for the letting of contracts and other details. Matters have progressed now so that the contracts will be let within a few days and it is expected that the addition to the Institution will be available for the reception of patients on or before January 1 1937.

ANTI-VIVISECTION ACTIVITY

The New York Anti Vivisection Society is working to have a bill enacted which is designed to prohibit vivisection of dogs.

CORRESPONDENCE

ELECTROBURGICAL CHOLECYSTECTOMY

Editor *New England Journal of Medicine*

In this *Journal* issue of October 9 1930 I published methods for electrosurgical removal of acutely inflamed and of sclerotic gall bladder. "The gall bladder is emptied, split to the cystic duct, which is tied, cut the gall bladder away along its attachment to the liver leaving the section in contact with the liver in place. The cutting can be done with the electrosurgical unit the hemorrhage controlled by clamping and tying the larger vessels and coagulating the smaller ones the remaining tissue of the gall bladder being fulgurated."

In November 1933¹ Thorek published a method called "cholecystelectrocoagulectomy" which was essentially the same, except that he used it on "unselected" cases, advocated contact coagulation of the portion of the gall bladder left in place, instead of fulguration, did not tie the branches of the cystic artery, but depended on coagulation to stop them, advocated "peritonization" of the coagulated gall bladder bed and the tied stump of the cystic duct. In this article, even though exploration of the bile duct was advised, drainage was decried, the idea being that drains are "inimical" to healing of electrocoagulated surfaces.

Recently I have reported (this *Journal*) experimental work which led to the development of the method² and its application in clinical cases³, *advocating, however, electrocoagulation of the remaining segment of the gall bladder according to Thorek in preference to the original method of fulguration*. I disagreed with Thorek on the question of peritonization of surfaces, and upon drainage.

In a letter published in this *Journal*, November 14, 1935⁴, Thorek accused me of sins of omission and commission, and in no uncertain terms held me up as a menace to society unless I should drop the electrosurgical applicator from my hand. Now, since I disagree with Thorek on a few points, and since he violently disagrees with me on everything, I fear that the reader may come to the conclusion that electrosurgical cholecystectomy is dangerous or worthless. That would be unfortunate, and warrants a discussion.

As a matter of fact electrosurgical cholecystectomy is safe, simple, and valuable. Be not disturbed by hairsplittings between fulguration, carbonization and coagulation so long as the biterminal coagulating current is used and a thorough job done⁵, and the larger vessels tied—and so long as drainage is used according to indications which hold for ordinary surgery⁶. The procedure is most helpful in the difficult case with sclerosis or inflammatory thickening in and about the gall bladder and ducts, and, though Thorek uses it on all cases, it is not worth while where the vessels can be easily dissected.

In his letter Thorek says, "Experience contradicts Whitaker's conclusions on the behavior of electrocoagulated tissues." My conclusions were based on experiments with thirty seven animals which were carefully reported⁷. In a new subject under investigation may not one man disagree with another, or even with the majority, if he believes his experiments justify so doing?

Thorek claims misrepresentation in my statement that he depends upon coagulation to stop the cystic artery. It is my belief that the artery and its branches should be tied instead of being coagulated, since it seems to me that the coagulum is likely to loosen sooner than the tie. I quote Thorek's answer to this⁸: "The fact is that I *never coagulate the cystic artery* but always ligate it. *Again, the coagulum never loosens* in undrained, properly performed operations but becomes absorbed." If the coagulum never loosens it would

seem safer to coagulate the artery than to tie it, a catgut tie does loosen. Thorek's first article¹ to which I referred⁴ makes no mention, either in the text or on the illustrations, of tying the cystic artery. His second and third articles^{2, 3} do to be sure. I am sorry for having overlooked this. But why did he change his method? Maybe the coagulum became "absorbed" too soon.

Thorek says, "Careful scrutiny of the sixteen cases recorded by Whitaker forces the conclusion that unless one is equipped with a thorough knowledge of the principles underlying electrosurgical methods he had better hold on to the time-honored cold scalpel in surgery of the gall bladder."

"Careful scrutiny" has disclosed (as the autopsies did⁹) that the method of electrosurgical cholecystectomy had nothing to do with the three deaths in my sixteen cases. One died weeks afterward from a stone left in the common bile duct. That happens occasionally in all the surgical families with which I am familiar—perhaps not in Dr Thorek's. Another died of cardiac infarct which, though unknown, was present at the time of operation. Electrosurgical cholecystectomy or any other kind was a mistake. It was performed in the hope of relieving intolerable suffering. In this case and in the third³ however, autopsy showed the coagulum on the gall bladder bed firm, no liver damage, no bile leakage, no peritonitis, nor other cause of death concerned with the operative site. It would seem that Dr Thorek was uncharitable to say the least in the foregoing statement and its implications.

Yet Thorek's condemnation of me as a dangerous individual is based on the death of these three patients in a series of sixteen—a mortality of "18.45 per cent" which he compares with "a global mortality of 9.6 per cent" in 12,144 cases¹⁰. (A series of sixteen selected cases, the majority with advanced disease, compared with a general series of 12,144¹¹.) Furthermore "accuracy demands"¹² that I "correct" one of Thorek's figures. Three of the sixteen died—a mortality, not of "18.45 per cent" but of 18.75 per cent! Thorek concluded⁸: "In other words twice as many people succumbed at the hands of Whitaker as in the *worst cases* (*italics mine*) operated on by surgeons elsewhere."

In view of these figures and this statement let us see how the "accuracy" invoked by Thorek in his letter fares when examined. His published articles^{1, 2, 3} state "a global mortality of 9.28 per cent", with no mention of "*worst cases*", also¹³: "From a careful survey of the literature it appears that the average surgical mortality in uncomplicated cases is about eight to ten per cent, and in complicated cases, ten to twenty per cent." In my series of sixteen cases, mostly complicated, because I do not advise this method in simple cases, the mortality was 18.75 per cent. Certainly *statistics should have a generous admixture of intelligence and honesty*.

Compare Thorek's results. His operation has been performed "on 149 consecutive unselected patients without a single fatality"¹⁴. These "unselect-

ed cases" naturally include every patient with a diseased gall bladder however complicated upon whom he operates—"acute and chronic cholecystitis cholelithiasis, gangrene of the gall bladder early perforation with escape of bile suppurations etc." In July 1934 the number of these consecutive unselected patients without a fatality was 76 to date it is 148¹

Thorek says that I had "above fifty per cent of bile leaks" Accuracy demands that I point out a fault either in his count and computation or in his intention. Seven out of the sixteen cases drained bile. In five of these no attempt was made to tie the cystic duct on account of the danger of dissection with obscured landmarks from inflammatory swelling. Perhaps Thorek can always safely dissect and tie the cystic duct so that there is no danger of leakage in these cases but others cannot and do not. In the remaining two of the seven who drained bile the common duct was explored. Perhaps Thorek does not have bile leakage in these cases.

Thorek in the summary of his second article² says "Drainage is entirely omitted. In the body of the article, however he hedges a bit on this point and says, In certain conditions drainage is a necessity (italics mine) namely in obstruction of the common bile duct, icterus progressive septic cholangitis inability to peritonize the cystic duct and gall bladder bed (italics mine) and the like. Examination shows that on account of extensive inflammatory changes these areas could not have been peritonized in ten of my sixteen cases (even if I had wished to do so) I drained them. Thorek according to the foregoing admission would have drained them. Why does he condemn me for doing what he himself would have done? Furthermore if according to Thorek, drainages in combination with electrosurgery is so dangerous in these cases though he grudgingly admits it should be done why does he not eschew electrosurgery here? Yet he does treat them electrosurgically because his cases are consecutive and "unselected." It appears that in this question of drainage Dr Thorek is inconsistent.

I shall perform a series of comparative experiments on dogs using my original method with drainage in one set and Thorek's method in the other. (In one experiment carried out according to his technique the dog was discovered a month later to have a large cold subhepatic abscess.) With patients, however in spite of Thorek's warning I shall continue to use drainage in all cases of empyema and gangrene of the gall bladder and where the cystic duct cannot be cleanly and safely dissected and securely tied and where exploration of the bile ducts is performed.

RECENT DEATHS

ROBERTS — FREDERICK ALPHA ROBERTS, M.D., of Pittsfield, Massachusetts, died suddenly November 30, 1935

He was born in Jacksonville, Vermont, in 1863, and graduated from the College of Physicians and Surgeons of Baltimore in 1897

He was a Fellow of the Massachusetts Medical Society and the American Medical Association. He is survived by his widow, an adopted daughter, Leonette Roberts, and a brother, Arthur Roberts, of Brattleboro, Vermont

PHELPS—OLNEY WINDSOR PHELPS, M.D., of Warren, Massachusetts, died at his home, December 2,

1935, after a brief illness following a year's gradual physical decline

He was born in Waitsfield, Vermont, February 11, 1848. Following graduation from the Dartmouth Medical School in 1878 he served as assistant physician in the Insane Asylum at Brattleboro, Vermont. In 1882 Dr Phelps moved to Bellows Falls, Vermont, where he practiced for three years. In 1891 he moved to Warren, Massachusetts. His total medical career covered fifty-seven years.

Dr Phelps was a member of the board of health and the school committee of Warren for several years and was active in civic organizations. He joined the Massachusetts Medical Society in 1892 and retired in 1914.

His widow, Mrs Florence Johnson Phelps, a son, Dr Olney Draper Phelps, of 27 Elm Street, Worcester, Massachusetts, two grandchildren, and a brother, Elleroy E Phelps, of Lebanon, New Hampshire, survive him.

ADLER—HERMAN MORRIS ADLER, M.D., died at the Phillips House of the Massachusetts General Hospital, December 7, 1935.

He was born in 1876 and graduated from the Columbia University College of Physicians and Surgeons of New York in 1901. His premedical education was acquired at Harvard College and later he returned to Boston, after having established a reputation in psychiatry, to serve as assistant professor of psychiatry at the Harvard Medical School from 1912 to 1917, and chief of staff of the Boston Psychopathic Hospital.

Dr Adler was especially noted for accomplishments in criminology and psychopathology and held the position of professor of medical jurisprudence and criminology at the medical college of the University of Illinois and later occupied the same chair at the University of California.

He was a Fellow of the Massachusetts Medical Society. Dr Adler is survived by his widow. His family home was in Berkeley, California.

NOTICES

MASSACHUSETTS MEMORIAL HOSPITALS

The problem of "The Application of Proper Surgical Technique in the Operating Room" will be presented for consideration at the next Surgical Section meeting on December 13, 1935, at 12 o'clock noon in the Ladies' Aid Room, Talbot Memorial.

The speakers' list, which was scheduled for that meeting, will be presented at a Special Meeting, December 20, 1935, at 12 o'clock noon.

MILO C GREEN, *Secretary*

REMOVAL

JOHN ROCK, M.D., has removed his office to the Free Hospital for Women, 8 Cumberland Avenue, Brookline. Telephone Longwood 0264.

UNITED STATES CIVIL SERVICE
EXAMINATIONS

Junior Medical Officer (Interne) \$2000 a Year
Junior Medical Officer (Psychiatric Resident)
\$2000 a Year

St. Elizabeths Hospital, Washington D C

Applications must be on file with the manager of the Fourth U S Civil Service District, Washington, D C not later than December 16 1935

The United States Civil Service Commission announces open competitive examinations for the positions named above. Vacancies in these positions and in positions requiring similar qualifications will be filled from these examinations unless it is found in the interest of the service to fill any vacancy by reinstatement, transfer or promotion.

Application forms—The necessary forms may be obtained from the Secretary Board of United States Civil Service Examiners, at any first-class post office or from the United States Civil Service Commission, Washington D C (the title of the examination desired should be stated).

Social Worker Positions

Applications for the positions of social worker (psychiatric) and junior social worker United States Veterans Administration must be on file with the U S Civil Service Commission, Washington, D C., not later than January 8 1936

Full information may be obtained from the Secretary of the United States Civil Service Board of Examiners at the post office or customhouse in any city which has a post office of the first or the second class, or from the United States Civil Service Commission, Washington D C

MEDICAL CLINIC AND STAFF ROUNDS AT THE
PETER BENT BRIGHAM HOSPITAL

At 3 30 P.M. on Thursday December 19 in the Amphitheatre of the Peter Bent Brigham Hospital Dr Henry A. Christian Physician-in-Chief Hersey Professor of the Theory and Practice of Physics in the Harvard Medical School, will give a medical clinic. To it are cordially invited practitioners and medical students.

Owing to the holidays the clinics of December 26 and January 2 will be omitted.

On Saturdays in the wards of the Peter Bent Brigham Hospital, from 10 to 12 staff rounds will be conducted by Dr Christian.

INTERNATIONAL MEDICAL POSTGRADUATE
COURSES IN BERLIN

The Berliner Akademie für Ärztliche Fortbildung the successor of the Dozentenvereinigung für Ärztliche Fortbildung in Berlin which is managed by the Chief Burgomaster of Berlin, is holding the

following medical postgraduate courses in the spring of 1936

- 1 Course on the practical results of recent research work in the domain of internal medicine (February 24 to March 4)
- 2 Syphilis of the internal organs (March 5 to 7)
- 3 Courses in tuberculosis in the City of Berlin's Tuberculosis Hospital "Waldhans Charlottenburg" in Sommerfeld (March 16 to 21)
- 4 A week's postgraduate course in obstetrics and gynecology (March 23 to 28)
- 5 Practical progress of x-ray diagnosis and radiotherapy paying regard to clinical pathological anatomical and physiological points of view (March 9 to 14)
- 6 A week's course in abdominal surgery (April 20 to 25)
- 7 Introductory course in homeopathy (April 20 to May 16)
- 8 Special courses in all branches of medicine with practical work at the bedside and in the laboratory are held every month

Courses 1 to 7 will be held in German, and the special courses also in foreign languages.

For programs and further information apply to the Geschäftsstelle der Berliner Akademie für Ärztliche Fortbildung Berlin NW7 Robert Koch-Platz 7 (Kaiserin Friedrich Haus)

REPORTS AND NOTICES
OF MEETINGS

LECTURE ON THE CARE OF THE PATIENT

Dr Arthur R. Crandell of Taunton Mass. delivered a lecture on "The Care of the Patient" Thursday November 14 at the Harvard Medical School. He presented views of a general practitioner in a modernized city which, although differing from those of physicians in rural communities and metropolitan districts, have the common aim with them of improving the general welfare of the patient. The family practitioner must be content with a life of general service instead of the brilliant career of the specialist.

The great increase in medical knowledge in the last half century has changed the situation of the general practitioner. He no longer can hope to possess a thorough knowledge of the whole field of medicine nor personally to give to his patients many of the benefits of modern scientific therapy. He must become a skilled internist referring patients requiring special forms of treatment to qualified specialists.

Dr Crandell commented on the state of medical knowledge forty years ago. At that time the public was well satisfied with "snappy diagnoses" and considered the physician as more or less of a 'neromancer'. There were relatively few hospitals, laboratories were poorly equipped, preventive medicine had not yet been developed, diphtheria control was inadequate, typhoid fever was rampant, diabetes

RECENT DEATHS

ROBERTS — FREDERICK ALPHA ROBERTS, M.D., of
Pittsfield, Massachusetts, died suddenly November
30, 1935

He was born in Jacksonville, Vermont, in 1863,
and graduated from the College of Physicians and
Surgeons of Baltimore in 1897

He was a Fellow of the Massachusetts Medical
Society and the American Medical Association. He
is survived by his widow, an adopted daughter,
Leonette Roberts, and a brother, Arthur Roberts, of
Brattleboro, Vermont

PHELPS—OLNEY WINDSOR PHELPS, M.D., of War-
ren, Massachusetts, died at his home, December 2,

1935, after a brief illness following a year's grad-
ual physical decline

He was born in Waitsfield, Vermont, February 11,
1848. Following graduation from the Dartmouth
Medical School in 1878 he served as assistant physi-
cian in the Insane Asylum at Brattleboro, Vermont.
In 1882 Dr Phelps moved to Bellows Falls, Vermont,
where he practiced for three years. In 1891 he
moved to Warren, Massachusetts. His total medi-
cal career covered fifty seven years.

Dr Phelps was a member of the board of health
and the school committee of Warren for several
years and was active in civic organizations. He
joined the Massachusetts Medical Society in 1892
and retired in 1914.

His widow, Mrs Florence Johnson Phelps, a
son, Dr Olney Draper Phelps, of 27 Elm Street,
Worcester, Massachusetts, two grandchildren, and
a brother, Elleroy E Phelps, of Lebanon, New
Hampshire, survive him.

ADLER—HERMAN MORRIS ADLER, M.D., died at the
Phillips House of the Massachusetts General Hos-
pital, December 7, 1935.

He was born in 1876 and graduated from the
Columbia University College of Physicians and Sur-
geons of New York in 1901. His premedical educa-
tion was acquired at Harvard College and later he
returned to Boston, after having established a repu-
tation in psychiatry, to serve as assistant professor
of psychiatry at the Harvard Medical School from
1912 to 1917, and chief of staff of the Boston Psycho-
pathic Hospital.

Dr Adler was especially noted for accomplish-
ments in criminology and psychopathology and held
the position of professor of medical jurisprudence
and criminology at the medical college of the Uni-
versity of Illinois and later occupied the same chair
at the University of California.

He was a Fellow of the Massachusetts Medical
Society. Dr Adler is survived by his widow. His
family home was in Berkeley, California.

NOTICES

MASSACHUSETTS MEMORIAL HOSPITALS

The problem of "The Application of Proper Sur-
gical Technique in the Operating Room" will be
presented for consideration at the next Surgical Sec-
tion meeting on December 13, 1935, at 12 o'clock
noon in the Ladies' Aid Room, Talbot Memorial.

The speakers' list, which was scheduled for that
meeting, will be presented at a Special Meeting,
December 20, 1935, at 12 o'clock noon.

BOOK REVIEWS

Handbook of Anaesthetics J Stuart Ross and H P Fairlie Fourth Edition 299 pp Baltimore William Wood & Company \$4 00

This country lacks, to a sad degree, a modern textbook of practical instruction in anesthesia The 'Handbook of Anaesthetics', written by two anesthesiologists of Edinburgh and Glasgow for the instruction of medical students, unfortunately fails to meet this need According to our present standards here, its atmosphere is unwonted and out of date, for it is permeated with the odor of chloroform, and, with its frequent descriptions of certain closed methods of gas and vapor administration, it is stifling from lack of oxygen

The chapters on shock, anoxemia, nitrous oxide, ethylene, and chloroform are notably good Also those on local and spinal anesthesia, written by a third author, are definitely praiseworthy, though they suffer from brevity The chapter on choice of anesthetics deals with only five drugs, two of which are chloroform and ethyl chloride, the carbon dioxide absorption method of giving gases, now well established in this country, is skeptically referred to as experimental, the use of carbon dioxide for hastening induction and recovery is not mentioned, and no modern gas machine commonly used in this country is described, for these reasons the book is unsuited to the student of anesthesia here Because suction is not mentioned among the methods given for clearing the respiratory tracts of fluids, because asphyxia of the infant is entirely omitted from the discussion of anesthesia during labor, and because a maximal dose of avertin is advised without any qualifying provisions, for such reasons the book appears to be even unsafe to put into the hands of those who most need a handbook of anesthetics

Midwifery By ten teachers under the direction of Clifford White Edited by Comyns Berkeley, J S Fairbairn and Clifford White Fifth Edition. 740 pp New York William Wood & Company \$6 00

This is a textbook on obstetrics written by ten well-known English obstetricians It is interesting to have such a book to refer to in order to see how our English confreres carry out obstetrical procedures For use as a textbook in America it will scarcely be a success, because the treatment that is advised in various complications and the techniques used are not those to which American obstetricians subscribe As a reference book, however, it is of value

NUMBER 25

THE ELECTROCARDIOGRAPHIC DIAGNOSIS OF ACUTE CARDIAC INFARCTION WITH SPECIAL REFERENCE TO THE VALUE OF PRECORDIAL LEADS*

BY JAMES M. FAULKNER, M.D.†

THE decision as to whether a patient is suffering from acute cardiac infarction is a momentous and often a difficult one. Therefore, any refinement of technique which promises more ready recognition of the condition is worthy of careful study and evaluation. The recent employment of chest leads in the electrocardiographic diagnosis of cardiac infarction has yielded encouraging results which have prompted this investigation.

The history of the clinical study of coronary thrombosis is a brief one. In 1912, J. B. Herrick¹ gave the first description in English of the clinical features of sudden obstruction of the coronary arteries. The same gifted observer called attention to abnormalities in the electrocardiogram following coronary thrombosis² and suggested to Fred M. Smith the study of experimental coronary occlusion in dogs by which the electrocardiographic changes seen in human cases were reproduced.³ Smith showed that these changes have marked variations from day to day, and even from hour to hour, and may eventually disappear.

In 1920, Pardee⁴ called attention to a particular form of inversion of T waves, i.e. late, sharp inversion with upward convexity of the RS-T interval which was frequently associated with occlusion of coronary arteries as shown at postmortem.

However interest in the clinical diagnosis grew rather slowly. For example, in 1924 only three cases which had received the diagnosis of coronary thrombosis during life had come to autopsy at the Massachusetts General Hospital.⁵

In 1928, Parkinson and Bedford⁶ called attention to a definite sequence of changes in the RS-T segment and the T waves of the electrocardiogram following cardiac infarction. "Shortly after the onset of symptoms a transient deviation of the RS-T segment from the isoelectric plane occurs. This is followed by a deep inversion of the T waves in either lead I or lead III, but not in both, and often by

a lesser degree of T inversion in lead II. Curves obtained after a few weeks conform to one of two main types according to the incidence of T inversion in lead I or in lead III. Subsequent T wave changes in the direction of normal are recorded, and even complete return to normal occurs." These authors speculated as to the possibility of correlating the site of the infarct with a specific type of electrocardiographic abnormality but drew no conclusions from their limited autopsy material.

In the following year Barnes and Whitten⁷ found that the electrocardiographic changes of the T⁺ type described by Parkinson and Bedford were usually associated with infarction of the anterior wall of the left ventricle, and the T⁻ type with infarction of the posterior wall of the left ventricle. They observed, as others had before, that infarction of the right ventricle was rare.

More recently the effect of cardiac infarction on the initial deflections of the ventricular complex have received attention. Pardee has pointed out that the incidence of heart disease, particularly the anginal syndrome, is high in individuals exhibiting a large Q wave in lead III in the presence of a normal electrical axis or left axis deviation.⁸ He presented evidence which suggested that the large Q III is due to disease of the left ventricle. A refinement of his criteria has added to the diagnostic value of Q-wave changes by excluding many normal individuals,⁹ and their importance in relation to cardiac infarction has been amply confirmed by others, notably Wilson and his coworkers.¹⁰ Wilson's observations indicate that deviations of the RS-T interval are due to currents of injury set up at the borders of myrred cardiac muscle whereas the changes in the initial ventricular complex (QRS) are explained by the death of areas of formerly active tissue. The former is, therefore a transient and the latter, a permanent change.

The most recent important contribution to the electrocardiographic diagnosis of cardiac infarction was the introduction of the chest lead by Wolfarth and Wood in 1932. Although chest electrodes had been employed by others previously, they were the first to demonstrate clearly that with this technique many cases of

From the Thorndike Memorial Laboratory Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine Harvard Medical School Boston, Massachusetts.

†Faulkner, James M.—Assistant in Medicine, Harvard University Medical School. For record and address of author see "This Week's Issue," page 136.

fresh infarction show electrocardiographic changes which do not appear in the standard limb leads. The changes in the chest lead have also been considered to be of value in localizing the site of the infarct.

In taking the chest lead, Wolferth and Wood placed the right arm electrode over the precordium* and the left arm electrode on the back of the chest just below and mesial to the left scapular angle. This lead they designated as lead IV. In subsequent studies they also made observations on an electrocardiographic lead taken from the precordium to the left leg which they designated as lead V, and on a lead taken from the posterior electrode to the left leg which they designated as lead VI. Comparison of the results derived from the three chest leads showed that leads IV and V were very similar in appearance and lead VI yielded little, if any, additional information of importance. Since their original publication, the clinical use of chest leads in the diagnosis of cardiac infarction has been made in a number of clinics. The practical value of the method has been confirmed by others and its theoretical validity soundly established. The subject has been somewhat confused by the fact that many subsequent investigators have used slightly or widely different parts of the body for placing the electrodes so that their results are not comparable one with another. While it is quite possible that one or more chest leads may be found which will yield even more information than those employed by Wolferth and Wood, their series, together with others using the same technique, represent the largest and best controlled from the point of view of autopsy protocols as well as for normal individuals. It appears, from their own observations, that in most cases all of the information desired can be derived from one of the two precordial leads. As pointed out by Wilson¹², it is the electrode nearest the heart which is the predominating factor in inscribing the electrocardiogram in chest leads. The position of the distal electrode is therefore of relatively minor importance. The records of Wolferth and Wood's lead IV (anteroposterior) are almost identical with their lead V (precordium to left leg) and, for practical purposes, the two may be used almost interchangeably. Since lead V is a little easier to take technically, it is perhaps, of the two, the method of choice. An excellent critical review of the subject of chest leads appears in a recent article by Roth¹³.

The amount of information to be derived from precordial leads not yet being fully established, it seemed worthwhile to report on our experience with this procedure at the Boston City Hospital with 250 individuals, in all of

whom there was a question of recent coronary thrombosis. The precordial lead employed in almost all of these was "lead V", only a few at the beginning being "lead IV". We have evaluated these records by the criteria set forth by Wood and Wolferth and more accurately defined as regards normals by Master¹⁴. The ventricular complex in the precordial lead as thus defined consists of an initial downwardly directed wave, the Q-wave, followed by an upward R-wave, an isoelectric interval and, finally, a negative T-wave. The Q-wave is normally at least 15 mm in depth and the R-wave at least 25 mm in height. The R-T interval is either slightly below the isoelectric level or just isoelectric. In normal persons it is never above the isoelectric level or more than 2 mm below it.

The changes observed in the precordial lead following acute cardiac infarction may be divided into two main types corresponding with the T¹ type and the T² type described by Parkinson and Bedford.

In the first type, the Q-wave of the precordial lead either disappears or is markedly diminished in size, and the R-T interval is at first markedly depressed. The depression of the R-T interval persists for from five to nine days and gradually disappears. A high peaked upright T-wave develops and tends to remain (see figure 1).

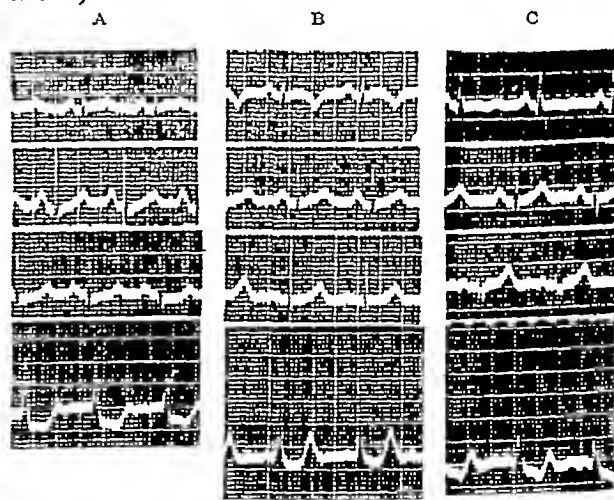

FIGURE 1. Electrocardiogram of the T¹ type. Leads I, II, III and V. A 3 days, B 19 days and C 9 months after coronary thrombosis.

In the second type, the precordial lead is often normal although it may show elevation of the R-T interval or upright or flat T-waves. Changes when they do occur are not usually permanent (see figure 2).

Before proceeding to the analysis of our cases, it may be pointed out that the possibility of factors other than myocardial infarction operating to affect the electrocardiogram have been ruled out as far as possible. By confining this study to the diagnosis of acute infarction, we have avoided the difficult problem of distin-

*The exact position of the precordial electrode is important. For the sake of technical simplicity and uniformity in this series a point 4 cm to the left of the mid sternum in the fourth intercostal space was used.

guishing between electrocardiographic changes due to old infarction and those due to myocardial damage from other causes. This has limited the electrocardiographic criteria to (1) deviations of the R-T segment or (2) marked variations in the ventricular complex from day to day. One condition, other than cardiac infarction which may be associated with deviation of the R-T interval is inflammation of the pericardium, such as tuberculous pericarditis. In this instance however, the characteristic feature is an elevation of the R-T interval in all

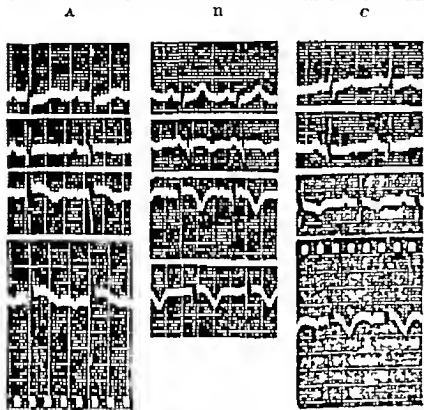

FIGURE 3. Electrocardiogram of the T₁ type. L, 1; II, III, and V, A, 6 days; B, 33 days; and C, 10 months after coronary thrombosis.

leads rather than in one or two leads only. Other conditions which may produce comparable changes in the electrocardiogram are diphtheria and other forms of acute myocarditis, massive pulmonary embolism¹⁴ and, perhaps, digitalis intoxication.¹⁵

A comparison of the electrocardiographic interpretation with the final clinical diagnosis is of some interest although, of course, it does not approach in significance a comparison with necropsy findings.

Of the 250 cases studied, fifty-one were interpreted as acute cardiac infarction from the electrocardiogram (see figure 3). Of these forty-four were so diagnosed clinically, three were classed as suspicious and four as negative. Nine cases had a questionable electrocardiographic interpretation of acute infarction. Of these four had a positive clinical diagnosis, three a questionable diagnosis and two a negative diagnosis. Of the 190 cases who had no electrocardiographic signs of acute infarction the clinical diagnosis was in agreement in 163 cases but twenty-four had a positive clinical diagnosis and three were classed as questionable. The discrepancy between the clinical and the electrocardiographic diagnoses is explainable in part by the fact that some of the cases in which a

positive clinical diagnosis was made did not have electrocardiograms until after the acute stage of infarction was over and the characteristic electrical changes might be expected to have disappeared.

In thirty-five of the fifty-one cases exhibiting the electrocardiographic signs of cardiac infarction the diagnostic abnormalities were present simultaneously in both the precordial and limb leads. In these instances the chest lead was of value only in confirming the evidence derived from the standard leads. In five cases the changes persisted in the limb leads after the chest lead had returned to normal. In two cases the abnormality appeared only in the standard leads. In one case, in which the clinical picture was unmistakable, the electrocardiographic diagnosis was made only by striking variations in the record from day to day, although no single record was in itself diagnostic.

In eight cases the diagnostic abnormality was present at some time only in the chest lead. All of these cases had a positive clinical diagnosis of coronary thrombosis. In three, the changes appeared only in the chest lead throughout, in two, it preceded the development of changes in the standard leads, in two, it followed them and in one it both preceded and followed them. This group of eight cases comprising approximately 16 per cent of our total positive diagnoses illustrates the importance of the precordial leads. In three cases out of fifty-one the diagnosis could never have been made without the chest lead.

Complete necropsy records were available on thirty-three cases in which precordial leads had been taken. These records were of routine hospital necropsies performed by a number of different pathologists. The exact extent or localization of the infarct beyond the statement that it was situated in the anterior apical or posterior portion of the ventricle was not always clearly recorded. This must be borne in mind in evaluating the correlation between the electrocardiographic and the anatomical localization of the infarcted areas. Thirteen cases showed acute cardiac infarction at postmortem. The electrocardiographic diagnosis was made in eleven of these (see figure 3). In each of the two cases in which the electrocardiographic diagnosis was not made a single record was obtained shortly before death. In one it appeared that the infarction although recent, was of too long standing to show the characteristic changes in a single record; the history indicating clearly that the thrombosis had occurred nineteen days before the record was taken. It showed an absence of the Q wave in the precordial lead a flat T₁, very low T₂ and inverted T₃. In the other, the record was obtained a few hours after the onset and showed intraventricular block. In both there was infarction of the anterior wall of the left ventricle and both showed

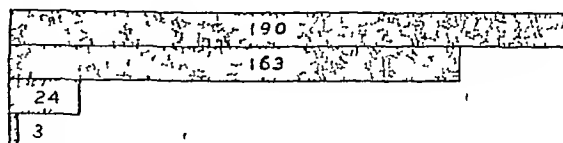

marked coronary sclerosis with extensive myocardial scarring

Of the thirteen cases with acute infarction, twelve were in the anterior or apical portion of the left ventricle and one in the posterior wall. The anterior infarcts were associated with the following electrocardiographic findings—five with changes of the T^1 type, three with changes of the T^s type, two with changes

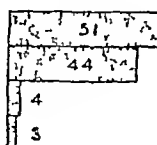

showed an upright T^1 —still with low origin. This patient died two days after the last record was taken and showed a dissecting aneurysm of descending thoracic aorta without involvement of the coronary arteries or pericardium. It seems obvious that there will always be instances of borderline or doubtful changes in the electrocardiogram which cannot be interpreted with certainty. The cases which are most difficult to

of a nonspecific type, and two with signs of old coronary disease only. The one case with posterior infarction showed electrocardiographic changes of the T^s type.

In this series the correlation was better between the electrocardiographic type and the artery occluded than with the actual site of the infarct. All of five instances of the T^1 type were associated with occlusion of the anterior descending branch of the left coronary artery and three out of four of the T^s type had occlusion of the circumflex branch.

In the remaining twenty autopsied cases in which there was no infarction, a questionable electrocardiographic diagnosis was made in four. One of these had left bundle branch block with a markedly depressed R-T interval in the chest lead (7 mm). Another had intraventricular block with an elevated R-T level in the chest lead (3.5 mm.). The third case showed an auricular tachycardia with two to one heart block and a ventricular rate of 115. The take-off of T^s was 4 mm below the baseline. The fourth case showed inversion of T^1 with low origin and upward convexity of S-T on two records taken two days apart, and three days later

evaluate are those in which there is electrocardiographic evidence of old myocardial disease and, particularly, bundle branch block.

SUMMARY AND CONCLUSIONS

In a series of electrocardiograms including precordial leads on 250 patients, a diagnosis of fresh cardiac infarction was made fifty-one times. In eight of these the diagnostic feature was present at some time only in the chest lead, and in three it was never present in the standard leads.

A comparison between the electrocardiographic and the autopsy findings was made in thirty-three cases. Out of thirteen cases with acute infarction the electrocardiographic diagnosis was positive in eleven. Localization of the infarct was not reliable by the method used.

Of the twenty cases who did not show infarction, four had a questionable electrocardiographic diagnosis, and in the remainder it was negative.

The findings here recorded support the following conclusions:

(1) During the first two weeks after the de-

veloping of cardiac infarction the electrocardiogram is a highly accurate method of determining the diagnosis

(2) The precordial lead offers additional information of definite value in the diagnosis of fresh cardiac infarction

NEW ENGLAND SURGICAL SOCIETY

SECONDARY CARCINOMATA OF THE LARGE BOWEL*

BY EDWARD L. YOUNG, JR., M.D.†

BY secondary carcinoma of the large bowel I have reference to those cases where following an operation for the disease, a second growth occurs in the colon at some distance from the primary tumor

The etiology of carcinoma of the colon just as in all malignant tumors remains obscure. Nevertheless we do know of certain contributing or predisposing factors, and in particular we recognize the fact that certain types of benign growths may show a malignant degeneration. This is a definitely recognized fact in relation to adenomatous polypi of the large intestine. We have no proof that they all become malignant but certain it is if a patient lives long enough, the vast majority will make trouble of this nature. Neither do we know with certainty that all carcinomata of the large bowel originate in polyps but there is a good deal of evidence to make us think that at least a large proportion of them do. It is of course, well recognized that these papillomata are very apt to be multiple. In fact the presence of one should put the burden of proof on the individual who tries to prove it is the only one. Although these facts are beyond dispute I think they have received too little attention in relation to the recurrence of cancer of the colon. When a patient comes back with a recurrence of this disease, it is too often assumed that it is a recurrent manifestation of the first growth when in fact it may be and I think often is entirely separate and just as amenable

to treatment if recognized in time as the first tumor. I believe that is the important fact relating to this subject and the justification for this paper. The following cases are illustrative of the problem at hand and I am putting them down in the order in which it seems to me they emphasize the story.

CASE 1. M. G. H., F. S. 281130 a male aged thirty eight. He came to the hospital in January 1927 with the story of one year of intermittent pain in the right lower quadrant. His bowels had been normal until two weeks before entry when they were loose but there was no blood. X-ray showed a tumor of the cecum. At operation a right colectomy was done and the pathological diagnosis was adenocarcinoma of the colloid type with intestinal polyps. Inasmuch as the mucous membrane above the growth showed numerous small adenomas from the size of a buckshot to a pea. Those examined did not show any malignancy. He has been followed in the tumor clinic. Shortly after operation he reported an occasional show of blood on the stool but he laid it to hemorrhoids which he undoubtedly had. X-rays were negative through December 1929 nearly three years and no rectal examination was done until just after the last x-ray. That examination showed rectal polyps. He was referred to the House where he was seen by Dr. D. F. Jones, in consultation on January 5 1929 who stated that inasmuch as the patient was known to have had polypi in the ascending colon and rectosigmoid region, he undoubtedly had them between and that he would eventually die of carcinoma if he did not have a total colectomy but that the operation was of sufficient severity so that if the patient could be made to understand the problem, he should be the one to decide. As a result the visible polyps in the rectum were fulgurated and eight months later a large papilloma of the rectum was excised with the diathermy current. The pathological report on this says: A growth 4 x 3 x 1 1/4 cm. microscopically showing atypical changes of the epithelium very suggestive of malignant degeneration.

Read at the Annual Meeting of the New England Surgical Society at Manchester N. H., September 27 1929.
†Young, Edward L., Jr.—Surgeon-in-Chief, Faulkner Hospital. For record and address of author see "This Week's Issue," page 135.

but no invasive growth and examination of the base or stock shows no malignancy." On the basis of this report, the patient was advised to have a total colectomy but at this time refused and in April, 1933 came back to the hospital with obstruction in the sigmoid and operation showed a generalized carcinomatosis from which he died four months later. No recurrence of the original growth was in evidence at any time.

This case is the typical picture which is seen so often where polyposis of the large bowel is present.

CASE 2 Private case, a female, aged fifty-three. This patient reported with thirty six hours of acute intestinal obstruction with no previous story that could be obtained at any time other than vague digestive disturbances. Immediate operation showed what was apparently a carcinoma of the sigmoid and a cecostomy was done. At the second operation careful palpation showed not only the growth but about two inches below a mass which, at first, was thought to be feces but was found to be fixed so that the resection was made to include it. The pathologist's report was somewhat of a surprise as he said that the carcinoma was actually a diverticulitis and that the mass below was a polyp with a definite beginning malignancy. That patient has been followed routinely since without evidence of recurrence by x-ray or laboratory study.

This case is, of course, what would be called a "lucky break" for the patient and shows what is apparently a single polyp inasmuch as in four years no evidence of other polyps has developed. Nevertheless, I believe the burden of proof is on us to watch her and make sure that no further secondary cancer develops.

CASE 3 M G H, E S, a man, aged fifty, came into the hospital in April, 1930 with symptoms extending back only a few weeks. Distress and in definite indigestion were the main symptoms. There was a palpable mass in the right upper quadrant and x-ray showed a tumor of the hepatic flexure. At operation a resection was done and no metastases were found. The pathological report was adenocarcinoma and no involvement of lymph nodes, only a moderate rate of growth and a relatively low malignancy. He had no further symptoms until February, 1933 and he reentered in April and at that time there was a growth in the upper end of the descending colon. Resection of the splenic flexure was done but this time there were metastases to the lymph nodes and when last seen four months ago he had a palpable liver and beginning jaundice. There was no evidence in the x-ray at any time either in 1930 or 1933 that there were polyps elsewhere in the colon and, at the last operation, careful palpation failed to show anything. This patient had not been followed between the two operations in the out-patient department.

I think this patient shows what is more apt to be the truth than the case previously noted, namely, that other polyps are present at the original operation but not palpable to the ordinary search. Had this case been followed in a routine fashion, it might well have been possible to recognize the secondary growth early enough to offer him still a good chance of per-

manent cure instead of which it has probably resulted fatally by this time.

CASE 4 A female, aged fifty five, went to her doctor with a slight temperature of unknown origin and an increasing constipation, no localizing symptoms. An obstruction was demonstrated at the splenic flexure and in 1931 operation was done with a resection of the splenic flexure. The pathological report at that time was adenocarcinoma, grade 3. The patient did well and her check ups were purely clinical until 1933 when it seemed to me that we must consider all of these cases as having potential malignancy elsewhere, and routine barium enemas were done as well as routine search for occult blood in the stool and rectal examinations. Everything went smoothly until the x-ray in September, 1934 which showed a slight filling defect in the low sigmoid. There was no other evidence of trouble, however, and she did not show positive gualacs until the first of 1935. At that time she did have two or three positive gualacs and another barium enema showed the same persisting suggestive area in the sigmoid. Accordingly, operation was done and an early carcinoma of the sigmoid was found. Because of the previous operation and the resulting tension, the large bowel from the middle of the transverse colon down to the lower sigmoid was removed and on section of the old anastomosis, an early recurrence was found in the wall. The lymph nodes were not invaded and it seems as though she had a better chance for cure than the usual secondary operation gives.

In this instance I had not reached the point that I now have where the suspicious x-ray should have resulted in earlier action.

With these cases as illustrations my thesis is simple. I believe that whenever a carcinoma of the large bowel is successfully operated on, that colon should be considered as having one or more starting points for later growths. Accordingly, I believe the following procedures should become routine. Before operation, the roentgenologist should report not only that there is an obstruction or a growth but also should, to the best of his ability, say whether there are other areas which suggest possible polyps. I believe that a proctoscopy should be done to see whether the rectum and low sigmoid will show polyps. At operation whenever it is possible, the surgeon should palpate carefully the whole area of the colon to see whether he can demonstrate other tumors. It is always difficult and oftentimes impossible to recognize small, soft, pedunculated papillomata so that this manoeuvre must not be considered sufficient to rule out future trouble. After the patient's recovery, these cases must be considered to have potential malignancy elsewhere in the large bowel until time and careful study have ruled it out. This study should mean a routine check-up at least every six months and should consist of the following: (1) A careful x-ray study by a roentgenologist competent to give reasonable hope of early recognition of trouble, (2) routine study of stools for occult blood. The patient should also be instructed to report any change in bowel habits that show

any tendency to persist or recur. It seems to me that we have here a clear indication to justify this bother and expense to the patient in contradistinction to innumerable cases of vague abdominal symptoms which when first seen suggest a functional background and where the patient would generally feel that it was an unfair hardship and expense to put him through a complete x ray, proctoscopic, and laboratory check up.

DISCUSSION

Dr. LUCIUS C. KINOMAN, Providence, R. I., Mr. President—Dr. Young has covered this whole matter very well. We have all seen cases such as he describes and we are of the opinion that secondary operations in cancer of the big bowel are quite justified when we have symptoms pointing to a local condition. On secondary operation I have found obstruction due to cancer of small bowel and of course that due to adhesive peritonitis is not uncommon.

As to how long a patient should be followed until we feel he is free from a chance of recurrence I do not know. Probably all malignancy should be followed as long as the patients live or as long as you can persuade them to remain under observation.

On the hospital cases, I think the only practical method is a special clinic for malignancy. We can not throw them into the general outpatient clinic or even the general follow up clinic on service. The

financial problem comes in as Dr. Young mentioned and at times we would be swamped if we followed these cases perhaps in the ideal way which he has mentioned.

I should like to give a little word of warning about x ray reports. I do not believe you can diagnose every case of malignancy of the big bowel by x ray even well advanced. I have been misled that way and in cases where they have been repeatedly x rayed by experts in more than one town.

What he said about the complete examination of the big bowel at the time of operation is a very important thing and probably most of us have not done that so well as we should. We go in and feel the growth locate that size it up. We are so interested in the job we go ahead and do it. We forget there is a bowel below that may have polyps or implantations or what not.

Dr. Young has told us several things that we should always bear in mind.

Dr. FRANK H. LAHEY, Boston, Mass.—I have one thing to add and that is the value of contrast enema. Lockhart Mummery has just reported a series of cases of carcinoma of the rectum and colon followed over a series of years in which there was a high incidence of secondary carcinoma.

We have had this same experience and everyone who deals with colons surgically is bound to have this same experience of there being coincident other papillomata which may degenerate into malignancy. For that reason I would urge strongly that everyone take advantage of the value of so-called contrast bismuth and air enema for the demonstration of possible other coincident papillomata.

RETICULOCTE RESPONSES IN THE PIGEON PRODUCED BY MATERIAL EFFECTIVE AND NONEFFECTIVE IN PERNICIOUS ANEMIA WITH DESCRIPTION OF THE HISTOLOGICALLY DIFFERENT REACTIONS OF THE BONE MARROW*

By GULLI LINDH MULLER, M.D.†

IN the experimental work undertaken to obtain a biological test for the potency of material effective in pernicious anemia, one fundamental principle has hitherto not been emphasized namely, that the reticuloocyte response in the peripheral blood may represent at least two fundamentally divergent reactions of the bone marrow. This is not a question of theoretical interest only, but a vital problem as a method must be found which will differentiate the response to the administration of the principle effective in pernicious anemia, and that of other substances closely associated with this principle but without affecting in a desirable manner blood formation in the specific disease in man. That a reticuloocyte response may be obtained in experimental animals which bears no relation to the response obtained with substances potent in pernicious anemia, is the subject of this paper.

In 1927 shortly after the introduction of liver therapy in pernicious anemia, it was noted that

†Record and address of author see "This Week's Issue" page 155.

the blood and the bone marrow of the pigeon were peculiarly susceptible to liver feeding.¹ In the autumn of 1929 comparatively pure sources of the principle effective in pernicious anemia were available and it was shown, that material capable of causing a reticuloocyte response with rapid blood regeneration in pernicious anemia also produced a reticuloocyte response in healthy, grain fed pigeons kept under standard laboratory conditions.² This has been confirmed by Edmunds and coworkers³ and Penbody and Neale.⁴ Wills⁵ and Homann Connery and Goldwater⁶ found that the reticuloocyte percentage of all their birds showed large fluctuations and that no significant change occurred in the control animals and those which had liver extract. In a recent communication Gurd⁷ suggested that these differences may be due to the method of staining and counting reticuloocytes. He found that the concentration of the brilliant cresyl blue exerted a marked influence on the number of reticuloocytes in the pigeons' blood and that when a sufficiently strong solution was used some stained granular material was found in practically all the cells.

The variations in experimental results obtained by various observers using different techniques may be explained by a consideration of the sensitivity of the hematopoietic organs of the pigeons. Lack of food or inadequate diet may deplete the bone marrow even to the point of aplasia¹, and infection exerts a powerful influence⁸. Consequently in our comparative work on the effect of various substances on the hematopoietic organs of the pigeon over a period of years, the experimental conditions have been kept as identical as possible. Birds showing unexplainable variations in weight and in the blood during the control period were discarded. The pigeons were kept in small individual cages with space sufficient only for movement of the wings, and they were fed, and blood examinations made at the same time of day avoiding all undue excitement by rolling the animal in a towel. Great care was taken to avoid bleeding as in small animals the loss of several drops of blood may cause bone marrow changes. Also as was pointed out by Vaughan, Muller and Zetzel² more brilliant cresyl blue was used in the preparation of the blood smear than is necessary for mammalian blood by making thicker films using 0.5 per cent alcoholic solution of brilliant cresyl blue on *both* coverslips used for the smear. In counting the cells the fact was not emphasized in former communications that a few dust-like fine granules in the red blood cells were not considered as reticulum. Since the young cells of the birds' blood, as a rule, show heavy reticulation, the qualitative differences after the administration of certain substances were as striking as the quantitative change. In all our experiments the same technic was always employed, and the results obtained, therefore, may be considered significant. Reticulocyte responses accepted as positive were always in the form of a definite progressive rise rather than fluctuations back and forth between normal and higher levels. In addition, the response in the peripheral blood has been checked in most cases by microscopical examination of the bone marrow. Differences, therefore, found by some observers may be due to variations in the experimental conditions, and, as has been suggested by Gurd⁷ to the staining and standard employed in counting the reticulocytes.

The megaloblastic character of the bone marrow in pernicious anemia and allied conditions is well established. Apparently, so far as is known, it is this type of bone marrow alone that responds to material effective in pernicious anemia. The quantitative and qualitative changes which occur in the bone marrow of patients receiving liver therapy have been described by Peabody⁹.

The bone marrow of the healthy adult pigeon likewise is characterized by an abundance of megaloblastic tissue. The administration of liver, or liver extract, potent for pernicious

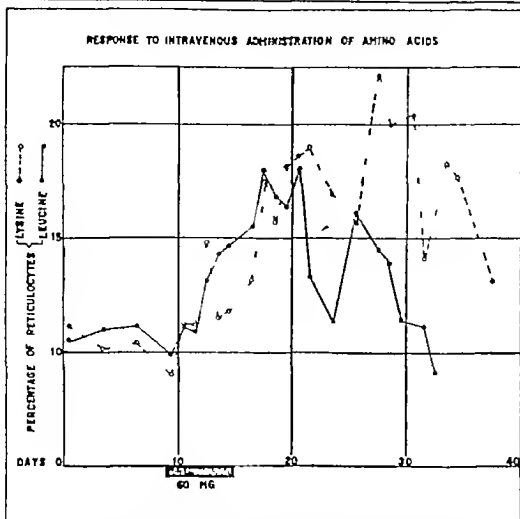

anemia, produced a reticulocyte response and changes in the bone marrow of the pigeon^{1, 2, 9} similar to those observed by Peabody in man.

As no demonstrable effect had been obtained at that time in other laboratory animals with the principle effective in pernicious anemia, it was thought that this reticulocyte response in pigeons might furnish a convenient test for the potency of the principle effective in the disease. Further work demonstrated, however, that although most clinically inert fractions of liver elicited no reticulocyte response in the birds, one fraction, clinically tested and found ineffective, caused a reticulocyte response in pigeons. This fraction was a comparatively pure preparation of the amino-acid, leucine², the preliminary work on leucine has been repeated and verified.

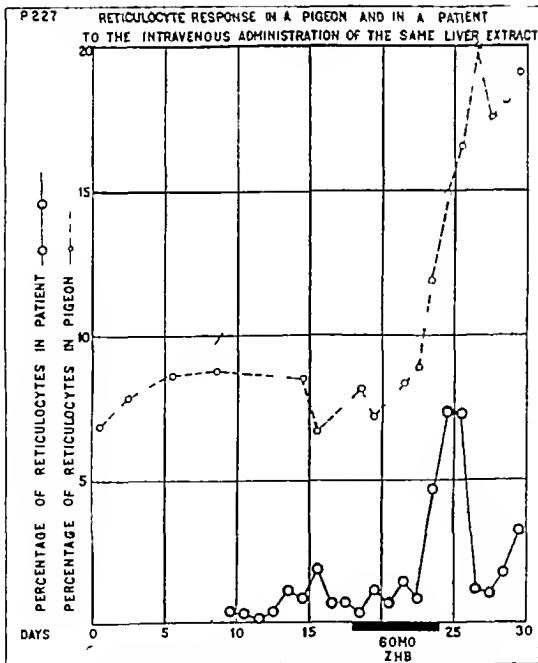

To find out whether commercial preparations of pure amino-acids, which are known constituents of red blood cells, produced a reticulocyte response in the peripheral blood of pigeons, three other amino-acids, lysine, arginine, and histidine have been tested. The experimental methods were identical with those previously employed². Ten milligrams, and in some instances 20 milligrams of the amino-acid was administered intravenously on six consecutive days to several birds.

In chart I the reticulocyte responses to lysine and leucine are illustrated and in chart II the response to a comparatively pure fraction of liver extract injected intravenously. The reticulocyte reaction to the principle effective in pernicious anemia usually was a moderate one, only occasionally exceeding 20 per cent. Similar reticulocyte responses were obtained with both leucine and lysine. When larger doses of lysine were employed (20 mg.) there was an outpouring of reticulocytes in the peripheral blood of the pigeon in some instances reaching values of 30 to 35 per cent. The two other amino-acids tested, arginine and histidine, gave indefinite or no reticulocyte responses.

An explanation for the rise of reticulocytes in the peripheral blood of pigeons to substances which are not effective in pernicious anemia was found by the examination of the bone marrow. As has been pointed out previously^{1, 8} the radial bone marrow in the normal pigeon has been found to be mainly fatty with some cellularity at the edges. The femoral marrow on the other hand was found to be hyperplastic and contains red blood cell islands consisting of a mixture of cells ranging from megaloblasts to mature red blood cells with a considerable proportion of the cells in the megaloblastic or early erythroblastic stage. Often mitotic figures are present. Occasionally the radial marrow is hyperplastic which occurs when the femoral marrow, for some unknown reason, has been replaced by cancellous bone. Hyperplasia, therefore, of the

I. Reticulocyte response in the peripheral blood of pigeons to the intravenous injection of 10 mg. of lysine and leucine on six consecutive days.

II. Reticulocyte response in a pigeon following the injection of 10 mg. of an effective liver preparation on six consecutive days and the reticulocyte response in a patient with pernicious anemia who received a total of 1.8 grams of the same liver preparation. The patient's red cell level was 2,700,000 per cmm.

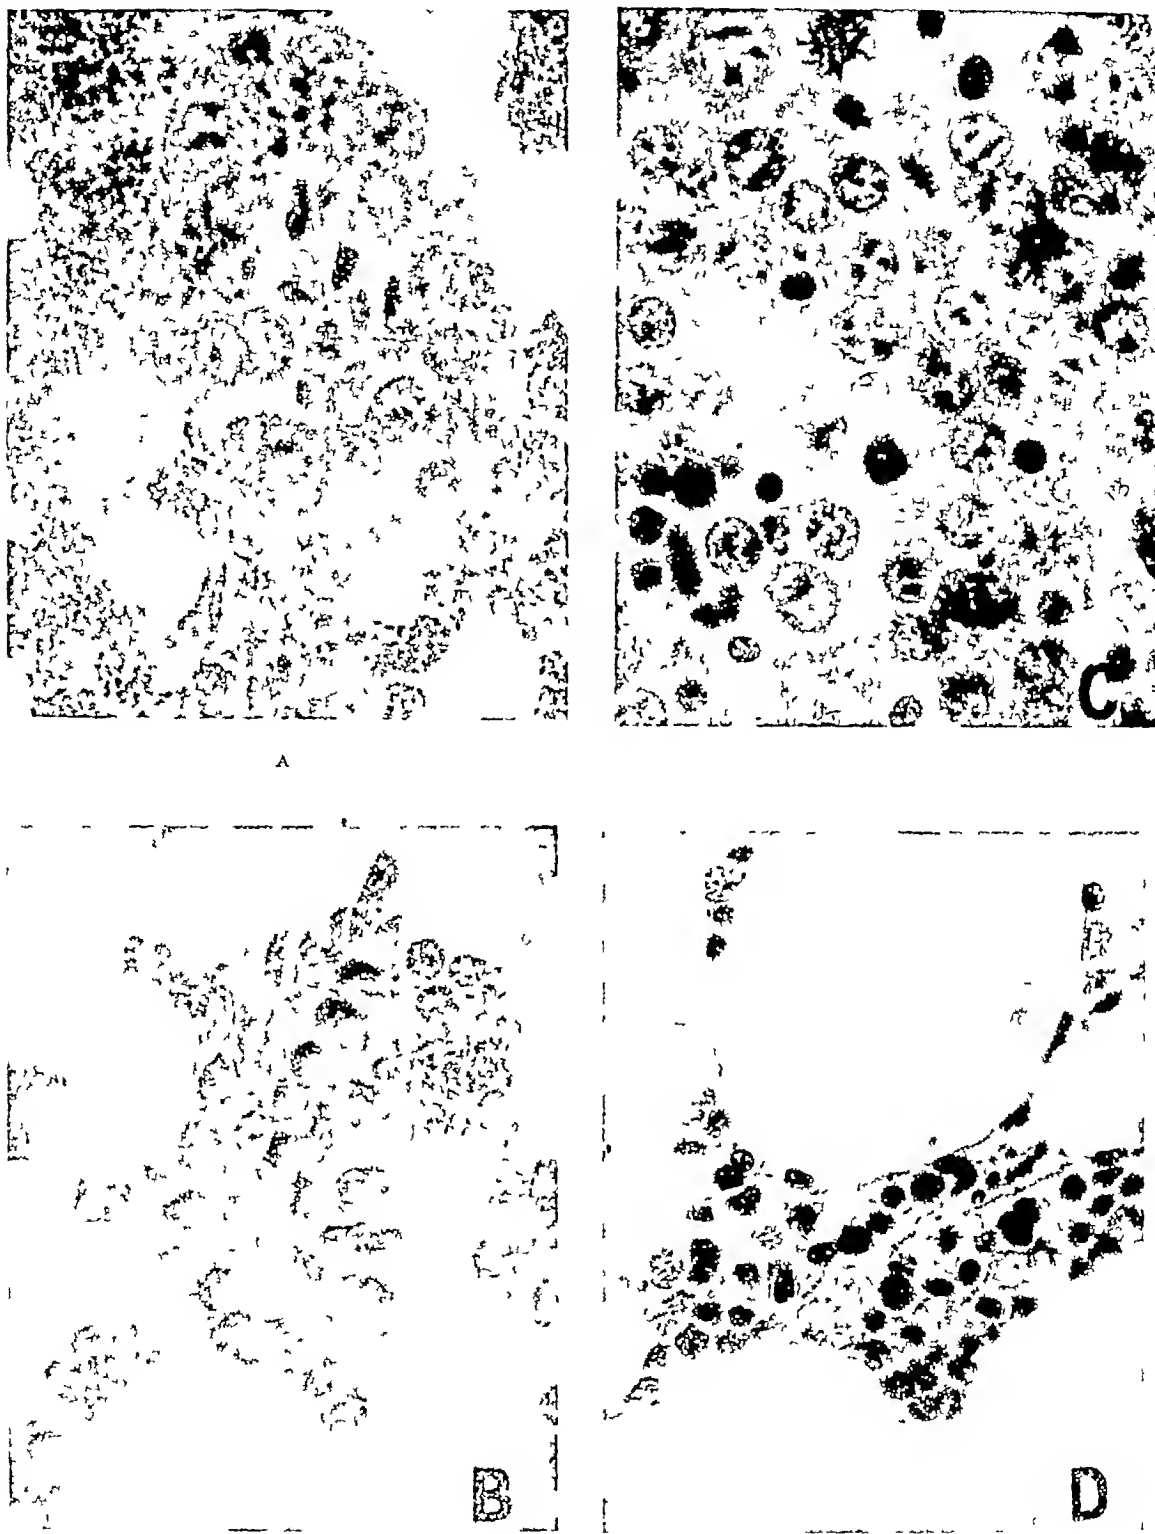

FIGURE 1 Bone marrow from pigeons and a patient with pernicious anemia before and after the administration of liver extract

- d Tibial bone marrow from the same patient as (c) in a remission produced by the administration of principles effective in pernicious anemia $\times 750$

radial marrow, as a rule, indicates growth and thus extension of the blood forming tissue

In fig 1a the appearance of the normal femoral bone marrow of a pigeon under the standard laboratory conditions is illustrated, and in fig 1b the femoral bone marrow after the administration of "liver extract." A marked change in the erythrocytic centers is discernible. The marrow obtained after the administration of liver extract, at a time when the peak of the reticulocyte response had passed showed a qualitative change of the red blood cells. The

In figs 2a and b is shown the *radial* marrow of a pigeon injected intravenously with lysine. The extension of erythrocytic centers and the hyperplasia of this normally practically fatty marrow and the activity, as evidenced by mitotic figures, is unmistakable. The reticulocyte response to lysine, therefore, and other substances examined giving the same bone marrow reaction, is thus easily explainable. New formation of erythrocytes in the femoral bone marrow, and more especially extension to the radial marrow accounted for the reticulocyte response both

FIGURE 2. *a* Radial bone marrow of pigeon injected intravenously with 70 mg. of lysine for ten consecutive days and killed sixteen days after the first injection.

- a*. Hyperplasia of erythroblastic tissue in a normally fatty marrow. X600.
b. Large erythroblastic centers from fig. *a* showing megakaryoblasts and several mitotic figures. X1500.

erythrocytic centers were small and shrunken and consisted mainly of cells in the late erythroblastic and normoblastic stage. Quantitatively there appeared to be a decrease of erythropoietic tissue. Thus the outpouring of the reticulocytes occurred without microscopic signs of activity and without extension of erythropoietic tissue into the radial marrow.

The similarity of this response in the birds bone marrow to the one obtained in patients with pernicious anemia is striking. This is illustrated in figs 1c and d. The former shows a section of the tibial bone marrow of a patient with pernicious anemia in relapse and the latter the marrow from the same patient, both obtained by biopsy after the administration of substances effective in pernicious anemia.

qualitatively and quantitatively. The reticulocyte response to the principle effective in pernicious anemia however seemed to be commensurable with the amount of megakaryoblastic tissue present and there was no stimulation of the bone marrow if with stimulation we postulate now formation of megakaryoblasts and extension of the erythropoietic tissues.

From the above, one is justified in concluding that a reticulocyte response in the peripheral blood may depend upon at least two diametrically opposite reactions. In one a megakaryoblastic marrow as is found in patients with pernicious anemia and allied conditions and in the normal pigeon is essential. This type of marrow is influenced in a specific manner by the principle effective in pernicious anemia. The other type

of reticulocyte response produced by leucine and lysine in this study, is caused by a stimulation and proliferation of red blood cells and an extension of blood-forming tissue. Qualitatively and quantitatively the reticulocyte response in the pigeon to substances causing a stimulation and extension of erythropoietic tissue cannot be differentiated from that due to the specific effect of "liver extract". It is obvious, therefore, that this reaction alone cannot be used as a measure of the potency of unknown principles as to their effectiveness in pernicious anemia. However, in the hands of the experienced observer, the reticulocyte response in the peripheral blood of the pigeon, correlated with the histological appearance of the bone marrow might become a valuable, although not ideal, biological indicator of the hematopoietic potency of substances effective in pernicious anemia. Recently a test for the potency of liver extract has been proposed by Jacobson¹⁰, namely, the reticulocyte response in particularly selected guinea pigs. A mammalian test animal has many advantages over the avian, but whether the guinea pig responds to other substances with a reticulocyte increase in the peripheral blood and hyperplasia and extension of the erythropoietic tissue has not been reported.

SUMMARY AND CONCLUSION

1 Previous work has been confirmed that the injection of comparatively pure liver extracts effective in pernicious anemia causes reticulocyte responses in the pigeon under standard conditions.

2 Similar reticulocyte reactions were obtained by the intravenous injection of lysine and leucine, while arginine and histidine gave but indefinite responses.

3 These reticulocyte responses in the peripheral blood were accompanied by two histologically different reactions of the bone marrow

a. After the administration of liver extract the megaloblasts of the bone marrow were transformed to more adult red blood cells. This occurs also in the bone marrow of pernicious anemia patients after liver therapy.

b. After the administration of lysine and leucine the bone marrow showed an increase and extension of erythroblastic tissue. Numerous megaloblasts and many mitotic figures were present.

4. A reticulocyte response in the peripheral blood, therefore, may be due either to a principle effective in pernicious anemia acting on a megaloblastic marrow, or to other substances such as lysine or leucine, which produce a growth and thus extension of erythrogenic centers. This dual reaction is a factor to be considered in any work undertaken for a biological test of the principle effective in pernicious anemia, as the peripheral reticulocyte response may be produced by two diametrically opposite bone marrow reactions.

SPINAL ANESTHESIA*

Agents, Methods and Indications

BY MEYER SAKLAD, M D †

WITHIN the past few years there have been added to the field of spinal anesthesia new methods and agents. This paper is offered as a review of the subject with an attempt to consider and contrast the more important agents, methods and the theories underlying their usage.

AGENTS

In considering agents employed in any field of usefulness to accomplish a given purpose it

is logical to investigate first their relative toxicity.

Some may argue that the toxicity of an agent employed in spinal anesthesia is not important since the dose necessary to accomplish a therapeutic result is so small that the danger from toxic absorption into the blood stream is negligible. Witness the statement of Babcock¹ who speaks of the successful use of cocaine intraspinally in the General Hospital of Mexico City. It is his feeling that "the danger lies more in the technique of the user than in the drug."

Nevertheless, if a difference in toxicity between agents does exist, it is important that we know and benefit by it. Toxicity of an agent

*Read before the Boston Society of Anesthetists February, 26 1935

†Saklad, Meyer—Anesthetist, Rhode Island Hospital. For record and address of author see This Week's Issue page 1255

employed in spinal anesthesia may manifest itself by absorption from the subarachnoid space with action on the body as a whole or secondly by its action on the structures with which it comes in direct contact.

First, its action on the body as a whole. A rather complete study of all available English literature on the subject failed to produce an investigation on the relative action of the several agents employed in spinal anesthesia determined through this method.

Marvin²⁷, in considering the present status of various spinal anesthetics, quotes the work of Nowak in determining the comparative fatal intravenous dose of the various anesthetics on cats. Nowak²⁸, in a recent communication states his conclusions are in this regard unchanged.

Another investigation of the comparative fatal intravenous dose of the various agents is that of Wiedhopf¹⁸. This work was done on rabbits.

Their work is summarized in table 1. In the

TABLE 1
COMPARATIVE FATAL INTRAVENOUS DOSE

	Avg Fatal Dose Mgm/kgm	Ratio (Com pared to Pro- caine)	Dose Ratio	Cor- rected Tox icity Ratio (Com- pared to Pro- caine)
Cats (Nowak)				
Procaine	49.6	1.0	1.0	1.0
Metycaine	28.8	1.7	0.8	1.36
Pantocain	8.6	5.8	0.1	0.68
Nupercaine	3.5	14.2	0.05	0.71
Rabbits (Wiedhopf)				
Procaine	57.5	1.0	1.0	1.0
Pantocain	8.0	7.18	0.1	0.71
Nupercaine	3.0	19.16	0.05	0.958

first column we see the average dose in milligrams per kilogram necessary to kill the animal. In the second column we note the toxic ratio of the various agents compared with procaine. Thus, giving procaine unity we find, in Nowak's work, that metycaine is 1.7 times as toxic as procaine, pantocain 5.8 and nupercaine 14.2 as toxic. In Wiedhopf's work metycaine was not considered. Here we find pantocain 7.18 times and nupercaine 19.16 times as toxic as procaine.

These studies up to this point show the relative absolute toxicities of the drugs. To stop here would be unfair to the different agents and would not be truthful. To approach the truth a bit closer it would be necessary to consider another factor—that of relative dosage

Marvin²⁷ gives us the relative dosage of the agents. Table 2. To his list of relative dosage

TABLE 2
RELATIVE DOSAGE
(Marvin)

	Mgm	Ratio
Procaine	200	1.0
Metycaine	160	0.8
Pantocain	20	0.1
Nupercaine	10	0.05

I have added the dose ratio. Giving procaine unity we find that metycaine is effective in 0.8 the dose, pantocain 0.1 and nupercaine 0.05 the dose of procaine. Transposing this dose ratio to table 1 and correcting the ratio of absolute toxicity we arrive at a corrected toxicity ratio. Here we find in Nowak's work that metycaine is 1.36 times as toxic as procaine, pantocain 0.58 and nupercaine 0.71 times as toxic as procaine. In Wiedhopf's work we see that pantocain is 0.71 and nupercaine 0.958 times as toxic as procaine. Here I wish to stress a very important factor. The work here quoted was not done on human beings. It is true that animal investigation is very helpful but we must not lose sight of the fact that animals are prone to react to drugs differently than is the human being.

Another reason why we should not accept this corrected ratio at its face value is the fact that the final ratio arrived at is dependent to a large extent on the dose ratio of the various agents. There exist in the minds of many anesthetists marked disagreements as to the relative dosage of the various drugs. Were we to accept the finding of Israels and MacDonald¹⁰ that in intraspinal injection in the cat nupercaine is as effective as procaine in 1/40 of the dose instead of Marvin's feeling that it is as effective as procaine in 1/20 the dose, we can see the difference it would make in the corrected toxicity. As far as I have been able to determine no one has subjected a human being to the tests necessary to determine the relative dosage of the agents considered in preventing the passage of impulse in an exposed motor or sensory nerve.

In considering the toxicity of the agents we should not depend entirely on laboratory findings. The clinical aspect is equally important. Lund²², in speaking of the advantages and disadvantages of the various anesthetic agents, divides them into two groups from the standpoint of immediate results:

1. Those in which there is little if any margin of safety between failure of the respiration and failure of the heart.

2. Those in which there is a wide margin of safety between failure of respiration and failure of the heart.

METHODS

The methods employed in spinal anesthesia are essentially attempts to place an anesthetic fluid subdurally about nerve roots. A knowledge of the anatomical relationship between the lower spinal vertebrae and segments of the cord is necessary.

A solution deposited at one point subdurally may be transferred in part to another location about the cord by one or usually by a combination of the following factors:

1 *Diffusion* Diffusion may be controlled by—

a *Dosage* A drug in solution placed intraspinally will very soon begin to lose its original concentration, becoming diluted with the medium in which it finds itself. This increasing dilution will occur in all directions. Any nerves exposed become affected in proportion to the concentration of the drug surrounding it. Nerves at a distant point may not receive a solution sufficiently strong to alter their action. Thus, the greater the original concentration the more widely will the action of the drug be effective. This factor may be spoken of as molecular diffusion.

b *Volume* Of two volumes of an anesthetic solution of like strength, the larger will occupy a greater area within the subarachnoid space and the smaller a less. In each case they involve an area in proportion to the amount of fluid injected. Whether we begin the injection with 2 cc of a solution and by barbotage increase it to eight or whether our original dose is immediately dissolved in eight cc and injected with no barbotage, it is an attempt to deliver the drug to a site within the subarachnoid space distant to the point of needle entrance, by diffusion. The difference is slight but it is there. Employing barbotage, we are continually injecting solutions of diminishing concentration whereas, in the absence of barbotage we are injecting a solution of definite characteristics the nature of which we know beforehand. Because of the difference in the characteristics of the solutions, varying results may be expected.

2 *Site of Injection* As readily seen by varying the level at which the anesthetic solution enters the dural canal one can approach a point closer or more distant to the nerve roots to be blocked.

3 *Speed of Injection* Likewise readily seen is the fact that a solution forcibly injected would reach a point farther from the site of needle entrance than had the solution been gently introduced.

4 *Specific Gravity* Considerable has been said relative to the importance that specific gravity plays in determining the height of anesthesia. Table 6 is a list of the different specific

TABLE 6

SPECIFIC GRAVITY OF SPINAL FLUID

Hoppe	1001 1005
Halliburton	1007 1008

Williamson	1006-1009
Hammerstein	1007 1008
Eskuchen	1006-1007
Levinson	1003-1007

gravities of spinal fluid as determined by various workers. This is a table from an article by Jones.¹ It is very important to note the wide variation that occurs, from 1.001 to 1.010. Others give the specific gravity of spinal fluid as from 1.0012 to 1.0060²⁵ and from 1.006 to 1.008¹⁶.

TABLE 7

SPECIFIC GRAVITY OF AGENTS USED IN SPINAL ANESTHESIA

	Specific Gravity
<i>Procaine</i>	
1 10 in spinal fluid	1.005
1 30 (200 mgm in 4 cc.)	1.013
1 40 (200 mgm in 8 cc.)	1.008
<i>Metocaine</i>	
1 20	1.020
1 10	1.036
<i>Pantocaine</i>	
1 100 in saline	1.0068
1 400 in saline	1.002
<i>Nupercaine</i>	
1 200 0.5% saline	1.0046
1 1500 0.5% saline	1.0030
1 1500 0.9% saline	1.0061
1 1500 in water	1.00005
10% Procaine in 1 200 Nupercaine	1.018

Table 7 lists the specific gravities of the various anesthetic solutions. The items in this table were taken from various sources.^{1, 12, 21, 30, 35, 42, 45} To use the terms employed by Jones to represent solutions with a specific gravity heavier than, the same as, or lighter than spinal fluid hyperbaric, isobaric or hypobaric—and, considering the extremes in specific gravity which spinal fluid might have, we find that the same agent in the same dilution may at different times assume any of the above relationships to spinal fluid.

Thus pantocaine, 1 per cent in saline with a specific gravity of 1.0068 may be hyperbaric to a spinal fluid of less specific gravity, isobaric to a fluid of like specific gravity and hypobaric to one of greater gravity. Solutions to be always considered hyperbaric

would have to have a specific gravity greater than 1.010. In this classification fall most of the procaine or metycaine solutions. Solutions to be consistently hypobaric would have to have a specific gravity of less than 1.001. Under this heading would be the 1.1500 solution of nupercaine in water.

Romberger³⁰ employs a small bulk concentrated solution of high specific gravity. He feels that a greater degree of control is thus obtained. It is his feeling that the rate of diffusion is fixed and certain and that gravitation can be regulated by the level or plane of the spine. Jones¹² attempts to create within the dura a long or short column of anesthetic fluid depending on the height of anesthesia desired. To this end he employs a 1.1500 solution of nupercaine with a specific gravity of 1.003. This "hypobaric" solution if introduced into a spinal canal the fluid of which has a specific gravity of 1.001 becomes actually a hyperbaric solution. Under this condition, employing Trendelenburg position, an anesthesia higher than that expected will occur.

It is difficult for many to believe that a small difference in specific gravity between the agent and spinal fluid is important, especially since the agent and spinal fluid are so readily soluble in one another.

The higher area of sensory anesthesia over motor which occurs under spinal anesthesia we have been led to believe is a result of the greater selective affinity of sensory over motor nerves for local anesthetics, particularly in weak solutions. Jones¹² offers an added explanation for the phenomenon. He reasons that to depend on gravity to give proper anesthesia and muscular relaxation, employing a hyperbaric solution, results in higher sensory anesthesia than motor since the posterior roots are bathed over a larger area than are the anterior (Figure 1A).

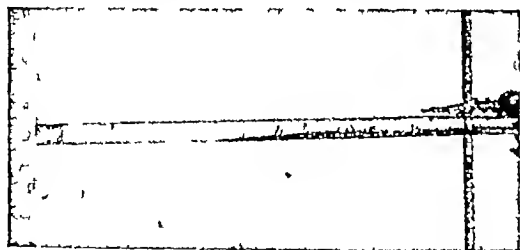

FIG 1A. Dye represents a solution of greater specific gravity than spinal fluid.

In employing a hypobaric solution the opposite occurs—a higher motor than sensory anesthesia. This is the result of a more widespread anterior root action (Fig 1B). Thus in using solutions of lower specific gravity than spinal fluid paralysis of intercostal nerves may be more marked than with the other type of solution.

5 Position of Patient Changing the tilt of the table as employed in the various techniques of spinal anesthesia, is for one or both of the following reasons

a To place the anesthetic solution about some desired segments of the cord

b To prevent or treat certain dangerous complications which may arise as the result of the fall in blood pressure accompanying the anesthesia.

Most workers using agents with a specific gravity higher than that of spinal fluid employ the Trendelenburg position at some point in their technique to increase the height of anesthesia. Those dealing with a solution of lighter

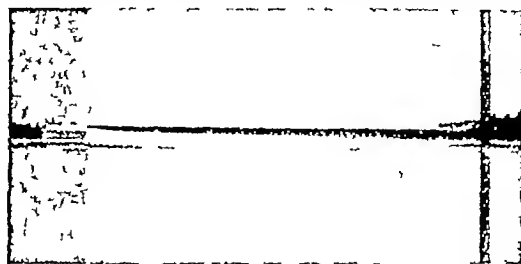

FIG 1B. Dye represents a solution of lower specific gravity than spinal fluid.

specific gravity place their patients in the same position to keep the solution low down in the canal. Occasionally, workers with a heavy solution will raise the head of the table to maintain the agent in the most dependent portion of the dural space. Thus Romberger³⁰ administering a concentrated procaine-nupercaine mixture uses Fowler's position to control height. He employs the Trendelenburg position later on as needed, but he warns that there is danger in the too early use of the head down position since nupercaine fixes slowly and in combination with procaine is heavier than spinal fluid. McCuskey also delays, for a period of fifteen to twenty minutes, assumption of the Trendelenburg position after the introduction of a pantocain-procaine combination, for the same reason as does Romberger. Rovenstine³⁸ in dealing with a procaine-dextrose solution, particularly in transurethral prostatic resections, recommends that the head and shoulders be elevated to maintain a low anesthesia. Etherington-Wilson⁴⁶ employs the sitting position for varying intervals following injection of a 1.1500 solution of nupercaine, allowing for rise of the agent in the canal.

Jones¹² feels that application of the Trendelenburg position to give height of anesthesia results not in moving a dose in high concentration to the most dependent part but to advance an ever-decreasing concentration over a distance which will be proportional to the amount of drug injected. Woodbridge⁴⁷ administering metycaine employs Trendelenburg in preference to barbotage to give height of anesthesia.

CoTui⁴⁸ in spinal anesthesia on dogs showed that in the head down position it takes less than one-half the dose to kill an animal than in the horizontal position. In the head up position it takes even more to kill the animal. The

above experiments were with procaine dissolved in 3 cc. of distilled water and injected in the first lumbar interspace. In the horizontal position it takes over 850 milligrams of procaine to cause death by respiratory paralysis in an average time of thirty minutes. In the head up position it takes from 900 to 1000 milligrams to result in death in an average time of fifty minutes. In the head down position 400 milligrams was followed by death in an average time of seventeen minutes. He concludes that the Trendelenburg position is not only useless but harmful. It must be remembered that CoTui was not dealing with therapeutic doses. The concentrations were tremendous and the specific gravity must of necessity have been extremely high.

Labat's theory behind the use of the Trendelenburg position to prevent certain dangerous complications incidental to the fall in blood pressure accompanying the anesthesia was to prevent cerebral anemia. His feeling was that with the tremendous vasodepression that occurs the one structure to suffer most was the brain. A fall in blood pressure, if severe would allow the cerebral blood vessels to collapse, since they have weak walls unsupported by musculature. A collapse of these walls would be followed by cerebral anemia. To prevent this collapse he felt that to maintain these channels patent would be to forestall any such disastrous occurrence and the best way to maintain patency most dependably was to take advantage of the increased blood flow to the brain that the Trendelenburg position would give. CoTui, in reaching his conclusion that the Trendelenburg position was both useless and harmful performed no experiments to learn if there was any basis of fact in Labat's theory.

Sise⁴¹ feels that in this position the blood gravitates toward the vital nerve centers and hydrostatic action tends to maintain a higher pressure in them than is present in other parts of the body. He⁴⁰ agrees with many others that operations should always be done in this position as far as possible except when using a heavy solution. He⁴¹ states as to the disadvantages of this position that if there are large masses of abdominal fat, the movements of the diaphragm may be impeded and respiration hampered. Woodbridge⁴² institutes this procedure in the presence of a falling pressure. Stout⁴² employs it as demanded to prevent cerebral anemia.

Tables 3, 4 and 5 represent summation of techniques by several workers with different agents. In the procaine series, table 3, we see that Labat employs 150 milligrams as a maximum dose, uses no epinephrine, varies the volume of the injected fluid but slightly, employs Trendelenburg position immediately, and varies the site of puncture. Evans using 120 milligrams as maximum, also employs no epinephrine,

substituting adrenalin, and applies the Trendelenburg position, if vasomotor collapse occurs or if the anesthesia is too high. He varies the volume injected much more than does Labat and keeps his punctures lower. Stout introduces more procaine into the spinal canal, administers epinephrine in varying doses, depending on the height of anesthesia, keeps the injected volume low, institutes Trendelenburg position if necessary and utilizes the same interspace for all levels of surgery. He modifies the duration of the injection depending on the level of anesthesia desired. Vohrs employs greater doses than any of the others here, administers no epinephrine, varies the dilution slightly, employs varying degrees of the Trendelenburg position and sites of puncture depending on height of anesthesia desired. Roventine's technique for transurethral surgery consists of moderate dosage plus dextrose solution, no epinephrine, reverse Trendelenburg position and low puncture.

Thus Labat depends on varying levels of puncture changes in dosage and the Trendelenburg position for height of anesthesia. Evans, on varying dosage, volume and site of puncture. Stout on varying dosage and speed of injection, Vohrs, on varying dosage, volume and site of puncture.

In the nupercaine series, Table 4, we see that Keyes, using the 1:200 solution, employs an unvarying dose, site of puncture and position but varies the volume injected. His dosage is full for he⁴³ states that the maximum therapeutic dose may not be far from 2 cc. of a 1:200 solution. On occasion he recommends 50 milligram doses of epinephrine. Jones, administering the 1:1500 solution varies dosage, volume and site of injection as does Ehrlich. Wilson varies dosage and volume but not the site of injection. He injects his patients in the sitting position and varies the duration of this posture. Romberger blocks all cases for abdominal surgery to the nipple line with this nupercaine procaine mixture, varying dosage, volume slightly, position of patient and site of puncture. Recently he has increased his nupercaine dosage slightly.⁴⁴

Table 5 Woodbridge with meteyaine, varies dose, volume and position of the patient. Meeker and McCreary⁴⁵ with this drug use 100 milligrams for lower and mild abdominal operations. They give no dosage for upper abdominal operations, utilize barbotage but do not state total dilution.

McCuskey with 1 per cent pantocain in saline, varies dosage, volume and site of puncture. He gives as dosage for pantocain⁴⁶ 1 milligram for each ten pounds of body weight plus 5 milligrams. The technique consists of diluting the 1 per cent solution with an equal quantity of spinal fluid so that the concentration as it enters the dural canal is 0.5 per cent. Since this

does not make much volume he advises higher punctures than when using procaine

INDICATIONS

In considering the indications of a method one of the best arguments against its use is unfamiliarity with either the agent or with the technique involved. When faced with choosing between two methods or agents the anesthetist is and should often be guided by this and administer the agent or procedure in which he has the greater confidence. An expertly administered ether anesthesia in the presence of a pulmonary condition may often be less disastrous than a spinal anesthesia poorly administered.

Operative Site

To list a column of indications for this method is not particularly satisfactory since so many factors enter into play. One can but generalize.

1 Operations on the lower extremity often indicate this method. Operations on the lower leg may be done under regional anesthesia, if the anesthetist is skilled in this latter method.

2 Operations on the perineum, rectum and external genitalia may be safely performed under either spinal or sacral anesthesia, depending again on the anesthetist.

3 All intra-abdominal surgery may also indicate the procedure.

4 Operations on the head, neck and thorax. Spinal anesthesia was suggested as possible for surgery in these areas by Koster and Kasman¹⁷. Their feeling was based on experiments carried out by them where neocaine was applied to the cervical cord and medulla of animals resulting in general anesthesia with no interference with respiration. CoTur⁵, however, was able to demonstrate that respiratory stoppage due to paralysis of the respiratory center does occur when procaine is introduced into the subarachnoid space in sufficient dosage. It is generally conceded that attempts to produce as high an anesthesia as is necessary for surgery of the thorax and higher are dangerous.

Condition of Patient

Lundy²⁵ feels that spinal anesthesia is contraindicated in all debilitated patients. Yet it does seem as though poor risk patients for perineal or lower extremity surgery do better than they would under other types of anesthesia.

Patients with advanced cardiac or vascular disease do not seem to do well, nor do patients with extremes in blood pressure. Where there exists a low functioning kidney condition and relaxation is necessary, spinal anesthesia often saves the added strain on this organ that might occur as result of ether anesthesia. Spinal anesthesia in place of ether in diabetics is very satisfactory.

The stout strong patient is often a better subject under spinal anesthesia than he would be under an inhalation method. The extremely apprehensive patient, unless heavily medicated, is usually a poor subject. CoTur² in animal experiments showed that, "pathologic states as dog pneumonia, postoperative infections and low blood pressure states produce a marked reduction in the lethal dose." He pointed out the possibility that anoxemia might be a responsible factor in reduction of the lethal dose.

Because of the relaxation produced by the method one is tempted to employ it under certain conditions. In intestinal obstruction spinal anesthesia is a great aid to the surgeon allowing better exposure and closure. In advanced intestinal obstruction where the operative field is to be limited as for ileostomy a simple field block would be the better choice of anesthesia. The surgeon must be familiar with the increased intestinal activity produced by spinal anesthesia and allow for intestinal drainage, where possible. Some workers feel that mechanical obstruction is a contraindication. Upper abdominal surgery, particularly in the healthy adult, is facilitated by this method. Because of the hyperperistalsis occasioned by spinal anesthesia it has been recommended in the treatment of paralytic ileus. Here splanchnic anesthesia, administered by the posterior route described by Kappis, is to be preferred³⁴.

Patients suffering from shock or hemorrhage do not usually fare well under this procedure.

Indications for the Drug

Procaine should be the drug most often used under all ordinary conditions. The forthcoming article on metycaine by Woodbridge may result in replacing procaine, because of its slightly longer action.

When it is necessary to employ an agent to give a more lasting anesthesia than either of the above it is necessary to turn to either pantocain or nupercaine. It must be remembered that because of the greater action of pantocain on the respiratory mechanism its dose should be kept down as low as possible and that its use should be restricted to those cases where a safe dose of procaine will not produce anesthesia of sufficient duration³⁰. Essex and Lundy feel that pantocain in a selected group of cases is the anesthetic of choice for long operations in the lower abdomen.

Nupercaine causes a lengthened period of induction of anesthesia. The addition of procaine, by method of Romberger, would shorten this. Nupercaine is claimed by some to have a greater tendency to cause postoperative headache than are the other agents.

In patients in whom it is desired to disturb the blood pressure as little as possible either pantocain or nupercaine may be indicated.

SUMMARY

A review of the agents and methods of and indications for spinal anesthesia is offered with an effort to contrast their several characteristics and an attempt to present the various views on some disputed aspects.

A COMPARISON OF POSTOPERATIVE COMPLICATIONS FOLLOWING GENERAL AND SPINAL ANESTHESIA

BY DORIS RAPOPORT, M.D.*

IN spite of recent advances in anesthesia postoperative pulmonary complications are attributable to the anesthetic agent still form a perplexing problem. For a time it was believed that spinal anesthesia would solve this troublesome condition because "ether pneumonia," inhalation pneumonia and pulmonary atelectasis due to mucus plugs in any part of the bronchial tree were entirely associated with the administration of general anesthesia. Experience however has compelled us to change our views in this matter. We have learned that there are many other factors besides the anes-

thesia, which are conducive to postoperative complications. Statistics have proved beyond doubt that spinal and local anesthesia do not render the patient immune against such complications.

King¹ reported a series of cases from the surgical service of the Massachusetts General Hospital and came to the conclusion that statistically the type of anesthesia bore no relation to the development of complications. McKittrick, McClure, and Sweet², who published a review at some previous date from the same hospital, of postoperative pulmonary complications following spinal anesthesia as compared with general, proved that the percentage of complications increased with spinal anesthesia. On

*Rapoport, Doris—Anesthetist, Beth Israel Hospital, Boston. For record and address of author see "This Week's Issue," page 1235.

the other hand, Brunn and Brill³ reported a number of cases where the pulmonary complications after operation were three and a half per cent larger under general anesthesia than under spinal. Judging from these varied reports it would seem that no two clinics agree as to percentage of complications under various anesthetics.

The practice of spinal anesthesia since its inception about thirty-five years ago has been marked by cycles of undue enthusiasm mixed with periods of criticism and censure. It is a well-known fact, however, that a well-developed method and a familiar drug in the hands of

neither condition should rule out this valuable method of anesthesia, since in numerous cases spinal anesthesia has been administered by me to patients with systolic pressures as low as 80 and as high as 250 without any bad effects.

As a rule, given a perfectly well patient having to undergo an operation of moderate severity, spinal anesthesia will cause very few complications. It is only in the sick patient or the severe operation that spinal anesthesia contributes its share of complications. But that share is much smaller than under general anesthesia, as will be shown in the following tables.

COMPLICATIONS FOLLOWING GENERAL ANESTHESIA

	No of Cases	Complications		(Pulmonary Comp)		Deaths

a few cannot always prove successful in the hands of the many. We must also take into consideration that the reported statistics do not take into account the condition of the patients before operation and the number of cases which had to be supplemented with a general anesthetic. A certain small percentage of deaths from anesthesia is unavoidable. It cannot be denied, however, that spinal anesthesia has in most cases been beneficial to all concerned: surgeon, anesthetist and patient. Also that many difficulties in patients with pulmonary conditions, nephritis, diabetes, and in some cases even cardiac diseases were easily solved by the administration of spinal anesthesia.

There is practically no contraindication to spinal anesthesia. More than half of all operations below the diaphragm can be performed with as low as 50 to 100 mgm of novocain, which is considered a safe dose. Formerly it was believed that patients with a low blood pressure should not be operated upon under spinal anesthesia. Now the tendency is to consider hypertension as a contraindication. It seems, however, from actual experience that

These tables comprise the records of five types of major operations performed at the Beth Israel Hospital, Boston during the years 1931 and 1932. The operations selected are the following: appendectomies, hysterectomies, herniorrhaphies, cholecystectomies and kidney operations. In the latter group the year 1933 was also included. These operations were chosen as both types of anesthesia were in nearly equal numbers represented in the total series. Patients under fifteen years of age were excluded, since spinal anesthesia was not administered to children. A total of 625 cases were studied consecutively: 238 males and 387 females, general anesthesia 295, spinal 330.

By comparing the two tables it can readily be seen that patients operated upon under spinal anesthesia fared much better than those under general. While the complications under general anesthesia were 11.5 per cent (pulmonary 7.4 per cent), those of spinal anesthesia comprised only 6.6 per cent (pulmonary 5.7 per cent). The percentage of deaths under general was 3.4 per cent, while under spinal it was 3 per cent. At the same time we must also take

into consideration the fact that, while the percentage of medical ailments before operation in patients operated under general anesthesia was only 7 per cent, those done under spinal amounted to 25.5 per cent.

There is no dispute, even among those opposed to spinal anesthesia, that for relaxation and absence of aftereffects there is no equal to it. Genito-urinary and orthopedic operations lend themselves more conveniently to spinal than does abdominal surgery. Lower abdominal surgical procedures are much more successfully accomplished than upper abdominal. The chances of successful anesthesia in surgery of the chest, neck and head, is greatly reduced in spite of the number of cases reported, while the element of danger is markedly increased. It is therefore wise to limit spinal anesthesia to operations below the diaphragm.

The only drawbacks of spinal anesthesia are the limited time to which the surgeon is confined for the completion of the operation and the nausea and vomiting which frequently hamper its progress. Both of these difficulties, however, can be materially aided by appropriate preliminary medication. Sodium amytal and nembutal in balanced doses have a tendency to suppress the vomiting reflex and to diminish the patient's sensitivity to pain. These drugs, which are given by mouth about an hour and a half before operation, may be augmented by morphin hypodermically half an hour before. The employment of a solution of pantocain has in many cases given a much longer and deeper anesthesia than the crystals. It seems, however, that it is slightly more dangerous than the latter, since it has a greater tendency to paralyze the muscles of respiration.

The question of supplementary anesthesia after the spinal anesthesia wears off has been troublesome. Where no relaxation is required gas-oxygen serves as a good adjunct. In abdominal operations, however, no relaxation can be obtained from the addition of gas-oxygen and the greatest difficulty is met with during the closure of the peritoneum. In these cases injection of novocain into the abdominal muscles at the sides of the wound by the surgeon facilitates greatly the suturing of the abdominal wall. This can also be augmented by slow drop ether on an open mask, sufficient to daze the patient, but not pushing the ether to the point of complete relaxation.

We must not, however, overlook the fact that sudden fatalities, chiefly soon after the injection of the anesthetic solution, do occur. Some of these seem to be caused by respiratory paralysis and others may be due to cardiac failure. The theory of toxic absorption of novocain described by Nowak in his experiments, seems reasonable only in cases where after fifteen or twenty minutes a severe reaction sets in, mani-

fested by a marked drop in blood pressure, slowing of pulse, nausea, vomiting, restlessness, and profuse perspiration with pallor. This, however, does not explain the immediate reactions manifested by respiratory or cardiac embarrassment, which must be due either to direct action of the drug on the respiratory centre or to the innervation of the heart.

Since my last report (in June, 1931*) of 1875 operations performed at the Beth Israel Hospital under spinal anesthesia we have added 1402 more operations under the same anesthetic. In this last series we had two deaths in which the spinal anesthesia was to all appearances the sole causative factor.

CASE 1 A fifty-six year old female patient with myocarditis, slightly enlarged heart and blood pressure of 180/100 was to undergo an operation on the knee joint. The injection was done in the third lumbar interspace with the patient in the sitting position using an ephedrin novocain solution as a local anesthetic. One hundred and twenty-five mg. of novocain crystals were employed for the spinal anesthesia. The patient was put on her back in slight Trendelenburg position. About two minutes after the injection of the solution the patient began to complain of a "weakness of the heart." She soon became pulseless but still kept on breathing slowly for about one minute and died. Heart stimulants and artificial respiration were of no avail.

CASE 2 A male patient, aged sixty-seven. Physical examination revealed hypertension with weak heart sounds, rales at the left base with a question of old tuberculoz and a slight trace of albumin with casts in the urine. He was to undergo a second stage prostatectomy, the first stage having been done under spinal anesthesia about ten days previously. The injection was done in the fourth lumbar interspace with the patient in the sitting position. As in the first stage 75 mg. of novocain crystals were used. The patient began to complain of difficulty in breathing soon after he was placed on his back. The anesthesia did not extend above the umbilicus. His blood pressure remained practically the same 165/90 and his pulse rose from 84 to 108. There was no cyanosis. In view of the patient's good general condition it was decided to go on with the operation which lasted about fifteen minutes. Soon after the operation the patient became cold and clammy and his finger tips were cyanosed. His pulse and blood pressure did not as yet undergo any material change. He was put to bed and given 500 cc. of ten per cent glucose in saline intravenously. His respiration became more embarrassed, cyanosis increased and his pulse began to show slight weakness and irregularity. The blood pressure dropped to 115/75. Stimulants were administered and for a while he rallied. However he soon became more cyanosed, gasping respiration developed and he lapsed into unconsciousness and died. Death occurred about one and one-half hours after the spinal anesthesia was induced.

In the first case it was apparent that the cardiac factor was the more pronounced in the fatal termination, while in the second case respiratory embarrassment was more manifest as a cause of death. Since these two catastrophes the sitting position for the administration of spinal anesthesia has been abandoned and in the last 750 cases we have had no fatality.

So far the ideal drug, which should give a lasting and safe spinal anesthesia, has not been discovered. But, with proper technique, careful selection of the patient, gradation of the dose of the least dangerous drug, and the right care during and after operation, the mortality from this procedure should be reduced to a minimum and the complications brought down much below those of general anesthesia.

SUMMARY

- 1 The postoperative complications following spinal anesthesia are greatly exaggerated, when compared with those of general anesthesia
- 2 In certain cases, where a general anesthetic would present some difficulties or danger, spinal anesthesia offers the best solution
- 3 Effective preliminary medication suppresses

vomiting and allays the patient's apprehension. It also aids in prolonging the anesthesia.

- 4 Should the anesthesia wear off before the operation is completed, then gas-oxygen serves as a good supplement in cases where no relaxation is required. In abdominal operations, the injection of novocain into the muscles at the sides of the wound facilitates the closure of the peritoneum.

MEDICAL PROGRESS

PROGRESS IN NEUROLOGY IN 1934

BY JULIUS LOMAN, M.D.*

ONE of the most important contributions to the neurological literature of 1934 is Brodie and Elvidge's¹ experimental work on poliomyelitis establishing the portal of entry and neurogenic distribution of the virus. Petersen's² studies on the effect of weather in nervous and mental diseases are intriguing and may open a new field for interpreting many of the symptoms of such diseases as migraine, multiple sclerosis, and tabes. Interesting physiological studies on epilepsy, migraine, and studies on the chemistry and treatment of the muscular dystrophies continue. The results of the intensive investigations on the 1933 St. Louis epidemic of encephalitis with important data of etiology, epidemiology, and pathology are reported. In addition, the neurological literature of 1934 contains many interesting descriptions of clinical conditions and a few new therapeutic procedures.

EPILEPSY

Experimental Studies

Gibbs, Lennox and Gibbs³ have investigated the possible etiological rôle of vascular spasm with consequent cerebral anemia in epilepsy. By means of a thermoelectric blood flow recorder, inserted through a hollow needle into the internal jugular vein of epileptic patients, the cerebral blood flow could be observed before and during seizures. In none of the ten patients studied was there a significant reduction in blood flow immediately preceding the attacks. During several convulsions the blood flow in-

creased markedly. It was concluded that this change is the result of, rather than a cause of, the seizures. These experiments strongly indicate that vascular spasm is not the important precipitating factor in cases of epilepsy.

Experiments by Finesinger and Cobb⁴ tend to corroborate the above authors' results. Using the skull window technique of Forbes and measuring the diameter of the pial vessels following the administration of convulsants, Finesinger and Cobb observed in cats that large intravenous injections of caffeine caused marked convulsions which were preceded by vasoconstriction, a fall in systemic blood pressure and a decrease in cerebrospinal fluid pressure. Similar changes were noted following intravenous injections of absinth and homocamphor. On the other hand, monobromated camphor convulsions were preceded by dilatation of the pial vessels. The authors conclude that since fits caused by drugs are produced in the presence of either vasoconstriction or vasodilatation, the state of the blood vessels is not the essential factor. The authors believe that the drugs probably cause the convulsions by direct action on the nerve cells in some way as yet unknown.

In studies on mineral metabolism in young epileptics, Engel, McQuarrie and Ziegler⁵ point out the dependence of epileptic attacks on water and mineral metabolism. To illustrate this dependence, two interesting cases are cited. In the first case, a child who was given pituitrin to create a positive water balance, the amount of urine excreted became diminished and in the pituitrin-free periods, the amount of urine excreted became greater than that of the fluid taken in. Furthermore, under the influence of

*Loman Julius—Research Associate in Psychiatry Boston State Hospital. For record and address of author see "This Week's Issue" page 1255.

pituitrin, the amount of chlorides excreted was considerably greater than the amount taken in. Sodium followed a similar but less striking course. Potassium, too, was increased in the urine under the influence of pituitrin. Usually calcium and magnesium were uninfluenced. Such disturbances in water and salt balance following pituitrin injections occur both in normal and in epileptic patients, but only in the latter are attacks produced. The above authors also showed that when the mineral loss is balanced by the addition of sodium chloride a much greater retention of water with much more pituitrin is required to bring on an attack. On the other hand if the diet is restricted as to sodium chloride, the pituitrin experiment acts much more quickly in producing an attack. In the other case, the diet was kept as low as possible in sodium chloride and potassium. After three days no more attacks occurred. Then when sodium chloride was added in large amounts, the body weight rose and one severe attack occurred on the same day. Here the retention of salt water precipitated the attacks. In the first case cited the great loss of minerals with the simultaneous retention of water precipitated the attacks.

Since it has been demonstrated that retention of fluid in the body tends to induce seizures, Jacobsen⁴ has used the following test to confirm or exclude the diagnosis of epilepsy. To produce a positive water balance Jacobsen gives 300 cc of water every two hours and an injection of pitressin (containing the antidiuretic principle of pituitrin without smooth muscle stimulating principle) every four hours—0.2, 0.3, 0.4 cc and thereafter 0.5 cc until a seizure occurs or until eight to ten doses have been given. Jacobsen has found the test reliable in a series of forty cases. If the condition is epilepsy, a typical seizure will occur when sufficient fluid has been retained to raise the body weight by three to six per cent.

MIGRAINE

Physiological Studies

In his studies on the "patient and the weather", Petersen⁵ associates migraine (and headache in general) with a sudden alkalosis (increased pH) with a reduction of CO₂ content of the blood) with vascular spasm, and in some cases with a "potassium leakage of the blood". He points out that the migraine equivalent is also associated with similar chemical and spastic states. Petersen also found that the onset of the attacks is meteorologically conditioned occurring in most instances with great regularity, with polar infalls (inflow of cold polar air which occurs in frequent intervals in the region of the American storm tracks). In some instances, the headache occurs with a barometric down turn from a high stable barometric pressure or sometimes at the first up-turn of the barometric pressure from a barometric low.

Relationship between Migraine, Epilepsy and Some Other Neuropsychiatric Disorders

Paskind⁶ points out very strongly, after a review of the literature, that the studies of those who have stressed an epilepsy migraine relationship are largely vitiated by the lack of controls. This author compared the incidence of migraine among patients with epilepsy, among patients without neuropsychiatric disorders and those with manic-depressive psychosis, trigeminal neuralgia, psychasthenia, dementia praecox, constitutional inferiority and paranoid states. The records of 3,326 patients were studied. The findings were as follows. In the group with non-neurologic disorders migraine was found in the family in 14.4 per cent of cases, in the parent in 10.2 per cent and in the patient in 3.3 per cent. In the group of epileptic patients, the percentage of migraine was much higher being found in the family in 35.2 per cent, in the parent in 30.8 per cent, and in the patient in 8.4 per cent. There was however, even a greater association between migraine and trigeminal neuralgia being found in 37.7 per cent, 30.1 per cent and 20.3 per cent in the family, parent, and patient respectively. Again, there was a greater incidence of parental migraine in tic and in constitutional inferiority than in epilepsy. Thus, it is concluded that there is no special relationship between migraine and epilepsy; that migraine occurs as evidence of a familial neuropathic trend in other neurologic conditions.

Treatment of Migraine

Lennox⁷ studied the effect of ergotamine tartrate (gynergen) on thirty-nine men and six women. In forty of the cases abrupt termination of the headache occurred, in three there was no relief, and in two an apparent shortening of the attack occurred. In most instances, before the headache began to be lessened nausea and vomiting or both occurred. When the drug was given intravenously relief occurred in fifteen to thirty minutes, when given subcutaneously in one to two hours and when given orally in one to three hours. Relief of severe headaches was rare when the drug was given orally. The mechanism by which ergotamine relieves migraine is unknown. Many authors accept the theory of vascular spasm and assume that the drug paralyzes the motor sympathetic fibers, thereby relieving the spasm and pain.

The experiments of Lennox, Gibbs and Gibbs⁸ throw light on the above theory. By means of a thermo-electric blood flow recorder inserted into the internal jugular vein injections of ergotamine tartrate in unanesthetized patients were observed to cause a moderate increase in cerebral blood flow which is readily explained by the concomitant increase in systemic blood pressure. Since ergotamine which relieves headache increases blood flow only moderately,

strate the advisability of slow removal and careful pressure for pressure replacement of air in encephalography and ventriculography

ENCEPHALITIS

Etiology, Epidemiology and Pathology

Further studies on the St. Louis epidemic of encephalitis were reported in 1934. Muckenfuss, Armstrong and Webster²⁰ were able to isolate a number of strains of a virus that seem to be the etiological agent of the 1933 epidemic. The virus acted on monkeys and white mice and appeared to be distinct from other previously known viruses. It was found that the number of strains of similar characteristics isolated and the neutralization of the virus by serum of individuals already recovered from the encephalitis in this epidemic but not by the serum of patients recovered from other diseases, justified the conclusion that it is the etiological agent of the recent epidemic.

Webster and Fite²¹, as a result of bacteriological studies, conclude that the active agent of epidemic encephalitis is a specific virus. Gay and Holden²² present evidence tending to incriminate a neurotrophic strain of the virus of herpes simplex as the causative agent of epidemic encephalitis. They were able to isolate the herpes virus from five cases of encephalitis.

Leake, Musson and Chope²³, studying the epidemiology of the 1933 St. Louis encephalitis epidemic, point out that individual susceptibility, in which age plays a part, appears to be more important than contagion. There were few multiple cases in the same family. Water, milk and the mosquito were eliminated as the means of transmission.

Pathologically, according to McCordock, Collier and Gray²⁴, the only constant macroscopic alteration in the central nervous system of twenty-eight cases was vascular congestion of varying degrees. Microscopically, intense congestion of the vessels down to the finest capillaries was present. Small arachnoid hemorrhages and occasionally extravasation of blood into the perivascular spaces and into the substance of the brain, or petechial hemorrhage in the brain tissue were found. Both perivascular, diffuse, or focal collections of various types of inflammatory cells were found. Various degrees of pathology were seen in the nerve cells.

Treatment of Epidemic Encephalitis

Neal²⁵ gives her experience in the case of a formalized herpes virus. In controlled experiments of a year, much better results were obtained with this virus than with a vaccine prepared from normal rabbit serum. In twenty-eight cases treated with the vaccine the mortality was lower than in the control group. The least percentage of improvement was found after use of Rosenow's serum. The author warns

against the use of malarial therapy as being dangerous and considers other fever methods of little value. Bulbocapnine was found too toxic.

Mutch²⁶ recommends calcium aspirin in all forms of chorea on the following basis. The drug supplies calcium (which has been considered to be deficient in the body in chorea), it produces a sedative effect on the brain and combats the causes for the rheumatic disorder. The neutral solution (1 Gm dissolved in 5 cc of water) may be given intravenously, subcutaneously, rectally, or orally. It is tasteless and is not irritating to the kidney or stomach. Mutch treated nineteen patients who were kept in bed. The average daily dose of the drug varied up to forty-five Gm for a child of twelve. The average time taken to control the chorea was seventeen days with limits from seven to forty-six days respectively.

Fate of Encephalitics

In a follow-up investigation of forty encephalitics who had survived the acute stage, Sauter²⁷ found that six had died in the interim, six were not heard from, thirteen cases were affected with parkinsonism, seven were in a pseudo-neurasthenic state, four showed subsequent disease (2 bradyphrenia, 1 character alteration and 1 epilepsy). The pseudo-neurasthenics were able to work and showed only slight signs of encephalitis. In most of the cases the memory was more or less affected. The disease was stationary in one-half of the cases.

MULTIPLE SCLEROSIS

Etiology

An attractive theory of this disease has been proposed by Petersen² in his discussion on the patient and the weather. He regards multiple sclerosis as meteorologically induced, primarily due to vasomotor spasm in tissues in which anoxemia leads promptly to injury. In unstable individuals living in the northern latitudes, particularly in the region of the storm tracts. This concept would explain the clinical symptomatology, its transient and variable nature, the exacerbations and remissions. It also explains why such agents as nicotine, lead, ergot, cold, chilling, and dampness which may accentuate spasm, have been incriminated as etiological factors in multiple sclerosis.

Therapy

Weinberg²⁸ reports his results with lecithin treatment in multiple sclerosis. This treatment is based on the theory advanced by Marburg (in 1906), who believed that multiple sclerosis might be related to a disturbance in the fat metabolism of the nervous tissue. Weinberg treated twelve patients who had been resistant to other procedures. The therapy consists of four intraspinal injections, in ten to twelve day intervals, of 2 cc of lecithin mixed in four

cc of warm normal saline solution diluted with an equal amount of the patient's spinal fluid. The author states that in nine of the twelve cases, there was greater or less improvement. Three of the severer cases showed particularly gratifying results. The method is harmless although headache and a rise in temperature followed the injections.

By means of diathermy, radiotherapy or the electric blanket, Neymann and Osborn²³ have treated twenty five cases of multiple sclerosis. Treatments were applied biweekly. A temperature curve with a quick rise to 103.5°F and a high plateau ranging between 103° and 105.5°, was considered the optimum of the therapeutic requisition. The temperature was maintained by enveloping the patient in airtight bags. In four mild cases, improvement occurred to a point where without the history the clinical diagnosis would be difficult. In eleven advanced cases only two attained a practically normal gait. The other nine showed improvement in their gait but retained spasticity. Four returned to work and seven lived at home in a semi invalid state. Four of six bedridden cases regained the use of their upper extremities. Of the entire advanced group two were much improved and four lost some of their more troublesome symptoms. The cases were observed for a period of a few weeks to eighteen months following treatment. The authors conclude that it is too soon to evaluate the results of the treatment.

THE MENINGITIDES

Acute Lymphocytic Meningitis

This syndrome which is believed by many authors to be related to either poliomyelitis or epidemic encephalitis is discussed by Abramson²⁴. Following a period of one to two weeks during which time symptoms of an upper respiratory infection may be present there occurs a sudden onset of headache vomiting mild fever, and a varying degree of rigidity of the neck and a mild Kernig sign. In adults blurring of the discs is fairly common. The spinal fluid characteristically shows a marked lymphocytosis varying from a few hundred to thousands. The fluid is clear. The illness is relatively short and the prognosis is good.

A similar syndrome is described by Viets and Watts²⁵ who report four cases. The onset in these cases was acute with meningeal signs and with lymphocytosis of the spinal fluid. The sugar and chlorides were found to be all ways normal which differentiates the disease and tuberculous meningitis. Rarely coma and convulsions occur which disappear after the first or second withdrawal of the spinal fluid.

Cases of "Fatal" Meningitis with Recovery

Reports of recovery from various types of meningitis are given by several authors. Fel-

zen and Osofsky²² cite a case of streptococcus (viridans) meningitis which followed a head injury with laceration of the scalp. The spinal fluid contained 5,000 cells, ninety six per cent of which were polymorphonuclear leukocytes. The sugar content was 16.6 mg per cent, total protein 43 per cent. Because smears of the fluid showed cocci and a gram positive bacillus, suggestive of the anaerobic group, gas gangrene serum was given intraspinally. Further bacteriological studies revealed pure culture of streptococcus (viridans). The serum was contained since improvement occurred. Four doses of five cc each were given. The patient had a rapid convalescence. Immunologic studies showed that the gas gangrene serum by increasing the degree of phagocytosis inhibited the growth of the strains of streptococcus (viridans) isolated from the patient's spinal fluid and from his throat.

A case of recovery from cerebrospinal fever by treatment with intravenous injections of urotropin is reported by Chopra²⁶. After injections of antineurococcic serum was used with insufficient effects five cc of urotropin (40 per cent strength) was injected intravenously for twelve days. Improvement seemed to follow each injection. The patient was cured after about six weeks.

A case of Type IV pneumococcus meningitis, which recovered following continuous cisternal drainage frequent lumbar punctures cisternal-lumbar irrigations, cisternal irrigations, and periodic cerebral dehydration with hypertonic dextrose, is reported by Bedell²⁷. Approximately 200 cc of spinal fluid was drained from the cisterna magna every twenty four hours.

Reveno and McLaughlin²⁸ report a case of pneumococcus meningitis Types I and II which recovered after intravenous and intraspinal injections of 120,000 units of stock Felton's anti-pneumococcus serum. Recovery occurred after seven days of treatment.

Spontaneous recovery from tuberculous meningitis in a fourteen year old girl was observed by Parr²⁹. Only one lumbar puncture, which showed the characteristic changes of tuberculous meningitis including the presence of tubercle bacilli was done. The patient remained well in every way. Her case was followed for four years.

SPINAL CORD

Anterior Poliomyelitis

By means of the following unique experiments on the Macaca rhesus monkeys, Brodie and Elvidge³⁰ demonstrated the portal of entry and pathway of the poliomyelitis virus into the brain. Nasal installations of cord containing virus failed to infect monkeys in whom by lateral section and partial removal of the olfactory bulb and tract were carried out where as control monkeys were paralyzed after single

nasal installations of the virus. Furthermore, it was demonstrated that although the nasal mucosa is innervated by the V and VII cranial nerves, as well as by the olfactory nerve, only the last named nerve transmits the virus to the central nervous system, for no infection occurred when the olfactory tract was cut. These animals received nasal inoculations over a period of three weeks, during which time much must have dribbled into the gastrointestinal tract, yet no infection occurred. This observation would tend to eliminate the gastrointestinal tract as a portal of entry. In another set of experiments, Brodie and Elvidge demonstrated that the spread of the poliomyelitis virus to the central nervous system is by way of the nerve tracts rather than by way of the cerebrospinal fluid.

Geiger, Becker and Gray³⁷ analyzed the records of eighty-four cases of acute poliomyelitis which occurred in San Francisco during May, June, and July of 1934. The percentage of fatalities was 95 per cent. Seventy-one per cent of the cases were from four to fifteen years of age. Initial symptoms referable to the nervous system were the most frequent. In thirty-four out of the eighty-four cases, paralysis of one or more types occurred. Paralysis was more common in the sixteen to twenty-five year age group.

Cord Bladder

In a series of 250 cases in which disturbances of bladder function caused by lesions of the nervous system were studied, Lendrum and Moersch³⁸ found that the diagnosis was central nervous system lues in 106 cases, developmental defect of the caudal end of the spinal cord in fifty-two, arteriosclerosis of the central nervous system in fourteen, and traumatic injury to the spine with or without fracture in thirteen cases. In thirty-two cases various other neurological conditions caused the cord bladder. In thirty-three cases neurologic findings were negative.

Rupture of the Intervertebral Disc

Mixter and Barr³⁹ report a series of cases of rupture of the disc with herniation of the nucleus pulposus into the spinal canal. These authors point out that this condition should be kept in mind when orthopedic abnormalities of the spine do not respond to appropriate treatment. The symptoms depend on the location and size of the lesion and are similar to those due to any cord tumor. X-ray may show a narrowing of the disc, which is usually significant of migration of the nucleus pulposus, not necessarily but possibly into the spinal canal. Lumbar puncture or combined puncture with lipiodol injection are of aid in diagnosis. A partial or complete block may be demonstrated. Total protein is moderately elevated. By laminectomy the tumor is easily removed unless

very small, when it may be very difficult to find.

Peet and Echols⁴⁰ also discuss herniation of the nucleus pulposus as a cause of compression of the spinal cord. They report two cases operated on in 1927 and 1928 at which time the tumors removed were considered to be chondromas, but which finally proved to be herniations of the nucleus pulposus.

Neurologic Complications in Pernicious Anemia

Grinker and Kandel⁴¹ studied the effect of liver therapy on the neurologic symptoms in fifty cases of pernicious anemia over a period of several months. They make the following conclusions:

(1) Liver therapy is not efficacious in improving or preventing degeneration in the central nervous system complicating pernicious anemia.

(2) Liver improves the general strength of the patient with combined degeneration of the cord by increasing the number of red cells in the circulating blood or by some obscure direct action. Weakness may closely imitate the effects of damage to the spinal cord.

(3) Liver cures the mental symptoms of pernicious anemia which are usually caused by the anemia.

(4) The peripheral nerve complications of this disease, consisting of dysesthesia, atrophic changes in the skin, and perhaps other dissociated sensory defects are alleviated by the recession of the anemia. Such complications are much more frequent than they are usually believed to be.

(5) The majority of cases of combined degeneration of the cord develop rapidly at the onset, they then progress slowly no matter what therapy is employed. Gradual progression of signs may be falsely interpreted as signifying improvement.

(6) Combined degeneration of the cord develops not infrequently before the anemia and should be diagnosed by the character of the cord syndrome, the achlorhydria, glossitis, and the blood smear.

(7) Liver therapy in pernicious anemia should be controlled by the height of the blood count. Quantities of liver in excess of that necessary to maintain a normal blood level are wasted.

Syringomyelia

The postoperative results of seventy-eight cases of syringomyelia collected from the literature and including four of his own are recorded by Ley⁴². Immediate results were 68.9 per cent improved, 12.9 per cent unimproved, 18.2 per cent worse (six deaths). Late results, (for only sixteen cases) were 64.7 per cent improved, 11.8 per cent unimproved, 23.5 per cent worse. The symptoms responding best to surgical treatment are as follows: objective sen-

sory changes, trophic disturbances, and signs of compression. In some cases there may be improvement in sphincter disturbances. Providing other conditions which may cause a syringomyelic syndrome (syphilis, cervical ribs, vertebral lesions and other external causes) are excluded, the indication for operation is a partial or complete spinal block. In other cases, radiotherapy should be employed. If, however, in these cases there is no improvement after radiotherapy, surgery may be indicated. In serious cases, in which marked trophic disturbances are present or in which rapid progression of symptoms occur, surgical intervention should not be delayed.

NEUROSYPHILIS

Asymptomatic Neurosyphilis

O'Leary⁴² points out that asymptomatic neurosyphilis is the forerunner of clinical neurosyphilis and the prevention of the latter type depends on the early treatment of the former type. The diagnosis of asymptomatic neurosyphilis can be made only by examination of the spinal fluid. The increase in the number of lymphocytes and particularly in the number of polymorphonuclear leukocytes means activity of the process and indicates also a more serious type of involvement. A negative spinal fluid, obtained after the second year of primary infection, suggests that clinical neurosyphilis will not develop subsequently. O'Leary states that in 90 per cent of the cases, arsphenamine, bismuth and mercury will control the disease. However lymphocytosis of the spinal fluid and the presence of the paretic types of colloidal benzoin curve require other measures such as intraspinal therapy, which is now rarely used or malaria. These measures will prevent the development of asymptomatic neurosyphilis into clinical neurosyphilis in fifty per cent of the cases in which specific therapy has failed.

The Weather and Neurosyphilis

Petersen⁴⁴ has included tabes and paresis in his study of the effect of weather on disease. He associates the meteorological disturbances (infall of cold and polar air) with undue damage to the cord and brain, which is to be found in the region of the storm tracks. Thus, although lues is common in the southern states, tabes and paresis are rare.

Therapy and Neurosyphilis

In a report on twenty-five cases, including various types of neurosyphilis, Spiegel⁴⁵ concluded that acetarsone (stovarsol) is a valuable addition to the remedies used in neurosyphilis. In most of the cases observed for seventeen months, there was marked serological improvement in the spinal fluid. The blood Wassermann reaction was, however, less favorably influenced in most cases. There was also marked decrease in

cell content, normal counts being obtained after from six to ten injections of acetarsone (25 or 5 Gm. intravenously once a week). The protein also approached normal figures. No visual disturbances, such as seen after trypanamide therapy, occurred in any of the cases.

Glande and Masquin⁴⁶ make a comparison of the early and late effects of malarial therapy in 327 male cases of paresis treated between 1924 and 1932. An analysis of the immediate effect of the treatment showed 13.2 per cent greatly improved, 21.2 per cent moderately improved, 28.4 per cent slightly improved, 32.8 per cent unimproved, and 4.4 per cent died in the course of the treatment. Of 260 survivors (1932) there were 23.6 per cent greatly improved, 17.6 per cent moderately improved, 17.0 per cent slightly improved, 18.0 per cent unimproved, 23.8 per cent died in the course of the treatment.

In thirty-two cases of tabes treated with malaria and twenty-four cases treated with arsenic, mercury and bismuth over a period of five years, Yates⁴⁷ found that 34 per cent showed improvement by the former therapy and 45 per cent by the use of the latter remedies. Subjective symptoms were used as the basis for evaluating treatment. It was shown that malaria has a definite effect on the spinal fluid cell count and the globulin count. The prognosis was found to be much better when the disease is of shorter duration with a high cell count and globulin, than when the duration is longer with a lower cell count and globulin, whether under malaria or other therapy.

Kuhns⁴⁸ gives his experience in the use of the electric blanket for general paresis. Of 230 patients treated by this method at the State Psychopathic Institute of Elgin, Illinois for the past four years, seventy-two per cent were definitely improved, thirty per cent were discharged, and fourteen per cent are on parole. Ten have remained stationary, seven per cent have deteriorated, and eleven per cent have died. With the exception of improvement in speech in eighteen per cent of the cases and in gait in eight per cent, there was little alteration in the other neurological signs. The Wassermann and Kahn tests on the spinal fluid remained the same. The cell count and the colloidal gold test on the spinal fluid often showed marked improvement. Kuhns regards the electric blanket method the safest and simplest form of fever therapy.

CRANIAL AND PERIPHERAL NERVES

Treatment of Trigeminal Neuralgia

Dandy⁴⁹ recommends section of the posterior half of the sensory root of the gasserian ganglion for this type of neuralgia. By this procedure not only is the pain abolished but sensation of the face is unaffected. In 300 operations the neuralgia recurred in only eight cases probably

due to inconsistency of the arrangement of the pain fibers

In addition to the trichlorethylene method of treatment for trigeminal neuralgia which relieves many cases, Caldwell⁵⁰ recommends the Moyer or castor oil treatment carried out as follows. One or more ounces of castor oil is administered three times a day for several days in succession until the pain is relieved or the treatment judged to have failed. Caldwell states that he has had several remarkable cessations of pain following this treatment.

Dyes⁵¹ reports favorable results in the treatment of trigeminal neuralgia by means of deep Roentgen therapy. Only three out of twenty cases did not respond. Attacks were eliminated for periods varying from three and a half months to eleven years. In eight cases a single radiation or a series extending over several days relieved the attacks. In more chronic cases a repetition of series of treatment was found necessary. The x-ray technique used was 180 kv (tube), 5 ma, 0.5 mm. Cu, 2.0 mm. Al.

Treatment of Contused Injuries of Peripheral Nerves

Because of his experience with thirty-four cases of injury to nerves contused by such means as fracture, pressure from a cast or tourniquet, Brown⁵² recommends early operation. For exploration of the injured nerve in every instance disclosed an intraneural scar between the nerve bundles sufficient to hinder passage of nerve impulses. Expectant treatment with massage, electricity or exercise continued for four to six months is unjustified, Brown feels, in view of the changes occurring in the involved parts during this period, in which the nerve function is absent. Continuous improvement with restoration of function, varying from fifty to one hundred per cent, occurred in Brown's cases. He advises that if no motor or sensory improvement has occurred within one month after injury or if partial involvement tends to become more advanced, operation should be performed.

Facial Palsy

Duel⁵³ reports very good results in traumatic facial palsy by excising a piece of the injured nerve in the aqueduct and bridging it with a freshly excised nerve graft. Either motor or sensory nerves are used. For filling large gaps the author chooses the anterior femoral nerve as a transplant. Following the operation, there was always a period of muscular inactivity before faradic stimulation elicited a response and then a return of spontaneous movement of the muscles occurred. Final regeneration depended upon whether the injury to the nerve was of recent or of long duration. The author stresses the advantage of immediate exploration of the site of accidental injury of the

nerve. In many, an almost perfect recovery will follow removal of a spicule of bone, the lifting of a fractured plate of bone, decompression or cleansing. On the other hand, if extensive damage of the nerve is observed, one should proceed with the transplantation operation. The author also advises early operation in most cases of Bell's palsy, for recovery is much earlier than when the paralysis is allowed to run its course.

Local Anesthesia in the Treatment of Peripheral Nerve Manifestations

Caron⁵⁴ states that by the use of local anesthesia many peripheral nerve conditions may be relieved without the necessity of operative procedures. The author has had good results with injections of novocaine, quinine urea hydrochloride, and alcohol in the following conditions. Certain neuritic conditions found in persons with an adipose tendency who, following trauma, develop troublesome tenderness, particularly over the internal aspect of the knees and ankles and the lumbar sacral regions. Spectacular relief may be obtained by injecting a few cubic centimeters of a one per cent solution of quinine urea hydrochloride into the subcutaneous fat. In severe cases of pruritus ani, Caron recommends injections of ten to fifteen cc of forty per cent ethyl alcohol under the itching area. Ten to twenty mm of forty per cent alcohol frequently relieves coccydynia. Visceral pain from the heart, gall-bladder, kidney, pelvis, or pain from other intra-abdominal origin can be temporarily relieved by subcutaneous infiltration of novocaine. For the pain of laryngeal tuberculosis, Caron uses two cc of a ninety-five per cent alcohol injected into the superior laryngeal nerve on each side. In six of every ten cases of sciatica, the author has had good results from single injections of one per cent quinine urea hydrochloride into the sheath of the sciatic nerve.

MUSCULAR DYSTROPHY AND MYASTHENIA GRAVIS

Chemistry

Nevin⁵⁵, in his chemical studies of muscles, found that the phosphorus-holding compounds which play an important rôle in the chemistry necessary for muscular contraction were normal in myasthenia, whereas in pseudohypertrophic muscular dystrophy and in myotonia some alterations from the normal were found. In myotonia the total acid-soluble phosphorus was found to be below normal and the creatine phosphoric acid content slightly diminished. In contrast to the view held by Remen (who has observed improvement in myasthenia from glycine therapy) that in this disease creatine-creatine metabolism is primarily disturbed, Nevin holds to the theory that such disturbances in metabolism are secondary effects of the disease.

Therapy

Kostakow⁵⁴, studying three generations of a family comprising fifty five persons, forty seven of whom are living, found that fifteen of them developed muscular dystrophy. These were all males, the females acting only as transmitters. The author has treated seventeen cases with glycocoll (glycine). Two cases, treated for two months showed no improvement. Three were able to walk five km. without tiring, seven were able to walk ten km. without tiring, four were able to walk fifteen km. without tiring. The degree of improvement was found to be in direct ratio to the muscle volume still present and in inverse ratio to the duration and degree of involvement of the disease. The effect of medication depended in particular on the length of time it was given without interruption.

Tripoli and Beard's⁵⁵ experience with glycine and glutamic acid treatment for progressive muscular atrophy and progressive muscular dystrophy was found to coincide with that of other authors. Of sixty nine cases collected from the literature by these authors, clinical improvement has been recorded in fifty-one cases.

Reinhold, Clark, Kingsley, Custer and McCounell⁵⁶ found that glycine feeding in nine cases of progressive muscular dystrophy caused a definite regeneration of muscle as disclosed by biopsy. Clinical improvement however did not appear to coincide with the change in the composition of the muscle. Better clinical results were noted in children than in adults. One child, after three months of treatment, regained the ability to stand for brief intervals when supported. Contractures of the hamstring muscles were ameliorated in another child, after a similar period of treatment. Although muscle function was not very encouraging, there was noted, particularly in children, improvement in mental and physical activity.

Guthbertson and MacLachlan⁵⁷ treated nine cases of various types of muscular dystrophy, most of which showed improvement in the power of some of the specific muscles affected. In two cases of muscular atrophy, some general improvement was observed. The authors believe that in most cases the changes noted were greater than might be expected to occur from hospitalization alone.

Effects of Lightning and Electricity on the Central Nervous System

Ortchley⁵⁸ discusses the neurological manifestations of electrical injuries and lightning stroke. Pathologically the main effects were found to be (a) focal petechial hemorrhages scattered throughout the brain, especially in the medulla, and in the spinal cord, the anterior horn cells were particularly involved, (b) chromatolysis especially in the pyramidal cells

in the cells in the medullary nuclei, in the anterior horn cells and in the Purkinje cells of the cerebellum, (c) wide dilatation of the perivascular spaces, especially in the brainstem and cervical cord, (d) fragmentation and tortuosity of peripheral nerve axons with breaking down of the sheath of Schwann and infiltration of the epineurium with endothelial cells, (e) with unusually severe injury, the entire brain and parts of the cord are found to be swollen, softened, and even diffused.

Clinically, pain may be agonizing, unconsciousness may occur either from syncope or from immediate concussion. Late unconsciousness may result from cerebral edema. Deafness and visual disorders are common. Severe electrical injuries may cause great restlessness, irritability, and convulsions. Later effects may include (1) the syndrome of headache, dizziness, insomnia and forgetfulness, (2) spinal atrophic paralysis in certain muscle groups, (3) diffuse involvement called "electrotraumatic encephalomalacia", (4) peripheral nerve lesions, and (5) various psychoses.

THE NEXT STEP IN CANCER CONTROL

In the November Bulletin of the American Society for the Control of Cancer, the announcement of the plans for the instruction of the laity appears in these words

"The Society, therefore, proposes to turn the major portion of its energies, for the present, to a widespread and intensive campaign for informing the laity of the known facts concerning the prevention of cancer and the possible signs which may mean the presence of that condition or of a precancerous lesion

"It hopes and expects to enlist the services of organized medicine in every community to help it to keep the information given both accurate and up to date. It hopes to interest many thousands of persons in obtaining frequent complete physical examinations and in relying on the profession to advise them wisely as to treatment.

"It hopes and expects also that the medical pro-

fession will constantly bear in mind the extremely conservative attitude and continual reliance in the profession which our Society has shown. As a result of this the Society believes that the profession will completely understand and will cordially support in every possible way, the program of nationwide lay education which the Society now adopts.

"Cancer mortality can be cut. Ample clinical data support this conclusion. The profession will benefit by an organized lay effort in this direction. The cancer patient will be given the best possible chance for survival and for decreased suffering. The slogan—long in use by our Society — 'Fight Cancer with Knowledge' is about to be spread to millions now in ignorance of its value and truth. In this effort all should find a worthwhile outlet for humanitarian impulses. Within a few weeks more complete information of the general program will be made public. In the meanwhile volunteers both from professional and lay ranks are needed in the fight."

CASE 21511

PRESENTATION OF CASE

A forty-five year old white Italian housewife was admitted complaining of pain in the head, and stiff neck.

Two days before entry the patient was suddenly seized with pain in the head, dizziness and stiffness of the neck. She did not fall but required assistance to her bed. The pain in the head and neck persisted and she vomited several times. She became drowsy, then unconscious and remained in this state until her admission.

The patient had been moderately dyspneic after exertion for the past eight years. This had gradually become more marked during the two years preceding her admission. She had occasional epistaxis and her vision seemed to be failing gradually. For about three weeks before admission she had generalized headache of moderate severity. During this time she suffered a gripping pain over the heart which recurred approximately every three days, lasted for about five minutes and subsided spontaneously. There was no radiation. Causative factors were not recorded. She had frequent gaseous eructations following these episodes and occasionally vomited. Her diurnal urinary frequency had increased and there was a nocturia of two to three times. For about one year she had noticed a mass in her left lower quadrant which had gradually increased in size. Her abdomen occasionally became so large that she was unable to wear corsets. Her catamenia were normal.

She had been admitted to this hospital five years previously for pain in the chest and fever, following an acute upper respiratory infection which had begun eight weeks before. Pleural fluid removed at this time was thought to be consistent with tuberculosis although guinea pig inoculation and culture were negative. She had a febrile course and was discharged to a sanitarium after one month in the hospital. She remained in the sanitarium for eight months and left there much improved. Since that time she had no symptoms of respira-

tory disease. Because of hypertension (195/115), which had been recognized at her previous admission, her activities were restricted and she had adhered to a diet which caused the loss of thirty pounds.

Physical examination showed a rather obese, semicomatose woman. The neck was rigid. The fundi showed notching of the veins with slight thickening and tortuosity of the arterioles. The discs were normal. The heart was slightly enlarged to the left and the blood pressure was said to be high although no figures were recorded. The abdomen was distended and there was a hard rounded freely movable mass believed to be attached to the fundus of the uterus in the left lower quadrant. Bilateral positive Hoffman signs and left Babinski were elicited. The tendon reflexes were found to be more active on the left side.

The temperature was 95.6°, the pulse 60. The respirations were 25.

Examination of the urine showed a specific gravity of 1.028. There was a trace of albumin and a Benedict's test produced a green precipitate. The sediment was loaded with red blood cells and there were a few white blood cells. No casts were seen. The blood showed a red cell count of 4,350,000 with a hemoglobin of 90 per cent. The white cell count was 7,200, 87 per cent polymorphonuclears. A stool examination was negative. The nonprotein nitrogen of the blood was 50. A lumbar puncture showed an initial pressure of 500 millimeters and a final pressure of 200 millimeters. The cell count of spinal fluid showed 600,000 cells per cubic millimeter, practically all of which were red blood cells. An ammonium sulphate test was positive. The total protein was 261 milligrams. A spinal fluid Wassermann examination was negative.

The patient received five daily lumbar punctures, each of which showed decreasing amounts of blood. The pressure likewise diminished. On the second day the patient regained full consciousness. She improved generally but still had a severe headache and a stiff neck. She was discharged on the eighteenth day.

Final Admission, twelve days later

After her discharge the patient restricted her activity and felt fairly well. Four days prior to reentry she developed constant severe pain in the lower abdomen associated with nausea and repeated emesis. Her last normal bowel movement occurred three days before entry and she passed neither stool nor gas thereafter despite the administration of enemas.

Physical examination showed the patient to be quite ill and complaining of severe abdominal pain which was more tolerable when she sat up right. The skin of the extremities was cold and clammy. There was profuse perspiration. The pupils were constricted, equal and did not re-

act to light. The mucous membranes of the mouth were dry and red. The breath was foul. The heart was unchanged except for a pulse of 110. The blood pressure was 100/80. The lungs were clear. The abdomen was full and distended. Audible peristalsis was absent. No fluid wave was elicited. There was generalized tenderness with deep pressure and voluntary muscle spasm. In the lower abdomen a smooth, readily movable pumpkin-sized tumor was palpated, lying more on the right side. Pelvic examination showed a moderately lacerated high cervix. The fundus was not felt. The mass appeared to be separate from the uterus. The vaults were otherwise clear.

The temperature was 99.6°. The respirations were 20.

Examination of the urine showed a specific gravity of 1.030 with a trace of albumin. The blood showed a white cell count of 20,000, with a hemoglobin of 90 per cent. A lumbar puncture showed clear fluid with an initial pressure of 140 and a final pressure of 65. The nonprotein nitrogen of the blood was 77.

By means of a gastric tube about twenty ounces of brown fluid with a foul odor was removed from the stomach. The patient was treated supportively by intravenous fluids, morphin, the application of warmth, and constant duodenal drainage. Her general condition improved slightly but shortly thereafter the blood pressure dropped to 68/54, the pulse rose to 130, the temperature to 107°, and she expired about thirty-six hours after reentry.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD L. YOUNG, JR. The past history gives the suggestion of hypertension and probably some accompanying chronic nephritis and the story of a mass in the lower abdomen which has gradually increased in size. Five years before that there was a story of prolonged upper respiratory infection with pleurisy and the belief that it was tuberculosis, so that she was put in a sanitarium for eight months and at that time she had a hypertension of 195/115. Following a diet she lost thirty pounds in weight.

"The urine showed a specific gravity of 1.028." That is rather high for chronic nephritis of any degree, although such a gravity might be explained by the presence of sugar, and there is a positive Benedict test.

It seems to me that the essential part of the picture on the first admission is a patient with hypertension and evidence of a cerebral accident.

"Four days prior to reentry she developed constant severe pain in the lower abdomen associated with nausea and repeated emesis." I think the time element may be important there.

"Her last normal bowel movement occurred

three days before entry and she passed neither stool nor gas thereafter despite the administration of enemata." I call attention to that because it is entirely possible that a carcinoma of the large bowel is present which has given no symptoms at all previously and has suddenly shut down. If that is true there would not be immediate vomiting. Obstruction of the large bowel is almost invariably followed by vomiting, not at once but two or three days later, and it is not an early prominent symptom. The immediate vomiting suggests a rather more serious accident than that and suggests that the blood supply of bowel is immediately compromised.

"The urine showed a specific gravity of 1.030 with a trace of albumin." Again suggesting the possibility of sugar, or if her bowels did not move she may have been taking magnesium sulphate and occasionally we get a high specific gravity of urine following magnesium sulphate where for some reason it is absorbed.

Her condition on admission was altogether too poor to justify any surgical interference, even if that were considered indicated at the moment.

There are two or three features about this case that I think we must mention, either to consider relevant or to rule out. First, is the tumor important? They say it is a tumor the size of a pumpkin. Of course there are various sizes of pumpkins but it does suggest a pretty large tumor. A malignant tumor of the ovary seldom gets to that size without causing more trouble from malignancy and more fluid. There was not enough fluid in the abdomen to be able to detect, in any event if it is malignancy from outside there should be evidence of carcinoma and, it seems to me, a slower shutting down of the obstruction. This was a very sudden catastrophe that she had. Secondly, is it possible that this is a chronic nephritis and that we are here seeing what we do see occasionally, the terminal stage of renal insufficiency? We do see those cases in which the abdominal symptoms are prominent, and it often happens that operation is undertaken in some of these cases for supposed acute abdominal emergency. It seems to me that we do not have sufficient evidence for a chronic nephritis of that severity to justify the belief that that is a probable diagnosis. That brings us back to the possible cause of an acute intestinal obstruction of sufficient severity so that immediate nausea and vomiting take place and the patient goes into shock. She was in shock on admission and died within thirty-six hours. Is it possible that her cardiac condition was such that it could account both for the cerebral accident four weeks before and for the present emergency presumably through embolism to a mesenteric artery? It is characteristic of mesenteric thrombosis that there is severe pain, that there is absent peristalsis at

the end of a relatively short time and that there may be perforation. The shock of a mesenteric embolus—I believe this sudden onset would be embolism rather than thrombosis—plus a perforation would have resulted in immediate death. Or did she suffer one of the other possible causes of sudden upper abdominal obstruction, an acute volvulus or a band both of which involved the small bowel and the mesentery and would result in the severe picture that she has? I have never made a diagnosis correctly before operation of mesenteric embolism or thrombosis and because I have everything to gain and nothing to lose I am going to say that that seems like the best bet to me, with volvulus second. I do not think the condition is connected with the tumor and I do not believe it is the end stage of a chronic nephritis.

DR. J. H. MEANS. I think the kind of cerebral episode is of some interest. The description here is almost the classical one of spontaneous subarachnoid hemorrhage. The patient was hypertensive and I suppose that the more usual kind of cerebral episode with hypertension is an ordinary form of apoplexy, not the so-called subarachnoid hemorrhage. I wonder if this may be the clue to some strange diagnosis in this case. I cannot suggest what it might be. I should be very much interested to find out what kind of cerebral hemorrhage it was. The picture is more that of subarachnoid hemorrhage than apoplexy with hemorrhage into the ventricle. I think the recovery is more in favor of the former.

A PHYSICIAN. Is there a possibility of there being a dissecting aneurysm there?

DR. MEANS. Dissecting aneurysm is a very good thing to have on the list of any differential diagnosis of cause of sudden death.

CLINICAL DIAGNOSES

Tumor of the ovary
Intestinal obstruction

DR. EDWARD L. YOUNG'S DIAGNOSES

Acute intestinal obstruction with vascular damage
1 Mesenteric thrombosis
2 Volvulus

ANATOMIC DIAGNOSES

Leiomyoma of the left Fallopian tube.
Volvulus of the small intestine with obstruction
Bronchopneumonia bilateral
Hemorrhage of the cerebellum right.
Infarct of the left putamen
Arteriosclerosis, moderate aortic and cerebral

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY. The findings at autopsy show that the large tumor which she had almost certainly had for many years, although it was not noticed on the first entry, was a fibroid loosely attached to the Fallopian tube not in the ovary or the uterus. It had picked up a blood supply from the omentum and from an adherent loop of ileum. It had then twisted on its stalk three times and carried the ileum around with it, producing a volvulus and complete intestinal obstruction. The gut was widely dilated above the point of twisting, and it had collapsed below.

She showed in addition the usual findings of hypertension, a hypertrophied heart, slightly atrophic kidneys and diffuse arteriosclerosis of the kidneys. There were no thrombi in the cardiac cavities to serve as sources of emboli. The lungs showed a terminal bronchopneumonia.

At the time of autopsy there was no longer any trace of subarachnoid hemorrhage though the history leaves no doubt that it must have been present on her previous entry. In view of the story Dr. Knibik made a very careful search for a congenital aneurysm of the circle of Willis but could not find one. He did find a fairly fresh area of infarction and hemorrhage in the cerebellum and a much older softening in the left putamen. The cerebellar lesion was in all probability the source of the subarachnoid hemorrhage.

DR. YOUNG. Why was not the tumor sensitive? That is why I threw out the question of twist. It says 'a freely movable tumor' and nothing is said about sensitiveness.

DR. MALLORY. I do not believe we can be sure what they were feeling on the last entry, it may have been the strangulated loop of bowel rather than the neoplasm itself.

CASE 21512

PRESENTATION OF CASE

First Admission. A twenty-seven year old American shoe factory operator entered complaining of severe abdominal pain.

During the past month he had had 'indigestion' off and on characterized by mild attacks of cramplike abdominal pain. The pain was not associated with meals until one week before entry, when it began to occur about fifteen minutes after each meal and last for about half an hour. His bowels had been regular. There were no additional symptoms until three days before entry when he began to have sharp, cramplike severe, non-referred pain in the upper abdomen which continued until admission without relief. He had been unable to sleep since the onset of the pain. He was slightly nauseated two or three times on the evening, he

fore admission but did not vomit. His bowels had moved on the day of admission as usual.

There was no history of jaundice, hematemesis or tarry stools. There was no loss in weight. For several years he had had nocturia about once a night but during the past week he voided about three times a night.

Physical examination was negative except for the abdomen. In the right upper quadrant there was a rounded, fairly firm, quite tender, freely movable mass which was not attached to the liver and which could be pushed into the right or left lower quadrant with ease. There was slight spasm over the mass. The liver, spleen and kidneys were not felt.

The temperature, pulse and respirations were normal.

A Wassermann test was moderately positive.

On the day of admission an exploratory laparotomy was performed. When the greater omentum was turned back a somewhat lobulated mass approximately 15 by 8 by 6 centimeters was found involving the mesentery of the jejunum. The mass was cystic for the most part, but in places was firm and in other places definitely whitish in color and extended to the duodenojejunal juncture, making resection very difficult. A jejunostomy was performed short-circuiting the mass, which was left intact. He was discharged on the thirteenth day.

Second Admission, ten years later

He had been perfectly well and symptom-free during this period. Five days before this entry after lunch, he was suddenly seized with a fairly severe right upper quadrant pain exactly similar to that experienced before his previous admission. The pain continued unaltered until admission. It was steady and constant but not associated with nausea or vomiting.

Physical examination showed a localized round area of spasm and tenderness in the right upper quadrant but a definite mass could not be felt.

Two days later an exploratory laparotomy was performed and the tumor removed. He had an uneventful convalescence and was discharged on the eleventh day.

DIFFERENTIAL DIAGNOSIS

DR JOHN STEWART. We seem to have here a definite picture of rather unlocalized, frequent upper abdominal pains of peristaltic origin, and our attention is at once focused on the small intestine. The severity of the pain in the absence of vomiting is interesting. Ordinarily one expects to see vomiting associated with such severe peristaltic pain, arising in the small intestine, if the lesion is obstructive in type. The fact that obstipation was present is further evidence that we are not dealing with one of the usual types of intestinal obstruction.

An important observation in the physical examination is the mobility of the mass described. We infer that the mass either had a

pedicle of some length or else was attached to a mobile viscus, such as the great omentum, small intestine, or mesentery.

The fact that operation was performed so soon is interesting in considering the symptomatology. From the evidence at hand one hardly sees a pressing indication for immediate operation without further study. There is described a mass apparently fairly well circumscribed lying in the mesentery of the jejunum and evidently interfering with jejunal peristalsis. The mass is at least partially cystic, and the meager details concerning its physical nature bear out the presumption already established of absence of active acute inflammation.

To be considered in the differential diagnosis are the following: first, a chronic inflammatory mass, such as gumma or mass of tuberculous lymph nodes, secondly, a benign neoplasm, such as lipoma, fibroma or neurofibroma, thirdly, a malignant tumor, such as fibrosarcoma, lymphosarcoma, or one of the rarer tumors arising in tissue of the sympathetic nervous system, including paraganglioma and ganglioneuroma, fourthly, a mass arising in connection with misplaced tissue, possibly of pancreatic or splenic origin, in which group also might be placed the so-called mesenteric cyst, finally, the mass may be springing from the pancreas and presenting in the root of the intestinal mesentery.

The subsequent course in this case after the first operation is of much significance in the differential diagnosis. A malignant tumor is no longer to be considered, for not only has the mass not produced symptoms or increased in size during ten years, but the lesion can now be excised. The same considerations make a chronic inflammatory mass an unlikely possibility. Besides, if the lesion were tuberculous there should be other obvious tuberculous nodes noted in the findings at operation. It seems unlikely that the lesion arose in the pancreas itself, for it seems to be too freely movable. From the description of the findings at the first operation and from the statement about the second operation, one assumes that the lesion does not spring from the bowel itself, for we are told that the tumor was removed, apparently without resection of the intestine. The diagnosis, then, seems to involve a benign, at least partially cystic mass in the jejunal mesentery. Lipoma and fibrous tumor cannot be excluded but are unlikely. The most plausible diagnosis in the light of the facts given us seems to be mesenteric cyst. At any rate, this is certainly an unusual lesion.

PREOPERATIVE DIAGNOSIS

Tabes mesenterica

DR JOHN STEWART'S DIAGNOSIS

Mesenteric cyst.

PATHOLOGIC DIAGNOSIS

Lymphangioma of the mesentery

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY This patient was operated on for the second time by Dr. Vincent with a preoperative diagnosis of probable tuberculosis of the mesenteric lymph nodes. When he got into the abdomen he found a tumor mass about the size of a baseball situated in the mesentery of a high loop of jejunum. It was adherent along one surface to the intestine and on the opposite side it extended deeply into the root of the mesentery. It felt partly firm and partly cystic. He was able to dig it out from its attachment in the retroperitoneal tissues and resected it along with about a foot of the adherent jejunum. The patient made an uneventful recovery.

The specimen which we received in the laboratory showed a well encapsulated tumor mass 9 by 5 by 4.5 centimeters. On section it was found to consist of innumerable cavities varying in size from bare visibility to two centimeters in diameter. Many of the cysts contained creamy chylous material, others showed all

grades of blood staining up to frankly hemorrhagic content.

Microscopic examination showed that it was made up of a mass of anastomosing channels lined by endothelium, the majority of which contained partially coagulated protein material. In many places well formed lymphatics with connective tissue and smooth muscle in their walls can be made out. In other parts of the tumor the formation of lymphoid follicles and even of small lymph nodes is apparent.

This tumor is a characteristic example of the lymphangiomas of the mesentery. They probably arise in the region of the peritoneal tissues. Some of them tend to invade backward and downward along the aorta or about the kidneys. Others like this one, grow forward into the mesentery and eventually come in contact with a loop of small intestine. The formation of nodules of lymphoid tissue in the tumors has frequently been described and is apparently fairly typical of it. The condition is closely analogous to the so-called bygroma coli which is really a cavernous angioma of the neck. Sometimes the tumors grow much more rapidly than this one apparently did, but they evidently have little tendency toward metastasis.

IMPORTANCE OF THE PHYSICIAN IN A HEALTH PROGRAM

WHEN health was largely the concern of individuals not organized in groups, it was the persons who were sick and the healers who carried the chief responsibilities. As the significance of disease to the community came to fuller realization organizations of lay persons as well as of physicians developed, until, at present, with the enormous widening of lay interest, physicians may be said to constitute a minority group. There has been also a strong tendency for lay groups to tell physicians how they should practice medicine.

Nevertheless, the keystone of the arch is the physician, and it is of critical importance to the community that the physician shall receive the best kind of preparation for the exacting office he is expected to perform. To say that he shall be socially minded does not mean that he shall be a person of slight individuality. It means simply that he shall see the problems presented by the individual patient against the background of a group, a society, of which the patient is a member. The wider implications of

a social organism of which an individual part is sick must be taken into consideration.

With the growing realization of the complexities of civilized life, and underneath the realization that life is actually becoming more complicated, we are faced with the question of whether the minds of men can deal with the added burden. Are mental breakdowns due to unwillingness or incapacity to face the facts and to make the necessary adjustments?

The demands of advancing civilization are such that of the physician as well as of others, but especially of the practitioner of medicine, there is required mental flexibility and adaptability, toughness and resiliency of mind. The physician occupies one of the key positions in advancing civilization. Nothing less than the best can be expected of him and so nothing less than the best must be given him.

The preparation of the physician for his exacting duties must be the best preparation. About the details we may disagree, but the quality must be excellent. It must excel the ordinary, the mediocre, in thoroughness, in comprehensiveness, in adequacy and in appropriateness. It must have distinction.

It is on this account that the formal standards set by the state for admission to the practice of medicine shall be changed from time to time to keep step with the practice of medicine. Science must and will lead the way. Education brings the gifts of science to practice. If education is antiquated, defective, substandard, the patient pays, sometimes with his life.

There is a popular delusion, often apparent in political circles, though not unknown elsewhere, that information is identical with education. Translated into practical affairs, this means that a candidate who manages to acquire enough information to get a passing mark on examination is therefore supposed to be qualified for practice. But in fact the correlation between information and education is not close enough for the presence of the first element to be accepted as a guarantee of the presence of the second.

Education, the best possible education, of physicians is demanded for the welfare of the citizens of the Commonwealth. The state has educational standards. They should be applied rigorously. The chartering of a medical school by the state should mean, not that the institution is free to carry on its work in utter disregard of the principles of education, but that the state guarantees a reasonable approximation to generally accepted standards of education. Is this too much to expect? We think not. Furthermore it is the right of the citizens to demand of the government that it protect them adequately against substandard physicians graduates of substandard schools.

Christmas

We are entering upon another season, an other year is about to roll to its close, and fittingly enough the beginning of the sun's return to northern latitudes is marked by the most beloved and the kindest of our religious festivals. It is pleasant to believe that at the Christmas time, when a Saviour was born to bring spiritual salvation to an oppressed people we also may see the effulgent glow of an imaginary Star marking a goal and setting an ideal toward which we may at least strive with a renewal of that hope so necessary for the success of man's efforts.

Fortunate we are in belonging to a profession which, imperfect as it may be susceptible as it may be to the frailties of human nature, nevertheless has traditionally given of itself to a degree which sets it apart as a particular and a uniquely honorable Estate. That season of the year has come which has been immemorially dedicated to the giving and the receiving of gifts.

Let our choicest gifts this year be part of ourselves, as we remember that the gift without the giver is bare.

The Massachusetts Medical Society

A MEETING OF THE OFFICERS OF THE SCIENTIFIC SECTION

On the invitation of Dr. W. R. Morrison Chairman of the Committee of Arrangements the officers of the Scientific Sections of the Massachusetts Medical Society attended a luncheon at the Hotel Puritan, Boston, December 12, 1935 for the purpose of discussing the programs for the Annual Meeting of the Massachusetts Medical Society next June.

Dr. Charles E. Mongan, Dr. Channing Frothingham and Dr. Alexander Begg, officers of the Society, were also present.

Dr. Morrison reported the progress made by his committee in preparing the details of the facilities for the section meetings and the social features of the occasion, and called upon the chairmen of the seven sections for a report of plans under way. It was shown that all of the section officers have their respective duties well in hand and there is every assurance that the 1936 meeting will be of especial value to the members and their guests.

The President, Vice President and Secretary submitted important suggestions for general consideration.

Dr. Morrison urged this representative body to pay especial attention to getting the recently elected members of the Society to attend and

become acquainted with the officers and familiar with the functions of the organization

It was evident that everyone present was committed to making this meeting one of the best in the history of the Society

ANNUAL MEETING

For the next annual meeting to be held in Springfield, Massachusetts, June 8, 9, and 10, the following subcommittees have been appointed

Publicity Committee	R S Mace
Ladies Committee	W A R Chapin
Historical Committee	G L Schadt
Scientific Committee	Frederick Jones
Hobby Exhibit Committee	E P Bagg, Jr
Committee on Clinics	F L Dutton, Springfield Hospital, George B Corcoran, Mercy Hospital, Frederick Hagler, Wesson Hospital
Sports Committee	Richard A Rochford

DIAGNOSIS OF STERILITY

Although the diagnosis of the causes of sterility is a difficult and time-consuming procedure when one is dealing with actual cases, it can be discussed quite simply

There are four methods of diagnosis which are essential to a complete consideration of any case. The first is the number and character of the sperm cells. This can only be determined accurately by examination of the semen. Such an examination should estimate the number and vitality of the spermatozoa and should examine the individual cells for any morphologic changes. It should also determine whether the seminal fluid in which the spermatozoa are to be found is normally constituted.

The second test is made of the cervical secretions postcoitum. By this procedure it can be determined whether the sperm cells are able to get through the internal os in sufficient numbers so that they are practically certain to be able to reach the tubes. The test also shows whether the secretion itself is a favorable medium for this migration of the spermatozoa. Pus may be present or the mucus may be thick and stringy.

The third test is insufflation of the tubes. If they are normally patent no more need be done,

*A series of short selected articles by members of the Section is being published weekly.
Comments and questions by subscribers are solicited and will be discussed by members of the Section.

if not, some material like lipiodol which is opaque to the x-rays should be injected and pictures taken

The fourth procedure is to determine whether ovulation is occurring. This is best accomplished by getting an endometrial biopsy in the middle of the cycle and again at the end. From a study of stained sections of the endometrium one can postulate the occurrence of ovulation and tell a good deal about the hormone activity of the ovaries. Examination of the endometrium will also rule out endometritis. If all of these tests are satisfactory, one can predict pregnancy as being bound to occur sooner or later. If one or more of these tests are negative, treatment must be directed toward the correction of the conditions found before there can be any great expectation of success.

BOSTON MEDICAL LIBRARY

WILLIAM STOKES, 1804-1878

As an illustration of the influence of heredity upon the development of exceptional intellectual qualities the life of William Stokes, a celebrated Irish physician of the early part of the nineteenth century, may be cited as especially noteworthy. Whitley Stokes, 1763-1845, his father, was the son of Gabriel Stokes, D.D., a fellow of Trinity College, Dublin. He was also prebendary of Elphin, Chancellor of Waterford and rector of Desart Martin. The first of the family to settle in Ireland was another Gabriel Stokes, great-grandfather of the subject of this sketch, who was an engineer and Surveyor General of Ireland in 1735. Whitley, the father of William, entered Trinity College in 1779, became a fellow in 1788, procuring his degrees of Bachelor of Medicine in 1789 and Doctor of Medicine in 1793. On account of an early affiliation with the United Irishmen he came under the ban of English authority and was restrained from teaching for three years. However, he succeeded in removing the ban and was made a senior fellow in 1805 and a lecturer on Natural History in 1816. During 1830, he became the Regius Professor of Medicine, a position he held for thirteen years. So outstanding a figure did he become in the educational field that he was declared to be the best equipped man in the country to head a system of National Education in case Ireland should gain her independence of England.

Such was the immediate intellectual background of William Stokes who was born in Dublin in 1804, one of the nine children of Mary (Picknell) and Whitley Stokes, who were married in 1782. His education was conducted in the classics and mathematics by John Walker, a fellow of Trinity, and in the Sciences by his father. He pursued his medical studies at Edinburgh where he graduated in 1825. Re-

turning to Ireland that same year, he became a licentiate of the College of Physicians and was elected physician to the Meath Hospital, where he became a colleague of Dr Robert James Graves. Pursuant to substantial work which he had evidently done while at Edinburgh, under Cullen, in pathology and clinical medicine, he published in 1825, a monograph on "The Use of the Stethoscope" which was the first article on this subject to appear in English. This he dedicated to Cullen.

From his opportunities at Meath Hospital and his most congenial association there with Robert Graves, with whom he collaborated in many ways, he became an inspiring teacher. In fact, one of his greatest contributions to medical interests has been the prominence that he gave to bedside teaching. Typhus fever visited Dublin in 1826 and Stokes was prominent through it all in his efforts to check its ravages. He married in 1828 and with an increasing practice he moved to a more commodious home on York Street where he kept open house on Saturday evenings to which were attracted the cultured people of the town, for he had many interests outside his profession among which were art and archaeology. He was fond of collecting Irish antiquities and was the means of encouraging many a young man in various lines of artistic and scientific endeavor, notably George Petrie, the Archaeologist. He did not neglect any opportunities of foreign travel, which was of great assistance to him in developing his native, artistic tastes. These interests made him a great believer in the value of broad cultural training to a physician and he frequently emphasized this point of view in his writings and teaching.

His hospital work, preparation of his teaching courses and the exactions of a large practice did not prevent him from doing a considerable amount of literary work, for in addition to his first work on the "Use of the Stethoscope" he brought out very valuable and extensive works on "Diseases of the Chest," "Diseases of the Heart and Aorta," "Clinical Observations on the Use of Opium," and numerous lectures and papers published in the London Cyclopaedia of Practical Medicine and elsewhere covering a wide range of subjects. He founded the Dublin Pathological Society in 1838 and was for some years Editor of the *Dublin Medical Journal*.

To the profession in America the work done at Meath Hospital during the period of activity of Graves and Stokes should be of particular interest for it was largely from here that knowledge of the methods of bedside teaching practiced by them, was brought back to this country. Though Boerhaave, one hundred years before, had introduced this plan of teaching it was to the credit of these two that the method was widely introduced and popularized. This was doubtless done, so far as America was con-

cerned to the fact that fewer American students visited Leyden than came to Great Britain, and after the Edinburgh schools' influence began to wane, the school at Dublin enjoyed a short period (twenty years) of unusual popularity, largely due to the presence, there, of Graves and Stokes. During this time, many American youths found their way to Ireland and came under the spell of the teaching of these two master clinicians. It is a surprise to us, in this day, to realize what a battle had to be fought by those who were venturesome enough to employ the methods of Laennec and Auenbrugger in the study of diseases of the heart and lungs. It was done, in no small degree, to the championship of these methods that the renown of the Dublin School was achieved, as it was, of course, through their practical application that the discoveries in these fields, of such men as Graves, Stokes, Cheyne, Corrigan and Adams were made possible. It has been claimed by those competent to hold an opinion, that Stokes, after Corvisart, was the second greatest cardiologist the world has known.

Not only did these men cultivate the methods of clinical observation at the bedside but like all great diagnosticians and teachers they sensed the equally great importance of a knowledge of pathological anatomy, and the Dublin School became known in America as a place where such studies were prosecuted.

In 1861 he was made Physician in Ordinary to the Queen in Ireland, and the same year was elected F.R.S. In 1874 he was chosen President of the Royal Irish Academy and in 1876 the Prussian Government awarded him the Prussian Order, Pour le Mérite in recognition of his medical writings. This brief account of the life of a master mind may help us to see something more of a personality known to us chiefly if not solely, because it bore a name associated with a peculiar type of respiration and a rare cardiac lesion.

MISCELLANY

THE APPOINTMENT OF DR. KARL BOWMAN

After a civil service examination of sixteen applicants Dr. Karl M. Bowman, chief medical officer of the Boston Psychiatric Hospital, was selected to fill the position of Director of the Psychiatric Division of Bellevue Hospital.

DR. W. E. BROWNE, ADDRESSSES THE BRIDGEPORT MEDICAL ASSOCIATION

Dr. William E. Browne, Visiting Surgeon at Carney Hospital, Boston, recently was the guest speaker of the Bridgeport Medical Association. His exhibit of a variety of ingenious splints and the presentation of related cases made his address "Management of Infections of the Hand" most interesting and instructive.

RÉSUMÉ FOR OCTOBER, 1935

Infantile paralysis for the State as a whole continued on the decline although a few communities noted a slight increase

The decline of diphtheria continues to be striking. For the first nine months of the year there were sixteen deaths as compared with thirty four in the corresponding period last year

Tuberculosis pulmonary and other forms were reported about on a par with 1934

Lobar pneumonia continues to run ahead of last year's figure and the indication is that it will continue to do so through the coming winter

Scarlet fever was reported above last year's October figure and the indication is that the incidence this winter will be somewhat higher than in 1934

Epidemic cerebrospinal meningitis is running at a definitely higher level than in 1934 with nearly every part of the State represented

Typhoid fever was reported somewhat lower than last year. The number of deaths for the year to date (nine) is on a par with last year's figure, which was so low that some doubt was raised that it could be sustained

Undulant fever was reported thirty-four times this year as compared with twelve for the year before, the increase being due to better reporting

Although the number of reported dog bites is high, there were but nine reported cases of animal rabies as compared with twenty seven in 1934

Chickenpox and German measles are not remarkable

Measles was reported somewhat higher than in 1934 but below the five-year average

Mumps had its highest reported October incidence in the history of the State, while whooping cough was reported to a very low level

THE NEW PHARMACOPOEIA

THE U.S.P. BOARD ANNOUNCES THE RELEASE DATE AND
THE OFFICIAL DATE FOR THE U.S.P. XI

The new Pharmacopoeia, the Eleventh Revision, was available on December 16. This date was fixed by the Board of Trustees of the United States Pharmacopoeial Convention to enable the publishers, the Mack Printing Company of Easton, Pennsylvania, to place the books on sale in all parts of the country simultaneously

As directed by the U.S.P. Convention, the Board of Trustees has also fixed the date when the standards of the new Pharmacopoeia shall become official, superseding the Tenth Revision. This date is June 1, 1936

The following articles have been added to the Pharmacopoeia

Acriflavina

Acriflavinae Hydrochloridum

Aethylenum

Aethylhydriocupreinae Hydrochloridum

Aethylis Oxidum (Solvent Ether)

Antitoxinum Scarlatinae Streptococcicum

Bismuthi et Potassii Tartras

Calcii Creosotas

Calcii Gluconas

Calcii Hydroxidum

Carbo Activatus

Carbonel Dioxidum

Chlorobutanol

Digitalis Pulverata (Biologically standardized)

Emulsion Petrolati Liquidii (50 per cent)
Ephedrina
Ephedrinae Hydrochloridum
Ephedrinae Sulfas
Erythritylis Tetranitras Dilutus (Erythrol Tetra nitrate)
Extractum Hepatis
Ferri et Ammonii Citrates Virides
Fluoresceinum Solubile
Histaminae Phosphas
Hydrargyri Saccolimidum
Iodophthaleinum Solubile
Liquor Ergosterolis Irradiati (Vioosterol)
Liquor Hepatis
Liquor Hepatis Purificatus
Liquor Histaminae Phosphatiae
Liquor Parathyroides
Liquor Sodii Hypochloritis (4 per cent)
Mercurphenum
Nocinchophenum
Oleum Iodatum
Oleum Maydis
Oleum Morrhuinae Non-destearinatum
Oleum Rosae
Phenacinae Hydrochloridum
Phenobarbitalum Solubile
Pulvis Chinioformi
Serum Antimeniingococcicum
Serum Antipneumococcicum—F
Sodii Perboras
Sodii Stearates
Stomachus
Tabellinae Glycerylis Trinitratis
Theophyllina cum Ethylenediamina
Theophyllina cum Sodii Acetate
Tinctura Iodi Mitis (2 per cent)
Toxinum Diphthericum Detoxicatum
Toxinum Diphthericum Diagnosticum
Toxinum Scarlatinae Streptococcicum
Toxibellinae Hydrargyri Bichloridi Parvae
Trypanaspidum
Tuberculinum Pristinum
Vaccinum Rubeolae
Vaccinum Typhosum
Vaccinum Typho-paratyphosum

JAMES H. BEAL, *Chairman*
WILLIAM B. DAY, *Secretary*

PRESENT CONCEPTS OF TUBERCULOUS INFECTION

BY WADE HAMPTON FROST, M.D.

*Professor of Epidemiology School of Hygiene and Public Health Johns Hopkins University
Baltimore Md*

The most conspicuous fact in the history of tuberculosis in the last 50 years has been its steady and rapid decline in mortality. In view of the circumstances under which this has taken place and in the light of what is known of the natural history

of the disease is it reasonable to expect that the downward trend may continue indefinitely perhaps to the point of regional suppression of the disease, or is it more reasonable to anticipate a compensating upward swing to a higher level?

The fact that the tubercle bacillus is an obligate parasite of man transmitted directly from person to person by way of the respiratory tract, places tuberculosis in the group of diseases offering least hope of full control except by specific immunization. However tuberculosis is sharply differentiated from the other diseases in this group by the fact that two restrictions are imposed upon the propagation of the tubercle bacillus, namely (1) in order to spread the infection, it must produce natural disease—a lesion which becomes “open” and (2) it succeeds in producing this effect in only a limited proportion of those who become infected. Various other pathogenic organisms transmitted by way of the respiratory tract are subject to one or the other of these restrictions, or its equivalent, but the tubercle bacillus is unique in being subject to both.

Because of this combination of conditions limiting the propagation of the tubercle bacillus, it is reasonable to infer that the partial environmental control which has been established is definitely effective in limiting the spread of tuberculosis even though it be relatively ineffective against numerous other diseases transmitted directly by way of the respiratory tract. The fact that at present tuberculous infection is distinguished from the disease is highly prevalent, is not inconsistent with this view.

With improved measures of control which are within the limits of practicability including better detection and isolation of open cases with higher standards of living and personal hygiene there appears to be no fundamental reason why tuberculosis may not be eradicated eventually from large areas in this country. There are indeed certain contingencies which obviously might bring about a recrudescence after the disease has reached an extremely low level, but it does not appear that this result is inevitable in accordance with any accepted biological law or that it is especially to be anticipated.

Admitting that we cannot actually know the future of tuberculosis it is none the less important to define clearly what are reasonable expectations in the light of present knowledge since present activities in study and control necessarily are directed chiefly toward the future. If as now appears it is reasonable to anticipate eventual control to the point of permanent regional suppression, the establishment of this as the objective has obvious and important implications as to the scope and intensity of control measures. It has less obvious but important implications with respect to indicated lines of investigation.

Through the courtesy of the N. T. A. and of Dr. Frost, the above was published in *Neighborhood Health*, August-September 1935 Vol. 1 No. 2.

COMPARISON OF DISEASE INCIDENCE IN CONNECTICUT WITH 1934
AND SEVEN YEAR AVERAGE

MONTH ENDING DECEMBER 7, 1935

Diseases	1935				Average cases reported for week corresponding to Dec 7 for past seven years	1934			
	Week ending Nov 16	Week ending Nov 23	Week ending Nov 30	Week ending Dec. 7		Week ending Nov 17	Week ending Nov 24	Week ending Dec 1	Week ending Dec 8

Remarks No cases of Asiatic cholera, glanders, plague or yellow fever during the past seven years

"MAKING WAR AND MAKING PEACE"

That psychiatry, which played an important part in preparing men to be soldiers in the World War has an even greater responsibility in preparing them for peace was the keynote of an address delivered by Dr Stewart Paton at the twenty-sixth annual meeting of The National Committee for Mental Hygiene held at the Rockefeller Center, New York City, November 14, 1935. Dr Paton, formerly lecturer on neurobiology at Princeton and other universities, spoke on "Making War and Making Peace."

"One of the lessons that we learned during the war," Dr Paton said, "was that in order to insure military success it was necessary for the soldiers in active service to be sound in mind and body. The late Dr Thomas W. Salmon, first Medical Director of The National Committee for Mental Hygiene, and his associates, did a great deal to open the eyes of military leaders to the importance of the emotional

and mental preparedness that is necessary in order to make a good soldier. But as we have been exceedingly indifferent and reluctant about informing ourselves as to the emotional and mental preparedness required to be peaceful and human, relatively little progress has been made in finding ways and means for the pacific settlement of either individual or international problems."

Dr Paton expressed the opinion that the National Committee's outstanding contribution during the past quarter of a century has been in bringing about public realization that our most valuable possessions are our distinctive human characteristics, and that this must become an essential part of our outlook if we are to hope for an end of international strife.

"Man is gradually learning to fuse impulse and reason, and unless the strain is too great, he often succeeds in being peaceful, sane and human," he said. "However, the problem of how to make peace is a much more difficult one than how to make war,

and as we have given more intelligent consideration to the war than to the peace problem we should not be surprised nor shocked by the difficulties we experience in settling any of our conflicts.

Dr. Paton pointed out that while there is universal agreement that our military leaders may be physically and mentally sound we pay little or no attention to the equally important requirement of sound mental and emotional qualifications in our governmental and political leaders who are engaged in the vital business of diplomatic negotiation, discussion and arbitration. A great deal of valuable energy is wasted in promoting rather than in practicing peace he said due to the lack of appreciation that the rational and peaceful settlement of disputes requires definite and particular techniques and method of approach.

"Too many people are now engaged in trying to promote peace throughout the world who would not be competent to assist an individual in finding a peaceful solution of the problems that drive him to take refuge in a mental hospital.

Here Dr. Paton referred to the warning recently issued by the Netherlands Medical Association, in a statement signed by 229 psychiatrists from thirty nations which pointed out the war dangers of the present world situation and which, he said suggested the constructive psychological methods that should be adopted to avoid destructive and insane conflicts.

Although we have learned from hard and trying experience that men cannot be prepared for constructive service if they adopt prohibitive attitudes of mind he said we still rely to a large extent on prohibitions to make us temperate and sane. As a result mental hospitals and clinics are over crowded with patients who have not been able to settle the conflicts that disturb their lives on a rational and peaceful basis.

One of the basic factors that must be considered in planning for world peace Dr. Paton further said, is our "emotional immaturity."

"One of the signs that we are still children psychologically speaking is the intense interest we take in all the sensational aspects of life he said. "For centuries we have focussed attention upon going to war going insane going unemployed and going to the devil. Very little notice however is taken of the process of going more human more peaceful more sane. Yet, slowly but surely we are becoming aware of the fact that man is a human being in spite of the fact that the present plague of nervous and mental disorders the greatest epidemic that has ever afflicted mankind is seriously interfering with our attempts to be peaceful sane and human.

Mental hygiene as time goes on can assist the American people in finding peaceful and rational solutions of their personal, business, industrial and political problems. By continuing and supplementing the work that The National Committee for Mental Hygiene has already done much can be accomplished in opening our eyes to the significance of the fact that we are human beings.

One of the dangers at present is that technical science has supplanted us with means for annihilating the human race. This catastrophe can be avoided by securing the active cooperation of science and art, and mental hygiene can show the way in which we can secure this cooperation that is so essential to progress in the art of living.

CARE FOR INDIGENT HEART CASES IN CONNECTICUT

Mrs. F. Donald Coster of Fairfield, Connecticut, has developed plans for the reestablishment of a free clinic for indigent persons afflicted with heart diseases in Bridgeport, Connecticut. When the clinic is in full operation, fifteen trustees will be in charge of the endowment.

The facilities of the clinic will be available to any resident of Connecticut who is unable to pay for treatment.

CORRESPONDENCE

CONSULTATION A LA MODE

Editor *New England Journal of Medicine*

One of the handicaps of being a general practitioner is the painfully humiliating experience he is constantly called upon to go through at the hands of the well meaning specialist who sees nothing unethical in the usual procedure of lifting all the responsibility from the shoulders of the doctor who calls him in consultation and thereafter giving said patient such excellent attention that the erstwhile physician—in good and regular standing with his former patient—is utterly ignored and forgotten.

In spite of all that has been said and written to the contrary this hateful practice still goes on and it often seems true that the greater the man called in consultation the more inevitable the outcome. Today calling a consultation with many of these men of otherwise high standing is tantamount, not only to giving up your patient but your professional standing and prestige with all concerned. The process is apt to be about as follows:

Consultant suggests removal to hospital where case may be watched and studied. Very good. You would like to watch and study this patient yourself and that's why you called him in. Perhaps you simply wanted his judgment as to whether case is operatively urgent. From courtesy you accept the first suggestion. Presto! Your patient is removed as a private case to a semi-private institution with a "closed staff."

You make your first call full of interest and expectancy only to find your patient well established under the more or less exclusive care of Dr. Dash—who covers for Dr. Blank"—a man who doesn't know you from Adam and whom you did not ask for advice. You are told courteously that Dr. Blank said you were welcome to come in any time meanwhile "we are working up your case. Patient one day requests you to prescribe an aspirin for her headache and discovers it cannot be done.

You make several visits you see your patient in

bed (under covers) but you are never asked advice about any procedure whatsoever, or expected to make an examination. Interest flags. The patient seems well satisfied and thanks you patronizingly for sending her to such a nice place, and quotes Dr. Dash whom you now rarely see, or Dr. Blank who "looks in occasionally." "Very big man, you know, did ten operations yesterday," Dr. Dash assisting.

Eventually you learn that Dr. A has been called to examine nose and throat, Dr. B the eyes, and Dr. C is "going over" the heart and kidneys preparatory to operation. Finally you are invited to "witness" the operation. You may have thought you were something of an authority on some one of these lines yourself, but no questions being asked, your self-confidence gradually weakens so that when you receive the final notice of the patient's discharge with "follow up nurse" you accept the inevitable Patient to report monthly to Dr. Blank.

As a social duty you call at the house of your patient and are told everything is being taken care of and you will be sent for if needed. When the month comes around you debate on the policy of sending any bill whatsoever for services—except the initial call (\$3.00). If wise, acting on past experience, you simply pass it up to profit and loss, and wonder who, among the great luminaries of modern medicine, will be your next beneficiary in the sum of some hundreds of dollars.

As a physician of thirty-five years' experience, and near the retiring age anyhow—there is little to say from the standpoint of personal grievance. I am merely pointing to one of the conditions which make general practice difficult and frequently humiliating in the extreme. The doctor today not only sees his poorer patients drifting to the clinics (often run by young physicians and admiring nurses who "make suggestions") but his richer patients constantly being beguiled by a process so subtle that it takes his breath away and leaves him wondering like the man in the play "Am I now as big a fool as I think I am?"

What can be done about it? Unfortunately, the problem is not an easy one and it is futile to pass it up by implying unworthy motives to anyone. There was a time, within the memory of individuals now living, when it was reasonably safe for the family physician to call a first class consultant without the common danger of being utterly supplanted or ignored in the further conduct of the case. His opinions were often sought and respected in the presence of the patient or members of his family. "Follow up" engagements were arranged by mutual consent. If the case proved to be one for hospital care the consultant and the general man were in constant sympathy and intimate touch with the patient.

Whether this relation of mutual respect and genuine cooperation can continue under modern conditions in such manner as to prevent the humiliating situations above outlined is difficult to say. On the whole I have nothing but profound respect for

most of the talented surgeons and specialists who have assisted me over many difficult places in the past. On the surface it would appear that the general practitioner has no other recourse than to refuse to have his private patients transferred to any closed staff hospital unless he himself is on that staff. If there is any other way to avoid the inevitable situation above suggested, the writer, as a fair representative of the fast-disappearing fraternity of the general practitioner, would like to hear from those specialists in a position to speak for themselves.

WILLIAM W. HARVEY, M.D.

114 Fenway, Boston

CONCERNING JENNER AND JOHN HUNTER

Editor, *New England Journal of Medicine*,

The following is from "The Farrington Diary" by John Farrington, R.A., edited by James Greig George H. Doran and Company, 1923.

"Of Vaccination Fame"

"September 13" (1796) "Dr. Jenner was some years ago with John Hunter (The famous surgeon), and had He preferred a town life might have been connected with him in business. He knows Louthburgh, and observed that He does not receive remarks on his work graciously.

"While Louthburgh was painting one day John Hunter remarked that a certain part was too green, 'Not green enough,' said Louthburgh, and dipping his pencil in the strongest green colour put it on the canvass.

"Foote, the surgeon, became rancorous against John Hunter, because the latter had seemed to describe a Bougie which Foote had invented, as not necessary. To revenge himself He wrote of Hunter with much malignancy and asserted many falsehoods.

"Dr. Jenner has a great opinion of the Cheltenham Waters, but they may be drunk imprudently which He sees in the countenances of many Young Ladies at the well. Above 3000 people have drank them this Season, not one who came for the benefit of them has died.

"September 24th. Dr. Jenner has found that in insane patients He has moderated their violence by keeping them sick with tartar emetic. He observed that a person is more liable to take cold who suddenly removes from cold to heat than from heat to cold. Camphor water is an excellent medicine for nervous complaints.

"September 27th. Dr. Jenner shewed us some lines which the Revd. Dr. Stevens gave him as having been written by Gray as part of his Elegy in a Country Church Yard, but were omitted.

"Some rural Lais with all conquering charms,
'Perhaps now moulders in the grassy bourne,
'Some Helen, vein to set the fields in arms,
'Some Emma dead of gentle love forlorn'"

Very truly yours,

WM. PEARCE COUES, M.D.

12 Monmouth Court, Brookline, Mass.

ARTICLES ACCEPTED BY THE AMERICAN MEDICAL ASSOCIATION COUNCIL ON PHARMACY AND CHEMISTRY

535 North Dearborn Street Chicago Illinois
December 5 1935Editor *New England Journal of Medicine*

In addition to the articles enumerated in our letter of November 2 the following have been accepted

The Calco Chemical Co. Inc.

Tablets Methenamine—Calco 5 grains

Cutter Laboratories

Diphtherin Toxin for the Schick Test, Diluted Ready for Use

Diphtheria Toxin Antitoxin Mixture 0.1 L+ (Goat) ten 3 cc. vials package

Typhoid Paratyphoid Prophylactic 10 vials package

Lederle Laboratories Inc.

Gas Gangrene Antitoxin (Polyvalent) Without Tetanus Antitoxin Globulin Lederle-Modified

Tetanus Gas Gangrene Antitoxin Globulin Lederle-Modified

Parke Davis & Co.

Gas-Gangrene Antitoxin (Combined) Refined and Concentrated—P. D. & Co.

Yours sincerely,

PAUL NICHOLAS LECHE Secretary

RECENT DEATHS

CAHILL—CHARLES SUMNER CAHILL, M.D. of 311 Prospect Street, Cambridge, Massachusetts died at his home December 10 1935 aged seventy-one years. He graduated from the Harvard Medical School in 1886 and was a Fellow of the Massachusetts Medical Society and the American Medical Association.

Dr. Cahill was active in the formation of the Cambridge City Hospital and served as chairman of the board of trustees from 1912 until December 1931. He was active in civic affairs having served on the park commission of Cambridge and as an official of the Inman Co-operative Bank and the Central Trust Company. He was a member of the Cambridge Lodge of Elks and the Cambridge Knights of Columbus.

His brother, Dr. Thomas J. Cahill of Cambridge and four sisters survive him.

LAWLOR—EDWARD FRANCIS LAWLOR, M.D., of 83 Tremont Street, Lawrence Massachusetts died at his home October 6 1935. He was born in Lawrence in 1877 educated in the public schools of that city and graduated from the Baltimore Medical College in 1905. He began practice in Lawrence soon after graduating in medicine and joined the Massachusetts Medical Society and the American Medical Association.

For a year and a half he suffered with organic diseases.

He was the surviving one of three brothers who practiced in Lawrence. He is survived by his widow Mrs. Florence Lawlor a daughter Elizabeth Lawlor a son Dr. Edward F. Lawlor an internist at the Salem Hospital, and several sisters and brothers.

LOVITT—ISRAEL MELBOURNE LOVITT M.D., of Yarmouth Nova Scotia, died at his home December 7 1935.

He graduated from the Harvard University Medical School in 1885 then spent a year in European hospitals.

He began medical practice in Yarmouth but soon discontinued it to engage in business and public library.

Several children survive him.

NOTICES

AMERICAN BOARD OF OPHTHALMOLOGY

The 1936 Examinations will be held in Kansas City May 11 at the time of the American Medical Association meeting and in New York City in October at the time of the American Academy meeting.

All applications and case reports must be filed at least sixty days before date of examination. For information, syllabuses and application forms address Dr. Thomas D. Allen, Assistant Secretary, 122 South Michigan Avenue, Chicago, Illinois.

ANNOUNCEMENTS

CHARLES E. DUMAS, M.D., announces the opening of his office at 230 Main Street, Worcester.

JOSEPH HAIN, M.D., announces the opening of an office at 146 Chestnut Street, Springfield, Mass.

REPORTS AND NOTICES OF MEETINGS

THE WILLIAM HARVEY SOCIETY

The William Harvey Society met November 8 at the Bath Israel Hospital. Dr. Cadis Phipps presiding. Dr. E. B. Pardo, Professor of Medicine at Cornell Medical School spoke on "Arteriosclerotic Heart Disease." Dr. Pardo emphasized the fact that generalized arteriosclerosis is not an indication of heart disease unless there is also sclerosis of the coronary arteries. Atherosclerotic changes in the cardiac valves may lead to aortic insufficiency or to mitral stenosis, but such changes are usually slight, unimportant pathologically difficult to diagnose and are rarely the primary cause of cardiac symptoms although they may contribute to such symptoms as are caused by other disease processes.

Hypertension is a frequent complication of arterio-

sclerotic heart disease, although its exact rôle is difficult to state Dr Pardee believes that persistent hypertension can give rise to arteriosclerosis, both generalized and coronary On the other hand hypertension can cause cardiac hypertrophy and failure without the presence of any coronary disease whatsoever

There are three forms of coronary arteriosclerosis

(1) Generalized narrowing of all the coronary system, with degeneration of the muscle cells and fibrous tissue replacement

(2) Slow narrowing of one or more branches of the coronary system with resultant localized fibrotic changes There is usually an associated generalized process of less severity It is in this type that slow but complete limited occlusion may occur without clinical manifestations

(3) Abrupt thrombosis of a previously patent vessel with myocardial degeneration and subsequent rupture or fibrosis If the thrombosed vessel is small, and if collateral circulation is good, the involved area may escape acute degeneration

One of these forms is usually predominant, but the other processes are usually found in greater or less degree in the same heart

Although arteriosclerosis is the most usual cause of myocardial fibrosis, it is also a result of chronic passive congestion, chronic rheumatic involvement, or of narrowing of the coronary mouths due to luetic aortitis or rheumatic aortic disease with calcification

Coronary disease is usually manifest by some or all of the following characteristic symptoms

(1) The angina of effort which subsides with the cessation of exertion Occasionally there is recurrence of pain at night, which is relieved when the patient assumes a sitting position This type of pain is most often associated with localized narrowing of a coronary branch

(2) Severe prostration and persistent angina occurring with coronary thrombosis The prostration may persist after the disappearance of the angina, or may be the only manifestation of coronary occlusion

(3) Chronic cardiac insufficiency, characterized by dyspnea on exertion which steadily progresses in severity over a period of years Eventually shortness of breath is existent while the patient is at rest This dyspnea is usually accompanied by some degree of cough These patients may complain primarily of easy fatigue, rather than dyspnea Ankle edema and hemoptysis are relatively late symptoms Nocturnal dyspnea of paroxysmal or Cheyne Stokes type is often a troublesome manifestation

(4) Cardiac arrhythmias are commonly encountered Of these premature beats are the most common Auricular fibrillation is of frequent occurrence, if paroxysmal, causing distress at the moment of change of rhythm, and if persistent, attracting attention only after exertion or excitement Heart block is relatively rare, resulting in Adams Stokes syndrome in its advanced form

Just as the pathological features are usually mixed, so are the symptoms However, certain correlations between the pathological and clinical manifestations of the disease may be summarized as follows

Predominant Pathology	Usually Related Symptoms
A Generalized coronary narrowing	A (1) Cardiac insufficiency (2) Cardiac arrhythmias
B Localized coronary narrowing	B (1) Angina of effort (2) Paroxysmal nocturnal dyspnea (3) Cardiac arrhythmias
C Acute coronary thrombosis	C (1) Acute persistent angina and prostration (2) Cardiac insufficiency (3) Cardiac arrhythmias

Analysis of one hundred ambulatory patients with arteriosclerotic heart disease revealed the following incidence of initial symptoms

Angina of effort	33%
Shortness of breath	24%
Coronary thrombosis	34%
Palpitation	5%
No symptoms	4%

The incidence of coronary thrombosis as an initial symptom is undoubtedly greater than the 34 per cent noted above, inasmuch as many patients do not survive the first attack

Those patients with coronary thrombosis as the initial manifestation of heart disease have a much higher incidence of subsequent thromboses than do patients with initial symptoms of cardiac insufficiency The time between subsequent thromboses is extremely variant, being as long as twenty years in some cases Giving a prognosis as to life expectancy in such cases on the basis of average time between attacks is useless, and is to be condemned inasmuch as it may cause undue alarm on the part of the patient's family

The diagnosis of arteriosclerotic heart disease is confirmed by the presence of certain physical signs Such signs are derived from four main sources

(1) Inasmuch as atheroma of the aorta is usually accompanied by coronary arteriosclerosis, signs indicative of the existence of aortic atheroma are to be considered as evidence for the coexistence of coronary sclerosis Thus, the presence of a hard ringing aortic second sound (in the absence of hypertension), a harsh systolic murmur at the aortic area, and x ray findings of aortic atheroma and prominent aortic knob, are strong evidence for the existence of coronary arteriosclerosis

(2) Cardiac enlargement in the absence of hyper-

tension or valvular disease is indicative of arteriosclerotic heart disease

(3) A faint first heart sound with a normal or increased sound shows myocardial weakness and points to coronary sclerosis. Prolongation or duplication of the first sound and gallop rhythms are of similar importance

(4) Electrocardiographic changes when properly evaluated are of distinct value in differentiating various cardiac lesions. Electrocardiographic abnormalities in patients of a given age without other possible causes are to be considered as due to coronary arteriosclerosis. The most important of these suggestive changes are the following: inversion of the T waves in the first, or second leads; a diminished amplitude of the P wave; a small or biphasic T wave; a prolonged PR interval; a small amplitude of the Q-R-S complex; or a low take off of the T wave

BOSTON ORTHOPEDIC CLUB

The second meeting of the Boston Orthopedic Club for the year was held in the Boston Medical Library on November 12, 1935. Dr. George W. You Gorder opened the meeting and briefly introduced the speaker of the evening, Dr. Sumner M. Roberts. Dr. Roberts spoke on "Dislocations and Fractures of the Cervical Vertebrae." Contrary to the opinion commonly held, a broken neck does not always mean death and if treated properly the majority of cases recover. As in the treatment of all fractures, accurate knowledge of the regional anatomy is essential and Dr. Roberts discussed the structural differences between the cervical region and the rest of the spine. The range of motion is distinctly greater particularly in the upper part of the cervical spine than in the lower vertebrae and because of the location this region is especially susceptible to injury. Accidents resulting in damage to this region usually consist in a forcible forward flexion of the neck.

Stiffness of the neck may be the only sign of a slight fracture. Tenderness over the transverse and spinous processes of the involved vertebrae is usually present and may be very marked. There is frequently a definite abnormality in the position of the head. If the fracture is very severe there may be pain and sensory disturbances in the arms as well as paralysis. This may be due to hemorrhage or edema of the cord or surrounding tissues and may be transient. If there is no evidence of cord damage and this should be carefully ruled out, the patient may sit up to be examined. When the head is held in both hands by the examiner and gently lifted upward the pain is frequently relieved. The neck should not be flexed forward during the examination. X-ray examination is often necessary to make a definite diagnosis. Dr. Roberts has found lateral stereo views to be useful.

Fractures or dislocations of the cervical spine must be reduced just as any other similar injury elsewhere and the sooner this is done, the better

the results will be. Closed methods should be used except on rare occasions. Preliminary to reduction the patient is put flat in bed on a Bradford frame with a pillow under the shoulders and the head in a simple canvas sling and five pounds of traction exerted. The head may be gradually hyperextended by the use of a collapsed pillow under the shoulders which is slowly inflated with an air pump. After reduction has been accomplished a plaster cast is applied. This cast should extend over the entire head with only a hole for the mouth, nose, ears and eyes and perhaps another for the topmost part of the head. The chin and forehead should be well padded with felt and a window should be placed over the Adams apple. After the cast is molded, a leather collar is used with a band extending around and over the brow.

The simplest type of fracture is of the spinous process. These are often multiple and require four to six weeks of fixation. Dr. Roberts has had five cases of fracture of the odontoid process in his series. The fracture usually takes place at the base of the process and a resulting dislocation of the atlas is common. This fracture gives pain high up in the neck which spreads into the occiput and there is pain on rotation of the head. Careful x-rays through the mouth should be taken to establish the diagnosis. A period of two to three months of complete fixation in plaster is necessary and this must be followed by two months with a molded leather collar and then usually two more months with a Thomas collar. For the treatment of compression fractures, Dr. Roberts gradually hyperextends the neck over a period of forty-eight hours by means of the pneumatic pillow at the same time exerting five to eight pounds traction. Exercises can be begun gradually after two months. These fractures are more apt to be in the lower portion of the cervical spine. Fractures of the laminae, articular facets and pedicles were discussed briefly.

Dr. Roberts has had nineteen dislocations in his series. They are most frequent in the upper portion of the cervical region where the articular facets are almost horizontal. They are often accompanied by small fractures and are usually caused by fairly severe injury. There is usually pain and tenderness at the site to help localize the lesion. If the dislocation is complete on one side the head is tipped to the other side and the chin tilted to the same side. These conditions should be reduced immediately by traction and hyperextension. If incomplete and by closed manual manipulation if complete. For the latter process complete anesthesia is necessary and forward flexion of the head must be prevented. The patient is placed on his back with his head flush with the end of the table and a strip going around the chin and around the doctor's waist. The head is turned to the same side as the dislocation then tipped to the other side and brought back to the midline (Walton's maneuver). As the dislocated bone slips back into place a click is often heard. Reduction of dislocations may be attempted as long as ten months after injury if there is a

In conclusion it may be said that putrid abscess is the only lung abscess of clinical importance, that it is not uncommon, and that its only satisfactory treatment is immediate surgery

The paper was discussed by Dr Elliott C Cutler, Dr Frederick T Lord, and Dr Edward D Churchill. Dr Cutler expressed a variance of opinion relative to the pathogenesis of lung abscess, stating that although aspirational pathogenesis occurs in some instances, by far the greater majority are probably embolic in origin. He doubts the ability of anaerobic organisms to penetrate the usually resistant bronchial mucosa and set up an anaerobic suppurative process. In a survey of the literature and analysis of 1500 cases only thirty per cent were definitely postoperative in occurrence. Although one half of this thirty per cent followed tonsillectomy, tonsillectomy constitutes at least one half of the surgery in the United States. Tonsillectomy cannot be condemned of undue etiological importance. He does not believe in early operative procedures because the process is still in its acute phase at that time, with inadequate walling off of the abscess, pleural adhesions are not yet adequate, and some cases may heal spontaneously. He favors delaying operative procedures until the process has become more chronic with walling off of the abscess and the pleural cavity. Dr Frederick T Lord agreed with Dr Neuhoef in considering the pathogenesis as aspirational in most cases. In his experience at least two thirds of the cases occur after operations in which aspiration of infected material is a distinct possibility. The initial symptom of cough observed in most cases of pulmonary abscess is not the initial sign of embolism, in which pain is usually the first symptom. Pleural involvement with formation of adhesions in the early stage of the disease has not occurred invariably in the cases observed by Dr Lord. He condemned the use of exploratory aspiration of lung abscesses, stating that such a procedure is not necessary for diagnosis, and is apt to precipitate a fatal hemorrhage due to perforation of a large vessel. He does not advocate the use of bronchoscopy in every patient, and believes in the use of lipiodol only to differentiate bronchiectasis and abscess. The best treatment in his experience has been surgical. He advises conservative treatment of cases as long as they are progressing satisfactorily, however, since one third of the cases will heal spontaneously, and the average operative mortality is twelve per cent. Abscesses of two months or more duration usually require surgical intervention.

Dr Edward D Churchill agreed with Dr Neuhoef in all the fundamental concepts of the disease. He expressed a divergence of opinion as to the best time for operative procedures, preferring to wait until the fifth or sixth week for firm adhesions to be formed. He uses the two stage operation, and believes that this procedure minimizes the possibility of complications, allows a more adequate "unroofing", and lessens the chance of chest wall infection.

HARVARD MEDICAL SOCIETY

The Harvard Medical Society met Tuesday evening, November 12, at the Peter Bent Brigham Hospital, Dr Milton J Rosenau presiding.

Two cases were presented, the medical case by Dr Leo Sullivan. A twenty-two year old male Greek was first seen nine and a half months ago, at which time he gave a history of five or six months of recurrent joint pains, affecting ankle, wrist, elbow, and shoulder joints, with associated weakness, insomnia, malaise, and anorexia. He had spent two and a half months in bed prior to his entry to the hospital, and had lost thirty to forty pounds during this period. Physical examination at that time showed him to be markedly undernourished, and to be suffering from generalized muscle and bony tenderness. The spleen was palpable four fingers below the costal margin, and there was questionable enlargement of the liver. Laboratory studies were normal except for a hemoglobin of sixty per cent, and a white count of 18,000.

During his stay he was given intravenous administration of typhoid vaccine, with subsequent relief of his pain. It was noted that tender subcutaneous nodules appeared on both forearms. He was discharged home with instructions to remain in bed, which he did not do. He suffered exacerbations of his symptoms and an increase in number and painfulness of the subcutaneous nodules. He was admitted to the Boston City Hospital where one of the nodules was excised, and the diagnosis of periarteritis nodosa made on the basis of the histological picture of this tissue. Following this he had an irregular course of exacerbations and remissions of symptoms, the nodules swelling and becoming painful when he was physically active, and subsiding during bed rest.

On entry he was found to have gained twenty five pounds since he was last seen, and to have improved markedly as to his general condition. Small freely movable lymph nodes were present in the cervical and axillary regions, the spleen and liver were both palpable four fingers below the costal margin. There was generalized bony and muscular tenderness, and over his left leg there were reddish areas one half to one and one half centimeters in diameter which showed thickening of the skin. No nodules were present on the legs, although they could be felt on both arms. Laboratory findings were negative except for a hemoglobin of sixty-eight per cent. Biopsy of one of the subcutaneous nodes confirmed the diagnosis of periarteritis nodosa. Occasionally patients with this disease show pulmonary changes simulating tuberculosis, but the chest plates in this case were negative. The temperature and white blood count continued normal. He was again receiving intravenous administration of typhoid vaccine with relief of pain. Evanescent nodules appeared over his arms, persisting one to four days, with gradual disappearance. No eosinophilia was observed.

Dr Marshall N Fulton in discussing the case commented on certain similarities between the signs and symptoms presented by this patient on his first admission and those described in Felty's syndrome (infections arthritis with splenomegaly). The subcutaneous nodules were at first believed to be the nodules occasionally observed in rheumatoid arthritis although the distribution was not characteristic of the latter disease. Twenty per cent of patients with periarthritis nodosa have subcutaneous nodules biopsy of which allows the diagnosis to be made. In the absence of these peripheral nodules the manifestations of the disease are so bizarre and confusing that the diagnosis is rarely made during life except in cases subjected to exploratory laparotomy in which nodules may be found in the intra-abdominal arteries. Some cases have extensive liver involvement and jaundice others may have involvement of the meningeal arteries and show signs suggestive of meningitis.

Dr Robert Bates presented a case of man bite fever from the surgical service. A forty-nine year old Greek hotel keeper entered with a swollen painful right hand, which had increased in size and painfulness since he was bitten by an inebriate one week previously. For a period of approximately forty-eight hours after the infliction of the wound there was little untoward reaction except for moderate swelling and pain locally. After this period of mild symptoms there was an abrupt onset of acute illness with a rise of temperature to 102.4 F., prostration and enormous swelling of the hand to three times its normal size. The whole hand was a dark purple hue except for the fifth finger which was white and exuded extremely foul smelling pus. There was no lymphadenopathy. The blood showed a leucocytosis of 19,400 with ninety-one per cent polymorphonuclear leucocytes. Blood culture was negative. Smear of the lesion showed a myriad of various organisms with many staphylococci, streptococci and gram positive rods. Culture from the lesion revealed growth of anaerobic hemolytic streptococci only. The fifth finger was amputated but the process extended to the fourth finger which also had to be removed. Since the operation the hand had shown marked improvement although the temperature was still fluctuating between 100 and 102 F.

Dr Elliott C Cutler compared human bite wounds with gangrene of the lung. They show characteristically a period of twenty-four or forty-eight hours with little sign of infection and then gradual onset of gas formation, with the presence of innumerable organisms. The Welch bacilli causing such infections seem to be of lower virulence than those encountered in other cases of gas gangrene and these lesions are as a rule more easily controlled.

Dr Rosanna in introducing Dr Frederick F Russell, lecturer in Preventive Medicine and Hygiene at the Harvard Medical School told of Dr Russell's pioneer work in the study and control of typhoid and dysentery and of his introduction of vaccination against typhoid fever. Dr Russell presented the ad-

dress of the evening his topic being "Recent Studies in Yellow Fever—a Virus Disease." Extensive studies of Aztec literature and of the records of the Portuguese navigators have proved that yellow fever was originally an African disease and was first brought to the western hemisphere by the importation of Negro slaves to Gadeloupe. From this island it was carried over the Caribbean and to the mainland by the haccaneers. The possibility that the *Aedes aegypti* mosquito might be the carrier of the disease was first suggested by Carlos Finlay although he never proved the fact conclusively. Carter studied a yellow fever epidemic in Louisiana and established the existence of the extrinsic period of incubation which was very suggestive of the existence of an insect vector. The army commission under the direction of Walter Reed proved that the disease was carried by the *Aedes aegypti* mosquito and devised a method for control.

Carter and Shannon found that the *Aedes aegypti* breeds only in artificial collections of water due to the clumsiness of the larval forms which easily fall prey to other larvae in natural waters. This mosquito is a poor flier and experiences difficulty in crossing even a wide city street. It passes more readily from back yard to back yard and across narrow streets and alleys.

Davis found that the length of the extrinsic incubation period varies inversely with the temperature at which the mosquito is kept. This period is apparently the length of time required for the virus to pass from the gut to the salivary glands of the insect. Davis also proved that the virus does not multiply within the mosquito but diminishes gradually in concentration throughout the insect's life. The mosquito is not injured by the existence of the virus in its body and its natural life span of about six weeks is not shortened by infection.

Recent laboratory studies have shown that no less than twelve other species of mosquito are able to carry yellow fever and at least one epidemic in Brazil has been traced to the *Aedes scapularis*. There is also a possibility that infected ticks can carry the disease if they are crushed on the skin.

The researches of Noguchi into the etiology of the disease are well known. His work unfortunately was performed on patients suffering from infectious jaundice and he isolated the *Leptospira* responsible for that disease and not the organism causing yellow fever. Stokes, Baner and Hindsen succeeded in infecting Indian monkeys with inoculations of blood from active cases of yellow fever. They also succeeded in perpetuating the virus for long periods of time in mosquitoes. More recently Max Tyler has infected mice by injecting the virus intracerebrally.

The European hedgehog has been found to be susceptible to the disease and related species in South America and Africa are being studied to determine whether these animals acting as hosts for the bacilli may be responsible for the continuance of the disease in these regions.

The distribution of yellow fever, previously so widespread, has been narrowed in recent years, until it now embraces a relatively narrow band on either side of the equator in South America and Africa

Immunity conferred by an infection is lasting throughout life. The persistence of positive protection tests, after a lapse of seventy-five years from the infection, suggests that some focus of infection may be existent in the body, although no such focus has ever been demonstrated. Protection tests have shown that many subclinical infections of yellow fever escape positive diagnosis. Laboratory tests are not of aid in making the diagnosis in the first ten days of the disease, and clinical signs must be relied upon during this period.

The control of the disease is best effected by mosquito control in cities and thickly populated districts, but in sparsely settled, tropical regions such measures are not practical. Attempts at vaccination with dead virus have been uniformly unsuccessful, and it has been impossible to attenuate the virus sufficiently by animal passage. Recently, however, attempts at attenuation by growing the virus in tissue cultures seem to have been attended by some success.

Serum virus mixtures have been successfully used as vaccines in both Africa and South America, and this kind of vaccination has completely stopped infections among yellow fever laboratory workers.

THE NEW ENGLAND HEART ASSOCIATION

The first meeting of the New England Heart Association for the current year was held in the Ether Dome of the Massachusetts General Hospital October 28, 1935.

The meeting was opened by Dr. Paul D. White who presented a pathological specimen of chronic constrictive pericarditis. The patient was thirty-one years old and showed the classical signs and symptoms of Pick's Disease one year after an acute pericarditis of unknown origin: enlarged liver, ascites, engorged neck veins and but slight enlargement of the cardiac dullness without murmurs. There was fluid in both pleural cavities. She was too ill for operation. At autopsy the heart showed a closely adherent, greatly thickened pericardium about one-half centimeter thick. Dr. White believed that the patient could have been cured if Dr. Churchill and he had arranged to receive the patient for operation a few months earlier.

Dr. Sylvester McGinn spoke briefly of a triangular pad of fat that often is normally found at the left pericardial diaphragmatic angle outside of the pericardial sac. Because of its position it may cause confusion in accurately measuring the left border of the heart in soft x-ray films and because of this possible error, it must be kept constantly in mind. Orthodiagraphy easily avoids this error as does also physical examination. Dr. White spoke of his having had actually to testify in court concerning a case in which the size of the heart had been over-

estimated by the inclusion in the transverse diameter of 2 cm. of fat at the left pericardial diaphragmatic angle.

Two unselected cases of congenital heart disease were then presented to the audience by Dr. White for diagnosis. The first was a woman of sixty-four who had had a transient hemiplegia and who presented occasional extrasystoles, an enlarged heart, and a continuous humming murmur with a systolic thrill at the second interspace just to the left of the sternum. Dr. Samuel Levine correctly diagnosed this as a case of patent ductus arteriosus. The second patient was a child of four and a half years who tired easily, was dyspneic, had palpitation, and coughed frequently. There were a systolic thrill and a loud systolic murmur most marked in the third left interspace. The enlargement found by x-ray was thought by the roentgenologist to be consistent with a rheumatic heart. Electrocardiogram showed an *s a** tachycardia with a slight right axis deviation. At autopsy an interventricular septal defect was found. Dr. Paul Emerson correctly diagnosed this case at the meeting. Dr. White presented these problems, drawn at random, to counteract somewhat the impression that the diagnosis of structural defects in congenital heart disease is usually difficult or impossible, especially in children. He did agree, however, that in infants under six or eight months of age the diagnosis is far more difficult than in older children and adults.

Dr. McGinn then briefly reviewed the experience at the Massachusetts General Hospital in the past ten years as to the accuracy of diagnosis of congenital heart lesions. It was found that thirty-nine per cent of all the congenital heart cases had been either correctly diagnosed or the correct diagnosis suspected, and this was increased to sixty-three per cent if the entirely symptomless and signless valvular defects and coronary peculiarities were excluded. It was pointed out that in cases with congenital abnormality of the coronary arteries there may be inverted T waves in the electrocardiogram, that in cases of auricular septal defects there are large right auricle, right ventricle, and pulmonary artery and a small aorta, and that hearts with bicuspid aortic valves often develop subacute bacterial endocarditis but that there is nothing by which to diagnose the congenital heart lesion. Dr. White adds that there are now eight congenital cardiovascular defects that are diagnosable in adults and in children above infancy, provided sufficient care is taken in assessing all the signs, these are as follows: (1) patency of the ductus arteriosus, (2) interventricular septal defect, (3) interauricular septal defect, (4) the tetralogy of Fallot, (5) uncomplicated pulmonary stenosis, (6) coarctation of the aorta, (7) a right aortic arch, and (8) congenital heart block. In infants the diagnosis of idiopathic cardiac hypertrophy is also usually possible.

Dr. H. B. Levine spoke on pulmonary infarction complicating severe chronic mitral valve disease and

**Sinu auricular*

reported five recent cases. It was found in a series of fifty-two cases of mitral stenosis studied that 61 per cent of those with failure (twenty-six cases) had pulmonary infarction (there were only four cases without failure who developed this complication) in contrast to only 25 per cent of the twenty-four cases of hypertensive heart disease with failure who had infarction in the lungs. The cases which were presented demonstrated the fact that in mitral stenosis with failure the development of pulmonary infarction makes the patient refractory to treatment and the prognosis bad. This common complication is frequently missed and should be suspected if any of the common signs and symptoms of pulmonary infarction occur and especially if the patient is not doing well. Dr. Soma Weiss pointed out the hopeless prognosis in patients with congestive failure who develop jaundice and said that in Germany where more careful dissection of the whole body at autopsy is carried out than in this country thromboses in the veins of the legs are frequently found in cases of mitral stenosis.

Dr. H. B. Sprague discussed "A New Method in the Treatment of Paroxysmal Tachycardia." If the attacks of tachycardia are frequent and prolonged or if the patient also has organic heart disease it may become absolutely essential to limit their incidence and duration. A case was presented of a surgeon of fifty-four who has pure rheumatic aortic regurgitation and has had increasingly frequent attacks of paroxysmal tachycardia over the past eight years. In spite of all the usual methods his attacks continued to become more frequent and to last longer and he began also to have anginal distress during them. On one occasion an attack lasted seventy-two hours. Mecholyn failed to help and upon Dr. Soma Weiss's advice a syrup of Ipecac was administered. This produced very severe and prolonged nausea, and the attack ceased. Since this time the patient has frequently used this method with remarkable success and he has greatly reduced the duration of attacks, saving his heart many thousands of wasted beats. He uses two drachms of the syrup of Ipecac at the onset of an attack. Dr. Weiss discussed the method briefly. It has been used for some time at the Boston City Hospital. It is better than other emetics because it contains alkaloids that act centrally on the vagal center as well as having a local irritant action. The long-continued nausea and the accompanying vagal stimulation have never failed to stop an attack.

Dr. R. E. Glendy discussed the normal precordial lead (Lead 4) of the electrocardiogram. The P wave may be upright, inverted or diphasic. The QRS complex usually has a total amplitude twice that in other leads. The Q-wave is usually inverted and the QRS complex is slightly longer in duration than in the classical leads. The T wave is inverted but within very wide limits of amplitude. Dr. A. Graybiel presented the abnormal lead 4. This lead may give the earliest evidence of coronary thrombosis when the ST segment is diphasic or displaced

far downwards or the only evidence of old infarction at the apex of the left ventricle when the Q waves disappear. In posterior wall infarctions there is usually little or no change in lead 4. A shallow T wave in lead 4 may be caused by digitalis especially a high ST interval. Generally lead 4 abnormalities are in agreement with those in the classical leads. Occasionally lead 4 fails to show an abnormality when it is evident in the other leads and vice versa. Dr. White in conclusion pointed out that the precordial electrode should be applied just median to the apex, that lead 4 is occasionally useful but that it needs much further study.

WORCESTER DISTRICT MEDICAL SOCIETY

The regular monthly meeting of the Worcester District Medical Society was held at the Grafton State Hospital on Wednesday evening November 18, 1936 with Dr. William F. Lynch in the chair and Dr. Erwin C. Miller as secretary.

Dr. Harlan Paine was host at an excellent buffet supper which was served in the main auditorium prior to the meeting. After disposing of routine business Dr. William Lynch turned the duties of the presiding officer over to Dr. Paine, the Superintendent of the Grafton State Hospital.

Dr. Paine then presented the President of the Massachusetts Medical Society, Dr. Charles E. Mongan, who was enthusiastically welcomed by all the members present. Dr. Mongan called the attention of the members of the Society to the medical aspects of the Social Security Act. He also reminded them of the very excellent work and interest in the State Society by former doctors in Worcester County and urged each member of the Society to take an active interest in medical and civic affairs.

Dr. William R. Morrison, Chairman of the Committee of Arrangements for the next Annual Meeting of the State Society was introduced. He asked for the advice and support of the Society's members in making the next Annual Meeting a most successful one and requested that the dates of the Annual Meeting and dinner in Springfield next June 8, 9 and 10 be reserved for attendance at the meeting. Dr. Morrison said that a most excellent scientific and commercial program is being prepared for the Springfield meeting.

Dr. Benjamin Cohen, Research Member of the Grafton State Hospital Staff spoke on Repression Communicability in Catatonic Stupor. He was followed by Dr. Bardwell Flower, Assistant Superintendent of the Grafton State Hospital who talked on Parenteral Paraldehyde.

The meeting adjourned at 10 P. M. There were 130 doctors present at this meeting.

ERWIN C. MILLER, M.D. Secretary

ESSEX NORTH DISTRICT MEDICAL SOCIETY

The semi-annual meeting of the Essex North District Medical Society will be held at the Riverside Tavern, Haverhill, on Wednesday January 8, 1937.

at 12 30 P M The entire program will be in charge of Dr Charles E Mongan, President of the State Society, and will be entirely devoted to medical economics

E S BAGNALL, *Secretary*

MASSACHUSETTS MEMORIAL HOSPITALS

There will be a meeting of the Surgical Section in the Ladies' Aid Room, Talbot Memorial, 82 East Concord Street, Boston, on Friday, December 20 1935, at 12 noon

Papers will be presented by Dr Harry J Lee and Dr Kenneth Christophe

MILO C GREEN, *Secretary*

GREATER BOSTON BIKUR CHOLIM HOSPITAL

Greater Boston Bikur Cholim Hospital medical meeting Monday evening, December 23, at 8 15 o'clock, at the Nurses' Home, 45 Townsend Street, Roxbury Speaker Dr Soma Weiss Subject "Seven Aspects in the Management of Chronic Patients" The profession is invited

HENRY BAKER, M.D., *Secretary*

NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held at the Peter Bent Brigham Hospital, Boston, Mass., Monday, January 6, 1936, at 8 15 P M

PROGRAM

I Business Consideration of revision of Constitution and By-Laws

II Clinical

- 1 A Method of Determining Blood Volume Dr J G Gibson, 2nd
- 2 Blood Volume Changes in Congestive Heart Failure Dr William Evans
- 3 Concerning the Mechanism of Hypertensive Crises Dr Michel Pijoan
- 4 Hemopericardium as a Cause of Sudden Death Dr Marshall N Fulton
- 5 The Early Diagnosis of Aortic Stenosis Dr Samuel A Levine
- 6 Aortic Stenosis, Angina Pectoris, and Syncope Dr A W Contratto
- 7 Is Digitalis Present in Body Fluids in Digitalized Patients? Dr Maurice A. Schnitker

All members and interested physicians are invited to attend

JAMES M FAULKNER, M.D., *Secretary*

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING MONDAY, DECEMBER 23, 1935

Tuesday, December 24—

2 30 P M Pediatric Ward Visit. Massachusetts Eye and Ear Infirmary

Thursday, December 26—

*8 30-9 30 A M. Clinic, Surgical Staff of the Peter Bent Brigham Hospital, at the Peter Bent Brigham Hospital

Saturday, December 28—

*10-12 Staff rounds at the Peter Bent Brigham Hospital

*Open to the medical profession

December 20—Massachusetts Memorial Hospitals, Surgical Section See notice elsewhere on this page

BOOK REVIEWS

Bernardo de Gálvez in Louisiana 1776-1783. John
Walton Caughey 290 pp California University
of California Press

In this valuable monograph the author gives in
Part One The Background a complete account
of the establishment of Spanish control in Louisiana
and takes the reader in part two through Gálvez's
administration and the Spanish struggle for domina-
tion of the Mississippi and the capture of Mobile.

After the capture of Pensacola, the author tells
us that Gálvez was ordered to undertake the con-
quest of Jamaica, but after many delays and contro-
versies we are told that Rodney's victory over De-
Grasse brought the whole project to a standstill.

Gálvez returned to Spain, coming back to the New
World in 1781 as Captain General of Cuba but soon
he was sent to Mexico City to succeed his father as
Viceroy of New Spain His rule was short, however

as he died on November 30, 1786, apparently of yellow fever. He was then thirty-eight years old. He was mourned by all. "New Spain would praise him, and sing of a perfect Viceroy, a most upright Judge."

There is much of interest in this monograph to American physicians, who will enjoy the well documented and accurate account of the Spanish occupation of Louisiana.

1000 Questions and Answers on T. B. Edited by Fred H. Heise. 232 pp. New York City: National Tuberculosis Association.

This book of some 200 pages consists of a group of questions and answers relating to every phase of the tuberculosis problem, grouped in sixteen chapters.

It will prove of distinct value not only to the public at large but to the medical profession desirous of getting accurate information and advice from a well recognized authority on the subject concerning any point relating to tuberculosis.

The index makes it possible to find the answer easily and quickly.

The need for books of this type which are short, compact, low-priced and yet authoritative is a very real one. Such a book as this is welcome.

International Clinics. Volume II. Forty-Fifth Series, 1935. Edited by Louis Hamman. 327 pp. Philadelphia, Montreal and London: J. B. Lippincott Company.

As in preceding volumes, this one is marked by a group of excellent articles by authors well known for their contributions in their respective fields and well worth reading. Dr. Hamman in addition to editing this fine volume has also contributed a very interesting article.

The Medical Man and the Witch during the Renaissance. Gregory Zilboorg. Third Series, Volume II. 215 pp. Baltimore: The Johns Hopkins Press. \$2.50.

This volume consists of three lectures given before the Institute of the History of Medicine, Johns Hopkins University. It is the second of the Hideyo Noguchi lectures, the first of which, "The Renaissance of Medicine in Italy", by Arturo Castiglioni, was published in 1934 and reviewed in *The New England Journal of Medicine*, March 15 of the same year.

Dr. Zilboorg, a psychiatrist, presents a topic of unusual interest. For many years he has been studying the history of psychiatry and these lectures testify to his scholarship and spirit of investigation. The first lecture concerns itself largely with an account of a book, the "Malleus Maleficarum", first issued in the last years of the fifteenth century. This volume became the leading and practically the only textbook on the Inquisition and, before 1669, was printed ten times. It thus was a popular and useful book for its time, for it

"proved" the existence of witchcraft and witches and had behind it the authority of the church of Rome. Upon the basis of this book men assumed the power of judgment and many hundreds of people were burned as witches in the sixteenth century. A second lecture covers more definitely the relationship between witchcraft and medicine, and the third lecture is given over entirely to an account of Johann Weyer, the founder of modern psychiatry. Zilboorg's account of Weyer is by far the finest in existence and much of the value of this work for future historians lies in his excellent account of this man.

The book is heavy with quotations and facts, the style is not light, and the volume cannot be recommended for popular reading. For the serious student of medical history, however, it will have a definite appeal and it forms a worthy addition to the publications already issued in this series.

Historie Des Universités Françaises et Etrangères. Stephen D'Irsay. Tome II. Du XVII^e Siècle à 1860. 457 pp. Paris: Auguste Picard.

The first volume of this interesting history of the universities was reviewed in *The New England Journal of Medicine*, February 1, 1934. Before the second volume could be issued the author died a tragic death in Paris, November 16, 1934. Estimates of his importance to the history of medicine will be found in the *Bulletin of the Institute of the History of Medicine*, Johns Hopkins University, for June 1935. The second volume of his work, which is now at hand, has, therefore, been issued posthumously. The manuscript, however, was finished before the author's death and it was only the setting up and printing which had to be supervised. This has been splendidly done and the volume is in every way comparable with the first part of the work issued a year ago. In addition, one finds as an appendix a list of the manuscripts consulted, an extensive biographical index of inestimable value to scholars, and a complete index to both volumes.

The Evaluation of Symptoms. Offered after fifty years in medicine. Oliver T. Osborne. 163 pp. New Haven: The Yale University Press. \$3.50.

Solidly packed with precious material, important and useful, this little volume, privately printed by the author, should be on every doctor's desk and in every intern's coat pocket. With his wide experience Osborne is certainly the philosopher to discuss a considerable group of symptoms and their value to the clinician. As he well remarks only the consultant can ignore the complaints of the patient. Many a medico has built his reputation, and no mean one, on an uncanny ability to understand and relieve the complaints of his charges. And both care little whether a diagnosis is ever made. In this little book, which should be followed by others of its kind, there is nothing stale or irrelevant. Old truths are emphasized and new ones clarified. Rarely has a work given the reviewer so much genuine pleasure and profit.

NUMBER 26

NEW ENGLAND SURGICAL SOCIETY

STONES IN THE COMMON AND HEPATIC BILE DUCTS*

BY FRANK H. LAHEY M.D.,† AND NEIL SWINTON M.D.†

In eighteen hundred patients operated upon for gall stones in the Clinic, the common and hepatic ducts have been opened, explored for stones and drained in five hundred and thirty-one cases, approximately in thirty per cent of this group. Common duct stones have been found and removed in two hundred and fifty-eight cases, approximately fifteen per cent of the cases. Of these two hundred and fifty-eight cases, it has been possible to obtain satisfactory follow-up data in two hundred and twenty-one. The mortality for the two hundred and twenty-one followed proved common duct stone cases was 7.6 per cent as compared with a mortality of 3.8 per cent for the entire eighteen hundred unsegregated cases of cholelithiasis upon which we have operated exactly twice as high. The mortality in all cases having had common duct exploration was 4.3 per cent. We have lost only one patient following a common duct exploration which did not have stones in the ducts. The fact that in this series stones

common and hepatic stones in operations for cholelithiasis and to discuss some of our experiences with common and hepatic duct cases.

It is interesting to note that in our series, common and hepatic duct stones were found four times more often in women than in men due no doubt to the predominating number of females who have the condition as compared with males.

*21

were found in the gallbladder in the presence of common and hepatic duct stones in ninety-six per cent of the cases, the fact that by increasing the number of ducts which we now explore we have markedly increased the number of cases in which we have found common duct stones and the fact that jaundice the sign upon which the diagnosis of common duct stones used to hinge was absent both in the history and at the time of operation in thirty-nine per cent of these two hundred and twenty-one cases makes it desirable we believe to analyze these two hundred and twenty-one cases of surgically proved common and hepatic duct stones, to stress again the fact that particularly based upon older indications for exploration of the ducts, it is very easy to leave

These figures are of interest and value chiefly as relates to the fact that 7.4 per cent of these surgically proved cases were under thirty years of age. One does not usually think of stones being present in the common and hepatic ducts in relatively young people, yet when one notes that we have removed stones from the main bile

TABLE 3
SYMPTOMATOLOGY

A	Duration	
	Less than 1 month	13%
	1 month to 1 year	33%
	1 year to 5 years	26%
	5 years to 10 years	1.6%
	11 years to 20 years	11%
	Over 20 years	4%

Forty-six per cent had symptoms of less than 1 year's duration

ducts in a girl of seventeen and that of the whole series, one out of every thirteen surgically proved cases was under thirty years of age it is obvious that common duct stones are not confined to middle-aged and aged.

One notes in table 2 the successful removal

Read at the Annual Meeting of the New England Society at Society at Manchester N. H. September 2, 1935.

†Lahey, Frank H.—Director, Lahey Clinic, Swanton, Mass.—Surgeon, Lahey Clinic. For records and address of authors see "This Week" issue, page 1319.

of common duct stones in a patient of eighty-four years, a doctor's mother and seven cases between seventy and eighty years, but we wish to state emphatically that such operations at this age attended as they are with such a high risk rate, have never been done as duct explorations but as last resort measures in the presence of persisting or recurring colic or jaundice associated with cholangitis as evidenced by marked temperature reactions

A The fact that forty-six per cent of the cases had had symptoms for less than one year is, we believe, a tribute to the intelligence of the patients and doctors of this community and an indication that the attitude of the past against which we have for several years inveighed is changing, that is, the tendency both of the patient and family-physician to permit numerous attacks of gallstone colic to occur before deciding for surgery

TABLE 3

B Right upper quadrant colic
172 or 80%

B Right upper quadrant colic was present in one hundred and seventy-two of the cases or eighty per cent of the total. In twenty per cent, it was absent. When one appreciates that in twenty per cent of the cases in which common duct stones were found and proved by surgical removal, colic was not present, it is obvious that if we do not wish to leave common duct stones after cholecystectomies in patients who will later bother us and be reoperated on with higher risk rates, we must explore more common and hepatic ducts and upon different criteria than has often been the case in the past

TABLE 3

C Chills and Fever
9 or 4.2%

C Chills and fever were present in these two hundred and twenty-one proved cases with common and hepatic duct stones in a much lower percentage than one would expect, due we believe, to the fact that such a large percentage of the cases were operated upon early, due to the high percentage of ducts explored and due to the considerable number of cases in which the stones were small, not causing obstructive symptoms and probably having existed but for a relatively short period of time. One can, we believe, properly assume that a considerable number of patients in whom unsuspected stones were removed from the common duct at the time of cholecystectomy could have been saved from the dangers and difficulties associated with later deep jaundice and associated cholangitis

In reviewing our gall-stone cases, we have made three different studies of the percentage

of cases with surgically proved stones in the main bile ducts who were not and had never been jaundiced and it is of interest to note these percentages in the sequence of their determination. In the first series, thirty-seven per cent were without jaundice, in the second thirty-nine per cent and in this series, thirty-nine per cent. We have said before and again call attention to it that in over a third of the patients in whom stones have been found and removed from the common duct, jaundice was

TABLE 3

D Jaundice, present in the
history or physical ex-
amination 129 cases or 61%
Absent in both history
and physical examina-
tion 81 cases or 39%
(10 cases not given)

at no time present. This also helps to account for the low percentage (4.2 per cent) of serious cholangitis as seen in table 3C. These figures indicate that jaundice as an indication to explore the common and hepatic bile ducts is unreliable, and that where explorations limited to those cases in which jaundice was present or had occurred in the history, common duct stones might have been left behind after cholecystectomy in eighty-six out of the two hundred and twenty-one cases.

TABLE 4

X-RAY FINDINGS

Out of 95 Cases of Proved Common or Hepatic
Duct Stones with X-Rays

Intravenous dye positive for stones in the gallbladder	70
Oral dye positive for stones in the gallbladder	10
Flat plate positive for stones	13
Intravenous dye negative for stones in the gallbladder	2
X-ray diagnosis for gall stones was accurate in 98% of the cases x-rayed	
Forty-three per cent of the entire series of two hundred and twenty one cases had gallbladder x-rays	

This is about the usual x-ray finding in anyone's hands and is convincing evidence of the accuracy of x-ray diagnosis in cholelithiasis

TABLE 5

ACCURACY OF DUODENAL DRAINAGE IN 32 CASES

Duodenal drainage positive for stone	30 cases
Duodenal drainage negative for stone	2 cases

In thirty-two cases in which duodenal drainage was employed as a diagnostic measure in patients with questionable cholelithiasis, the positive factor being calcium or cholesterol

crystals in the drainage sediment and in all of which cases common or hepatic duct stones were demonstrated at operation, thirty cases were positive for stones and two cases negative for stones. This is another available diagnostic measure in doubtful cases of common duct stones and has its greatest value in those cases where common duct stones are suspected after a cholecystectomy has previously been done and therefore, x ray diagnosis not available. It is in these cases that it is so desirable to have some preoperative aid in deciding for or against reoperation and exploration of the common duct.

TABLE 6

END RESULTS IN 141 FOLLOWED CASES

1 Excellent	110 years	94.5% of the cases
2 Probable recurrent common duct stones		6.5%
3 Operative mortality		7.6%

Sixty four per cent were followed from one year to ten years

The cases in the second group have not all been proved definitely as having recurrent common duct stone. Cases are included in this group which have had colic following operation suggestive of common duct stone but there are several which we have not been able to bring to reoperation.

The cases in the second group have not all been proved definitely as having recurrent common duct stone. Cases are included in this group which have had colic following operation suggestive of common duct stone but there are several which we have not been able to bring to reoperation.

Sixty four per cent of the cases or one hundred and forty-one cases have been followed from one to ten years.

An excellent result (freedom from pain and jaundice) has been obtained in 94.5 per cent of these cases.

Probable recurrent or persisting common duct stones has occurred in 5.5 per cent of the cases.

Not all of the cases in this latter group have been proved by operation to have common duct stone but even though some of the cases may not have recurrent or persistent stones included in this group are all cases with colic after removal of common and hepatic duct stones. This is an extremely good showing as to end results and much better than I had expected would be the case because of the uncertainties at least up to recently of complete removal of all duct stones.

TABLE 7

1 Stones in both the gallbladder and bile ducts	212 or 96%
2 Stones in the biliary ducts only gallbladder being negative	9 or 4%

The fact that stones existed coincidentally in the gallbladder and in the common and hepatic ducts in two hundred and twelve cases, 96 per

cent, speaks in favor of the fact that whatever causes stones in the gallbladder tends likewise to result in stones in the bile ducts. When one realizes, however, that following removal of the gallbladder and removal of the stones from the common and hepatic ducts, there have been but 5 per cent recurrent stones, there is at least a suggestion of what we have always thought to be true, that long standing infection of the gall bladder results in eventual infection of the common and hepatic ducts which is relieved by removal of the gallbladder, drainage of the duct and removal of its stones.

With the introduction of the Bakes ampulla dilators by the passage of which the sphincter of Oddi can be so dilated that any average-sized common and hepatic duct stones will pass into the duodenum it was hoped that the danger of leaving behind small common duct stones was overcome.

We have now employed these dilators in a good many cases and with no intention to be critical of what appears to be a real advance in common duct surgery but with a desire to be helpful and frank about our own experience, we have to report that in two cases where we have widely dilated the ampulla gas bacillus infection resulting fatally has occurred apparently ascending from the duodenum through the dilated ampulla along the bile channels. Antopies were performed in both of these cases so that there can be no question about the cause of death and there seems little question about the origin of the infection. This experience must make us at least cautious in dilating these sphincters widely so that regurgitation of duodenal drainage into the ducts can occur. In a personal communication Dr Arthur Allen reports that this has never occurred in over two hundred dilations of the sphincter at the Massachusetts General Hospital.

It is disappointing to report these two unfortunate deaths because there are so many advantages to dilatation of the sphincter of Oddi. When a large dilator can be passed through the sphincter one is quite certain that any stones at the ampulla have been removed and that if small ones are left they will be washed down through the widely dilated duct by the secretory pressure of the bile within the ducts. One cannot, however, fail to appreciate the possible dangers of the method in the presence of these two proved fatalities and it would be wrong not to call everyone's attention to them.

These figures of the percentage of common and hepatic ducts explored have been published several times before. To these figures we have added the percentages explored and the percentages of stones found for the years nineteen thirty three, nineteen thirty four and for the present year up to September, nineteen thirty five, as graphic evidence of the incidence of stones discovered in the main bile ducts by

widening the indications for exploration of the ducts

As the result of this fairly large experience with common and hepatic duct stones, we have arrived at some quite definite convictions

There has been at least an impression that adding exploration of the main bile ducts to cholecystectomy, adds definitely to the operative risk of gallstone operations. Granted that the surgeon has had sufficient experience with

COMMON DUCT STONES

Common Ducts	Cases Explored	Stones Found	Total Cases
1910 26	96 15 %	52 8 4%	619
1927 28	91 32 7%	38 13 7%	278
1929 30	49 35 8%	22 16 1%	137
1930 31	61 42 5%	30 21 %	138
1931 32	45 38 %	22 19 %	118
1932 33	52 46 %	24 21 2%	113
1933 34	42 35 %	21 17 6%	119
1934-35	48 35 %	17 12 %	143
1935 to September, 1935	48 44 %	21 18 9%	112

common duct surgery, we do not believe that this is so. We are further convinced that even if the above impression were so, one would still have to have in mind that the eventual mortality of secondary operations for stones overlooked and left behind would have to be added to the primary mortality of cholecystectomies with a lower percentage of duct explorations if a fair comparison were to be made of the two types of operative procedure.

As the result of this experience, we are convinced that it is the obligation of all surgeons who operate on patients for gallstones to make every reasonable effort to be certain that, in operations upon the gallbladder for gallstones, or cholecystitis (recall that stones were found in the bile ducts with no stones in the gallbladder in four per cent of the cases) stones are not left in the main bile channels. In order to do this, one must establish, we believe, wider criteria for opening and exploring the common duct than have been commonly employed by many surgeons in the past years. We believe that common and hepatic ducts should be explored in all jaundiced patients and in all patients in whom a reasonably recent history of jaundice is present, in all patients with a markedly thickened or contracted gallbladder since long-standing cholelithiasis and gallbladder infection make conditions so favorable for the production of duct stones and is so frequently associated with stones. We believe that the common and hepatic ducts should be opened and explored when the common duct is either thickened or dilated particularly when the gallbladder has not previously been removed. We believe that the common and hepatic ducts should

be opened and explored when any suspicious lump suggesting stone can be felt on palpation of the ducts between the palpating thumb and finger.

We believe that the common and hepatic ducts should be opened and explored particularly in the presence of cholelithiasis or cholecystitis when the head of the pancreas is so thickened and indurated that stones at the ampulla of Vater within the thickened head of the pancreas could be overlooked. We believe that the common and hepatic ducts should be opened and explored when bile withdrawn into a hypodermic syringe, the needle of which has been passed into the duct, is not golden yellow in color and perfectly transparent and clear in character. While valuable information may be obtained by this latter procedure, we have not considered or recorded this measure as an exploration of the ducts.

Even in the presence of the above indications, we have found stones in only fifty per cent of the cases in which with these indications the ducts were explored. We believe, however, that stones exist in the main bile channels so often without definite evidences of their presence (jaundice, ability to palpate them, contracted gallbladder or dilated ducts) that many negative explorations must be made to accomplish a high percentage of complete removal of duct stones and a low percentage of a return of symptoms after the removal of the gallbladder for cholelithiasis or cholecystitis. (See table.)

CONCLUSIONS

A study of two hundred and twenty-one cases of common and hepatic duct stones is presented. This includes the sex incidence, the age incidence, the symptomatology incidence, the colic incidence, the chills and fever incidence, the jaundice incidence, the percentage in ninety-five cases of successful x-ray diagnoses and failure, the accuracy of duodenal drainage as a diagnostic measure in thirty-two cases, the end results in one hundred and forty-one cases followed for from one to ten years and the percentage of cases of common and hepatic duct stones in which stones were present and were not present in the gallbladder.

Figures are presented year by year showing our percentage of common and hepatic ducts explored and common and hepatic duct stones discovered up to this day.

Criteria are cited which, from our experience, justify exploration of the ducts for stones.

If one wishes to find and remove as many duct stones as possible, many ducts must be searched on suspicion and many negative searches must be anticipated.

Any argument that this teaching is dangerous in that it may cause additional mortality by prompting the inexperienced to open common

ducts is in our opinion fallacious. No one can justify the removal of a gallbladder with stones in it without adequate investigation for possible common and hepatic duct stones and with the proved high incidence of these stones, no one should undertake the surgery of cholelithiasis without the training and experience to investigate, adequately and with reasonable safety, the common and hepatic ducts

DISCUSSION

Dr. HOWARD M. CLUTE, Boston Mass. The frequency with which common and hepatic bile duct stones are found is certainly as Dr. Lahey, Dr. Cheever and others have shown related very definitely to the frequency with which we look for them.

It has always seemed a curious and anomalous situation when operating on a gallbladder filled with stones, to find two or three stones in the common duct in spite of the fact that the duct appears normal in size and consistency and that there is no edema or thickening in the head of the pancreas. Very commonly these stones closely resemble those in the gallbladder.

I believe that certain of these common duct stones are pushed through from the gallbladder and cystic duct into the common duct in the course of the operation of cholecystectomy. The first step in cholecystectomy is to grasp the gallbladder with forceps and then proceed with a dissection of the cystic duct. These maneuvers forcibly compress the gallbladder and could easily force stones or detritus from the gallbladder or cystic duct into the common duct.

I have had this year two experiences confirming this. In the first, the common duct was opened before removing the gallbladder and two stones were removed from it. Following this the gallbladder was removed. A second examination of the common duct after the gallbladder was out revealed two more stones which were identical with those in the bladder and which it was thought had been pushed into the duct during the dissection.

A similar situation arose in another case this year in which detritus in large amounts, similar to that in the gallbladder was discovered in a common duct which I had previously explored and found empty.

It would seem therefore that in the list of indications for exploration of the common duct, we certainly should include the presence in the gallbladder of small stones and detritus which could readily be pushed through into the common duct in the process of cholecystectomy. It would also appear to be a good plan to clamp the cystic duct before exploring the common duct. By this measure we may avoid some of the postoperative common duct stone colics which we all have now and then after an apparently simple cholecystectomy.

DR. ARTHUR W. ALLEN, Boston Mass. *Mr. President and Gentlemen*—I think we all ought to be grateful to Dr. Lahey for his contributions that have increased our consciousness of common duct stone. There isn't the slightest question of a doubt that in a great many of us have removed gallbladders feeling that the common duct was probably clear and not opening it because the indications for exploration of the common duct were not well organized in our minds at the time. There are all of fourteen good reasons why we should take the common duct

into consideration when dealing with biliary calculi. I am not going into those in detail again at this time.

I am very much interested in Dr. Lahey's statistics on mortality of common duct exploration. In a little less than five years at the Massachusetts General Hospital we have had twelve hundred and nine cases of biliary calculus operated upon. Three hundred and eighty-six of these have had their common duct explored—32 per cent.

There has been a total mortality in the twelve hundred and nine cases of fifty-one or 4.2 per cent. There has been a mortality in the common duct explorations of seventeen, or 4.4 per cent—an increase of only .2 per cent.

In the three hundred and eighty-six cases that have had the common duct explored two hundred and twenty-seven have had the outlet dilated with the Bakes dilators. Some of them have not had very much dilatation perhaps not more than Dr. Cheever would accomplish with his silk woven catheters which we used prior to the time we had these metal instruments but occasionally the dilatation was carried as high as fourteen millimeters.

In the two hundred and twenty-seven cases that had the papilla dilated there were nine deaths and in the one hundred and fifty-nine cases in which the duct was explored and the papilla not dilated there were eight deaths.

We have had no such serious sequelae following dilatation as Dr. Lahey pointed out. We have been on the lookout for serious complications because we thought they might occur particularly reflux of duodenal contents but as yet we have not had any such instance.

Showing the trend of the times and our becoming more common duct conscious in 1931 there were only forty-five ducts explored in our hospital. There were eight deaths in the entire group operated on in that year regardless of whether the ducts were explored. In 1934 ninety-two of the cases had the ducts explored and there were only seven deaths in approximately the same number of gallbladder cases.

Interestingly enough and perhaps due to some selection on my part because I have been particularly interested in the subject during this same period I have operated on one hundred and twenty-two cases of biliary calculus exploring the ducts in sixty-six, or 54 per cent. In those sixty-six cases I found stones in the ducts in thirty-five and stricture of the outlet in seven.

DR. DAVID CHEEVER, Boston Mass. *Mr. Chairman*—I became "common duct conscious" a little earlier than Dr. Allen possibly because I arrived at general consciousness somewhat before Dr. Allen.

I read a paper on the subject of my personal experience in gallstones before the Massachusetts Medical Society last June. I was led in preparation for that to review my experience. I realized that I had been rather more up than my colleagues in the early days of the Brigham Hospital at any rate to explore the common duct.

As a matter of fact as Dr. Allen knows and has noted, I began the purposeful dilatation of the common duct in the papilla of Vater in 1914, using olive pointed graduated woven French bougies. I determined at that time, by study in the anatomical department and by clinical experience that the normal calibre of the papilla is about number ten French and one could dilate it apparently easily up to about sixteen French.

I have carried that out quite regularly ever since in cases where the common duct has been opened not always dilating it to sixteen not always, in fact, dilating it at all but usually I simply want to

CASE 5 M L (M G H No 348958), a forty-seven year old woman, entered the hospital, October 16, 1935, complaining of progressive difficulty in swallowing of eight months' duration. General lassitude and easy fatigability were noticed six months before entrance with some difficulty in swallowing for ten weeks. There was paralysis of the palate, with inability to swallow solid foods. Her speech was nasal in quality, her grips weak and walking was difficult. The diagnostic test gave a reading of 36. Under the effects of prostigmin, swallowing and talking were performed normally twenty minutes after the injection. The patient also improved under ephedrine.

2 The action of prostigmin on patients with conditions other than myasthenia gravis

CASE 6 M M (M G H No 345299), a twenty-three year old male, came to the hospital on May 9, 1935, complaining of weakness in his arms of about six months' duration. His grip was weak and the calf muscles were hypertrophied. With 3 cc of prostigmin and atropine 1/100 grain injected subcutaneously, no change in his condition was noted. His diagnostic test score was 2. The final diagnosis was *muscular dystrophy, hypertrophic type*.

CASE 7 W H (M G H No 346205), a man aged thirty-nine years, had been losing strength in his legs for four or five years. Weakness was also noted in his back muscles, with atrophy of both the back and legs. A biopsy examination of the muscles disclosed *progressive muscular dystrophy*. Prostigmin in the usual dose caused no effect.

CASE 8 F P (M G H No 346002), a twenty-two year old male, complained of progressive weakness of both legs over a period of six months. Although the muscles of the shoulder girdle and pelvis showed some atrophy, there was none in the legs. A biopsy examination showed muscle tissue characteristic of *progressive muscular dystrophy*. Three cc of prostigmin were given without effect.

CASE 9 M S (M G H No 345928), a fifty-four year old woman, complained of the loss of the use of her legs over a period of two years. She also had difficulty in swallowing and talking. Her arms were atrophic and her legs spastic. The diagnosis was *amyotrophic lateral sclerosis*. Prostigmin gave a slight subjective sense of improvement, without objective signs. Her diagnostic test score was 7.

CASE 10 S M (M G H No 346578), a thirty-seven year old male, entered the hospital July 6, 1935, complaining of generalized weakness and difficulty in swallowing of six weeks duration following an attack of sore throat. His gait was awkward and his grips weak. There was some discomfort in swallowing considered as due to chronic, hypertrophied tonsils. Prostigmin was given with only slight effect, the diagnostic score being 6. The final diagnosis was generalized weakness following an acute upper respiratory infection.

CASE 11 I K (M G H No B M 18622, reported through the kindness of Dr Walter Bauer), a fifty-two year old woman entered the hospital May 20, 1935. She had weakness of swallowing, talking and moving the hands. Fibrillation of the muscles involved was marked. The diagnosis was *progressive bulbar palsy*. Prostigmin was given without effect. An autopsy confirmed the clinical diagnosis.

CASE 12 D E (M G H No P H 33287, reported through the courtesy of Dr J B Ayer and Dr J C White), a boy aged eighteen years, complained of

ptosis of both eyes. This came on about six years before admission. The movements of the eye were also limited in all directions. Under prostigmin there was very slight improvement, the diagnostic test score being 4. The diagnosis was *progressive ophthalmoplegia of von Graefe*.

DIAGNOSTIC SCHEMA

The extra-ocular muscles and other muscles supplied by the cranial nerves are usually observed while standing behind the patient's head with the patient lying down. His gait and posture, however, are also observed from time to time during the test. Tests are done at stated intervals of time and the patient is asked to express his feelings each time an observation is made. The results are listed on a scale of 0 to 4. "Subjective" (fig 1) relates to an increase in a general feeling of well-being. "General" indicates a decrease in paralysis of the larger muscle groups, such as the grip and ability to walk. "Local" reports the findings in smaller muscle groups that can be more accurately observed, such as the extra-ocular muscles, those of the face, and muscles used in talking or swallowing.

The "total" in cases of myasthenia ranged from 20 to 72, doubtful cases, from 10 to 20, negative reactions, from 0 to 10. Our positive myasthenia cases gave total scores of 55, 49, 49, 47 and 36. The negative cases tested gave totals of 2, 7, 6 and 4.

EARLY PHYSIOLOGICAL LITERATURE*

Rothberger¹⁴ pointed out as early as 1901 that physostigmine antagonized curare in the peripheral nerve-muscle preparation. Gunn⁶, in 1908, working on yohimbine poisoning, concluded that myasthenia gravis was a peripheral nervous, rather than a central, affection. Further light on the mechanism of the physostigmine-curare antagonism was cast by the work of the Lapicques¹⁰, who observed that curare caused an augmentation in chronaxie while physostigmine, nicotine and veratrin diminished the chronaxie of skeletal muscle. In recent years there has been some discussion as to the validity of chronaxie determinations as a means of elucidating the problem of neuromuscular transmission, but these theoretical considerations do not affect the primary fact which the Lapicques were the first to emphasize, that curare diminished, and the physostigmine group of drugs increased, the excitability of muscular tissues, and that this was undoubtedly the basis of the antagonism of the two drugs.

Granted, then, that the state of the muscles in myasthenia gravis is akin to the state produced in them by curare, it is not unreasonable to suggest the use of physostigmine as a therapeutic measure. Edmunds and Roth⁵ observed, moreover, that the effect of physostig-

*Contributed by Professor John F. Fulton

mine on muscle appears to be separate from its action on the gut and various other organs innervated by the parasympathetic system, an observation confirmed and extended by Langley and Kato⁹

Nicotine and veratrin also augment the excitability of muscle i. e., diminish the chronaxie and they, too, tend to antagonize curare. Owing, however, to other toxic actions especially of veratrin, it has not seemed advisable to suggest their use in myasthenia gravis

DISCUSSION

The earlier work on the physostigmine-curare antagonism gave a suggestion that physostigmine or one of its derivatives might be of value in the treatment of myasthenia gravis a disease characterized by weakness of muscles similar to the paralysis of curare poisoning. Such has proved, in part, to be the case. The rapid response to the derivatives prostigmin however, has furnished us with a new diagnostic test for myasthenia gravis, while its therapeutic action is still uncertain except for temporary relief of symptoms. A diagnostic schema is helpful in recording the action of the drug. While the diagnostic test is of some use to medicine it is to be hoped that prostigmin or an other preparation may in the near future furnish us with a form of therapy capable of prolonged effect and thus be more suitable in the treatment of myasthenia gravis

CONCLUSIONS

Prostigmin, a derivative of physostigmine, causes a marked but temporary, remission of

the muscular weakness seen in myasthenia gravis

The effect is so marked that the drug is suggested as a diagnostic test for the disease

Other diseases, either of nerves or muscles, respond only slightly to prostigmin

Prostigmin is injected subcutaneously, with an appropriate dose of atropine to counteract any intestinal stimulation. Three cc. of prostigmin (Roche) and atropine, 1/100 grain, has proved to be satisfactory as a diagnostic test.

A RECENT OUTBREAK OF FOOD POISONING IN SHOREHAM, VERMONT

BY R. F. DE WITT, M.D.*

OF a group of sixty men, women and children who ate home made ice cream in December 1933, forty three were taken with an acute digestive upset. The refreshments consisted of vanilla ice cream with chocolate sauce, angel food cake, and coffee with cream. There were four gallons of ice cream, three of which were made by the same person who stated that she had difficulty in freezing one gallon. The ingredients used were flour eggs whole cow's milk, evaporated milk, sugar and vanilla. The resulting mixture was greyish in appearance and flat in taste. There was a question as to the cleanliness of the freezers.

At 11 P. M. lunch was served. Between 1 and 7 A. M. forty three of the sixty persons were taken with acute symptoms which included, in most instances, nausea and vomiting,

headache muscular cramps and aches weakness and marked prostration. The weakness, prostration headache and muscular cramps persisted from ten to seventy hours from the time of onset. In the cases which were examined by a physician, temperature from 98.4 to 99.6 degrees F. and pulse from 72 to 96 were noted. No diplopia, nystagmus, photophobia, pharyngeal or aural difficulties were apparent. Four of the forty three victims had puffiness of the eyelids. One child of fourteen years who ate a considerable amount, had nausea and vomiting and an irregular and thready pulse of 140, which lasted about twenty four hours. Several individuals, who suffered milder attacks, had similar recurrences of their symptoms about twenty four hours later, with no possibility of obtaining any of the above mentioned food. In individuals, who felt general malaise and slight nausea about two hours after ingestion of the

*DeWitt, R. F.—For record and address of author see This Week's Issue page 1219

food, took large doses of saline or castor oil. Following this treatment their upsets were milder and recovery quicker than in those untreated.

In several instances diarrhea was noted at the onset, but in the majority there was constipation which lasted two to three days. In most cases, some degree of general malaise and gastric discomfort were present for about a week following the subsidence of acute symptoms.

Examination of ice cream, which was carried in a clean but not sterile container, was made four days following the party. Culture of the ice cream showed staphylococcus aureus, a streptococcus, bacillus coli, and an undetermined rod-shaped organism. Due to inadequate facilities an examination of the filtrate was not made.

A DETAILED CASE

The following is a detailed report of one case. The patient, aged forty-five, male, was seized with intestinal cramps and diarrhea four hours after the ingestion of the food, nausea and vomiting came on a few minutes later and continued for four and one-half hours at which time morphine and codeine were given. The patient was restless and confused, and vomited at short intervals during the next six and one-half hours. During this time he complained of a severe frontal headache and aches and pains in his muscles. These aches and pains lasted about eighteen hours. Prostration occurred about eight hours following the appearance of symptoms and lasted approximately thirty-six hours. Twelve hours after the onset of symptoms, the temperature was 98 degrees F, pulse 78 and respiration 17, with a maximum forty-eight hours later of 99.82-16. Eighteen hours after the onset, sodium amytal grs 6, sodium bicarbonate gr 15, sodium chloride gr 15, sodium bromide gr 15, were given per rectum in eight ounces of tap-water, this kept the patient quiet for about two hours. After the first twenty-four hours of the illness, a scarlatiniform rash appeared on the trunk and arms, this lasted about thirty hours, gradually fading away. Enemas and alcohol rubs had a sedative effect. General strength returned slowly the following week with no apparent complications or sequelae during a period of ten months.

SEVERAL SIMILAR OUTBREAKS RECENTLY REPORTED

Staphylococci were first reported as occurring in milk by Barber², who isolated both the white and yellow varieties, the white gave the investigator symptoms while the yellow did not.

Outbreaks of food poisoning ascribed to staphylococci following the ingestion of such foods as layer cake, cheese, devil's food cake,

chocolate éclairs, wedding cake, cream puffs, chocolate cream pie, French vanilla ice cream and Christmas cake have been reported by Dack³, Jordan^{4,5}, McBurney¹, Nelson⁶, and Arthur⁷.

Gilbert, Coleman and Laviano⁸, report *B. cloacae*, *B. proteus* and staphylococci as being the probable cause for gastrointestinal disturbances. In October, 1930, following an outbreak attributed to cream-filled pastries, from which staphylococci were isolated, symptoms were not produced by feeding filtrates to various laboratory animals, but upon feeding growths of a non-motile, gram negative, encapsulated bacillus, toxic symptoms were evident. Further study indicated that these organisms were of the *cloacae-aerogenes* group although they did not correspond exactly to any species for which a description could be found.

SUMMARY

Due to the short time between the ingestion of the food and the onset of symptoms, the probability of a chemical or a combined chemical and bacterial rather than bacterial origin appears logical. But, in view of the above reports of food poisoning with a staphylococcus or a member of the *cloacae-aerogenes* group as the apparent etiological factor, it seems probable, since the symptoms in the outbreak reported above correspond closely with other records, that the etiology in this instance might well be the same.

ACKNOWLEDGMENT

The author is indebted to Dr L. A. Sanders of Shoreham, Vt. for many of the data recorded above.

VERMONT STATE MEDICAL SOCIETY

PRACTICAL LIMITATIONS OF VACCINE
AND SERUM THERAPY*

BY AUGUSTUS B. WADSWORTH, M.D.†

THE practicing physician must do something for his patient—anything that promises to be helpful. Perhaps the less clearly the measures are understood the more alluring they are especially if they are in the nature of a specific. Specificity of course is the underlying principle of vaccine therapy and that relationship is thus connoted whenever a vaccine is suggested whether or not there is any real scientific basis for it. From this point of view, one must consider the practical value of vaccine therapy. Its limitations have been more sharply defined each year as medical science has been advanced by research in the laboratory and by clinical experience at the bedside.

One must understand clearly what one means by a vaccine. In the first place it is an antigen. Now an antigen is a substance that when introduced into the tissues induces a reaction, in other words varying degrees of injury followed by recovery—a reparative process which becomes specific in its relation to the particular agent that incited the injury. In general antigenic action has been limited to the protein substances but their action is now known to be modified by the presence of the carbohydrates. It is conceivable that a useful vaccine might be prepared from any microorganism that gives rise to an infectious disease but, up to the present time, the practical value of comparatively few has been convincingly demonstrated. In general, vaccines are used in the prevention and treatment of infection. Vaccine therapy differs fundamentally from serum therapy in that it induces an active immunity and a lasting one whereas serum therapy provides only passive immunization which is quite evanescent. Thus in general vaccine therapy finds its sphere of greatest usefulness in the prevention of infection by developing an immunity before infection has taken place where as serum therapy is limited more and more in practice to the treatment of infection. Serum therapy if effective is immediately effective. Immunization with vaccines requires time for the active immunity to develop and thus varies greatly with the different vaccines. Although this, in general, is true nevertheless vaccines are useful under certain conditions and in certain types of infection which may be defined as the prolonged infections of low grade in

which the disease process is not developing an adequate immunity and requires the further stimulation that might be derived from judicious treatment with a potent vaccine.

If one accepts the broad point of view I have taken in defining a vaccine, it is obvious that toxins as well as suspensions of the bacterial cells, should be included—although at the present time the term vaccine often connotes simply a suspension of bacterial cells. This usage disregards the origin of the term as applied to smallpox vaccine, which is not a bacterial suspension but a virus preparation. Moreover, smallpox vaccine is administered in the living state and owes its effectiveness to the fact that it is living and induces a modified form of the disease process from which is derived the immunity. This brings us to a fundamental differentiation in the action of these two types of vaccine—that derived from the bacterial inoculants of infection as contrasted with that from the filtrable viruses.

Immunity to bacterial infection can be and is obtained by immunization with dead bacterial cells or their toxins whereas it is extremely doubtful if an effective immunity against the virus diseases can be obtained without the introduction of the living virus and the development of some form of disease process in the tissues. There is another fundamental difference in the character of the immunity that is induced by these two agencies. Dead bacterial material whether derived from the bacterial cells or the toxins may induce an extremely high degree of immunity which subsides and becomes latent when immunization has stopped just as it does after the recovery of a person from bacterial infection. In many of the infectious diseases a second infection is rare in a few it occurs not infrequently, for example in pneumonia, as you all well know. After recovery from the virus diseases, a second infection is extremely rare. The immunity is lasting, practically permanent for the duration of life. Similarly after the administration of a living virus in a vaccine the immunity is likely to be lasting with extremely rare exceptions—as for example in the case of smallpox that develops in a person who has been vaccinated. The disease in such cases has been reported as modified and mild. The explanation that has been offered recently is extremely interesting although further study is needed before one can venture to accept it namely that when these filtrable viruses enter the tissues as the inciting agent of an infectious disease or are injected

†Wadsworth, Augustus B.—Director, Division of Laboratories and Research, New York State Department of Health, Albany, 1934. For record and address of the author see "This Week Issue," page 1219.

as a vaccine, a harmless state of parasitism or symbiosis develops with recovery, and the virus which, in the tissues finds its natural habitat inside the cells, persists and continues living in the cells of its host indefinitely. Thus it is that individuals who have recovered from some of these virus diseases continue to have in their blood, years after recovery, specific substances that have a protective action on the virus when tested in the laboratory.

Further elucidation of the broad principles underlying the practical limitations of vaccine therapy would require all the time at my disposal and might serve no very useful purpose. Then, too, I fear I should become involved beyond my depth. Practical illustrations may serve much more effectively and to a better purpose, especially since they are doubtless of more interest to you as practicing physicians.

The list of bacterial vaccines that are, in varying degree, effective, is a long one, doubtless the list of those that are of little or no value is much longer. A vaccine may be potent and not useful. When a vaccine is potent and its specific relationship to an infectious process established, its sphere of usefulness is also very sharply defined clinically. Theory and practice invariably coincide.

Suspensions of typhoid, paratyphoid, dysentery, pertussis, and influenza bacilli, of cholera vibrio, and of some of the pathogenic cocci and higher bacteria have all been used in the prevention or treatment of infection. *Staphylococcus aureus* and some of the actinomyces have been used in the treatment of localized infections under certain conditions. The treatment of furunculosis with staphylococcus vaccine, *ad interim*, to prevent recurrence, might be considered rational vaccine therapy but staphylococcus vaccine is of no value and may be harmful in the acute stages of infection, whether localized or an invasive general pyemia. Thus this agent is limited to prevention as are practically all this group of vaccines.

Typhoid vaccine is perhaps better known and has been more widely used for a longer period than any of these bacterial vaccines. Its practical value, however, is definitely limited to prevention of the disease and, in conditions of frequent exposure, as in the army campaigns, vaccination must be repeated at short intervals in order to maintain the immunity in the active rather than the latent stage. The latent or dormant period of the typhoid immunity that follows inoculation after longer or shorter periods in different individuals possesses some but not always adequate protection against the development of infection after exposure. There is considerable discussion at the present time regarding the selection of strains of the typhoid bacillus with which to prepare the vaccines. Some of the old Rawlins strains have been considered lacking in antigenic potency but, after all is said and done, our experience regarding

the practical value of typhoid vaccine is derived from the use of this strain during the World War and other campaigns in various parts of the world for more than twenty-five years. It is the opinion of the medical officers of our army that the campaign in Flanders would have been impracticable without typhoid vaccine. Although similar in many respects, paratyphoid vaccine does not appear to be quite so useful—not that it lacks potency, but the character of the disease and the effect of active immunization differ to such an extent that paratyphoid vaccine is not so generally combined with typhoid vaccine as it was a few years ago. Similarly, the administration of dysentery vaccines has been practically abandoned although bacillary dysentery is endemic in many districts.

Cholera is another enteric disease in which vaccines have been used extensively but only as a preventive measure to control the spread of epidemics, and thus it is of little or no interest to us here in this country at the present time.

During the influenza epidemics, various preparations of the influenza bacillus alone or in combination with other species of pathogenic bacteria were used quite extensively. In my experience and from a review of the work of other observers, I have been unable to ascertain that they have been in the slightest degree effective clinically. Preparations of the influenza bacillus and related species, as far as we have been able to determine in the laboratory, have an extremely limited potency so that, despite any specific relationship of these microorganisms, their value in the prevention or treatment of infection is negligible.

The terminal complication of influenza is pneumonia, and pneumonia, except in rare instances, does not yield to any form of preventive vaccine therapy. It was thought for a brief period that this might be due to failure to select the proper type of vaccine but it was soon learned that recovery from one type of pneumonia may be followed by a second attack of the same type so that protective inoculation with pneumococcus vaccine, for a brief moment advocated by some authorities as a public health measure, is not practical and has never been adopted.

Pertussis vaccine, like that of the influenza bacillus, from our studies in the laboratory, possesses extremely limited potency and, despite its specific relationship to whooping cough, is of very doubtful value in either the prevention or treatment of the disease. The prolonged course that whooping cough often follows suggests that a vaccine might be useful for treatment after infection had developed but its practical value clinically is far from sharply defined—extremely doubtful—but, lacking potency, it is a harmless agent. Most of the vaccines

now prepared contain a high concentration of pertussis bacilli, ten billion organisms per cubic centimeter. Lack of potency and failure to obtain clinical results have suggested the use of vaccines from freshly isolated cultures of this microorganism, as of others in the same category. This is not a practical laboratory procedure on account of the time required for safe preparation of the vaccine. Moreover there are no proofs as yet that it is necessary.

In presenting these examples of vaccine therapy, I have tried to stress not only the conditions in which they are useful and how these vary with the different vaccines and diseases in which they are used, but also to illustrate how closely theory, as developed from laboratory research, coincides with practice as revealed by clinical experience. I have accordingly selected examples concerning which we have considerable information—sufficient to define their practical limitations on the basis of sound reason but there is also a long list of vaccines concerning the efficacy of which we really know little or nothing. Take, for example the common cold. For the past fifteen or twenty years, various bacterial and other vaccines have been suggested but not one of them has as yet convincing support. The multiplicity of the vaccines or species selected bespeaks a lack of knowledge not only of their potency but of their specific relationship to the infectious process. The only basis for the selection of some of the bacterial species that have been used has been the fact that they were present and isolated. That they were the incitants of the common cold or that if a vaccine were prepared from them it would be potent, has never been determined. Moreover, theory and practice also coincide in these negative results—complete absence of a scientific basis and quite indeterminate clinical results from its administration. Now if recent studies are confirmed, the common cold is due to a filtrable virus. These nondescript vaccines of the present day will therefore fall in the category of the gunshot prescriptions of our forefathers.

In striking contrast to the common cold, the etiology of some allergic affections of the upper respiratory tract, such as hay fever or rose cold, can be determined and vaccines prepared from the toxic material, vaccine therapy is most effective as a preventive measure in such instances.

Lack of convincing clinical results often suggests the use of antogenous vaccines prepared from microorganisms isolated from the individual patient. These are not limited to the treatment of common colds and conditions of the upper respiratory tract but are extended to infection of any part of the body from which one can obtain bacteria—usually exposed parts, contaminated by species other than the in-

stant. The value of antogenous vaccines depends entirely upon their potency in the first instance and in the second place, upon proofs that the particular species selected is the specific incitant of the process to be treated—data which are often lacking in the common practice of preparing and administering these antogenous vaccines. I have no quarrel with the use of antogenous vaccines when these conditions are fulfilled and the patient is not suffering seriously from an acute infection.

Preparations of the toxins of the diphtheria and tetanus bacilli and of the hemolytic streptococci are all potent vaccines and their etiological relationship to the disease process is generally very clearly established, but even these preparations are of limited practical value. No one presumes to advocate their use in the acute infectious processes. Here we have general acceptance of the sharply defined practical limitations of this type of vaccine therapy and it very strikingly illustrates the points of view regarding other forms of vaccine. When these preparations are so toxic that it is difficult to use them unless modified treatment with formaldehyde when carefully adjusted destroys their toxicity without injuring materially their antigenic activity. These toxins can therefore be converted into toxoids and used effectively. Comparatively little has yet been done with tetanus toxoid but I believe it will have a very practical, although limited, sphere of usefulness. You are all familiar with the preventive immunization against diphtheria that is now so generally used. It was first modified by the addition of antitoxin, then by treatment with formalin, and very recently the formalin product has been adsorbed on alum or other substances and found to be far more effective when administered in this form. We have been interested particularly in the study of toxoid precipitated on calcium phosphate because it offers certain advantages over the alum and appears to be as effective, but we have not as yet distributed this preparation for general use. The precipitated toxoid can be given in somewhat larger quantities and in one dose. It is a more effective immunizing agent—doubtless on account of the slower absorption. There is no question but that the public health program of immunization against diphtheria has produced results in diminishing the morbidity and mortality of diphtheria. It does not mean, however, that diphtheria never develops in vaccinated persons. This, of course, is due to inadequate immunization. Individuals vary in their response and a few fail to develop the necessary immunity. The present procedures suffice for the great majority.

The hemolytic streptococcus culture may be divided into two parts from the standpoint of vaccine therapy: the toxic filtrates, which are potent antigens, and the bacterial suspensions

the action of which as a vaccine has not yet been determined. Vaccine therapy and serum therapy alike as they relate to streptococcus infection, are complicated by the fact that the toxins and antitoxins vary according to the strain. It is necessary to use a corresponding vaccine for preventive inoculation or a corresponding serum for treatment after infection has developed. The strains bear no specific relationship to any of the characteristic disease processes such as scarlet fever or erysipelas. The different strains are found with about the same frequency in each of these diseases. There is no specific etiological relationship, hence there is no specific vaccine or serum therapy as yet developed. Preventive inoculation with the toxin is therefore limited for the present to those who are constantly exposed, it certainly is not practical for general use with the preparations available. To obtain a combination of toxins that will protect against all hemolytic streptococci is the difficult problem. The time required for immunity to develop is also a practical limitation in epidemics. The number and size of the doses have been repeatedly increased since the procedure was first recommended.

Vaccine therapy may be said to date from Jenner's work on smallpox, which belongs to quite another group of infectious diseases. The vaccine therapy of this group differs fundamentally from that of the bacterial infections. Smallpox, rabies, and epidemic poliomyelitis in man and distemper in the dog are incited by filterable viruses. There is no convincing evidence that the agent of the disease smallpox and the agent of the vaccine are different species. By passage through the cow, the vaccine virus becomes so modified that it gives rise only to a modified infection as compared with the disease smallpox. From time immemorial, protection against smallpox has been dependent upon a "take." This is the result of the development of the living virus in the tissues.

Similarly, in rabies, the vaccine prepared from the cord of infected animals, dried or treated with various chemical reagents, is a modified form of the virus that gives rise to hydrophobia. Its practical value is to be attributed to the long period of incubation in this disease, which permits active immunization of the tissues with the vaccine before the disease has time to develop and thus is preventive in its action. If the administration is delayed treatment with the vaccine would be considered dangerous were it not for the fact that rabies is invariably fatal. In other words, when this virus finds lodgment and develops to the extent of inducing the disease, the virus survives but not the host.

There is corresponding experience with immunization of the dog against distemper. These vaccines proved of little or no value until it was recognized that the living virus must

be introduced. However, experience with new methods has established the fact that very slight but sufficient immunity may be induced in the tissues by the introduction of dead vaccine and that this must be given as a preliminary treatment to the inoculation with the living distemper virus in modified form. If the dog is a very valuable one, it seems wise to repeat the injection of the dead vaccine before giving the living virus. Moreover, to be certain of saving the dog, serum therapy is often recommended to control the disease process incited by the living vaccine if this should become alarming.

Attempts to develop a vaccine therapy to prevent, and thus control, epidemics of poliomyelitis have been unsuccessful. Research has now turned to preparations of the living virus in the hope of obtaining a modified living vaccine that might be safely given the human subject, and this has not yet been accomplished. These are concrete examples of the limitations of vaccine therapy in the virus diseases.

There is still another group of diseases incited by other species of microorganisms such as the *Plasmodia* or the *Trypanosomae*, for which we have as yet no vaccine therapy and comparatively little information concerning the problems involved.

Serum therapy is passive immunization in contrast to active immunization—vaccine therapy. Serum therapy is thus the transfer of the products of an active immunization to the infected individual. A horse is hyperimmunized, that is, receives a long and accumulative course of vaccine treatment to develop an active state of immunity. In some instances, this can be accomplished in two or three months, with other bacterial products it takes a year or two before the horse reaches a sufficient state of hyperimmunization. The horse is then bled and the serum or concentrated preparations of the globulins are used for the treatment of the homologous type of infection.

These sera may be divided into two classes: those that are predominantly or purely antitoxic in their action, such as the diphtheria, tetanus, and botulinus antitoxins, as contrasted with those that possess protective activity against, such incitants of infection as the meningococcus or pneumococcus. The sera obtained by immunization with the hemolytic streptococci may possess both types of activity. You are all quite familiar with the antitoxic action of sera in neutralizing the diphtheria, tetanus, and botulinus toxemias, but with the meningococcus, pneumococcus, and streptococcus, the disease is characterized by a bacterial invasion of the tissues that does not occur in diphtheria, tetanus, or botulism. The problems of serum therapy are therefore greatly complicated. It is not only necessary to neutralize the toxic products of the bacterial incitant of the infection, but the bacteria that have invaded the tissue must be destroyed also.

These different sera irrespective of antitoxic or antibacterial activities, are effective in the treatment of infection after it has developed. They may be useful as a preventive measure for a brief period. Diphtheria antitoxin as it was formerly extensively given to children exposed to diphtheria is an example and the administration of tetanus antitoxin following accidents is another. Passive immunization with antitoxin or serum has a very restricted usefulness.

You are familiar with the practical value of the antitoxic sera—their unquestioned potency and specificity in the treatment of the disease and thus also the remarkable clinical results you have obtained with them. Nevertheless, there are very definite practical limitations to their usefulness. Even with diphtheria antitoxin, reports have reached me of the failure of treatment to control the course of the disease. Different observers have attributed the failure of diphtheria antitoxin to differences in the character of the diphtheria bacilli which give rise to the outbreaks that fail to respond to treatment or to lack of potency in the antitoxins that were used. I personally have been interested in endeavoring to determine whether the rapidly fatal course of some cases of diphtheria might not be due to complicating infection of the necrotic lesions induced by the diphtheria bacillus in the upper respiratory tract. The work of Prudden in the early days of antitoxin treatment of this disease stresses the importance of the streptococcus as a contaminating agent. However, this point of view is speculative and lacks the necessary proofs.

With present methods of standardization in this country since federal control, diphtheria antitoxin has not lacked potency. No convincing proof has yet been obtained that the toxin produced by the different strains of the diphtheria bacillus differs in its neutralization by the standard antitoxin. On the contrary I have examined carefully strains of diphtheria bacilli isolated from serious outbreaks—notably one that occurred in Berlin in 1927—and found that the toxins of these diphtheria bacilli were all neutralized by the standard diphtheria antitoxin.

For the present, therefore, one must attribute the failure of diphtheria antitoxin to delay in its administration or to inadequate dosage. This is a most important conclusion because it not only applies to serum therapy in diphtheria but to serum therapy in all the infectious diseases. Serum must be promptly administered to be effective.

This is particularly striking when one considers the treatment of tetanus with antitoxin. Early in the disease it is of value but the course of the disease is so rapid and vital tissues become so early involved that serum therapy in this disease depends entirely upon the prompt

administration of the serum in adequate doses. For precisely the same reason, the practical value of treatment of another disease that involves the central nervous system botulism, is rendered practically useless by the delay in securing and administering the serum. The poisoning is so acute that the central nervous system is immediately involved. It is usually impossible to obtain antitoxin of the proper type to administer in time to be of value. Patients, therefore, die or recover irrespective of serum therapy.

I must again stress these very striking examples of the practical limitations of serum therapy dependent as they are upon prompt administration of these sera. In the treatment of epidemic meningitis pneumonia and scarlet fever and other streptococcal infections this is especially important on account of the fact that with these infections the disease is complicated by the invasion of the tissues by the meningococci, pneumococci and streptococci respectively whereas diphtheria tetanus and botulism differ fundamentally in that they are toxemias without invasion.

The botulinus toxin unlike the diphtheria toxin is characterized by type specificity and it is necessary to use antitoxin of the corresponding type. Meningococci, pneumococci and streptococci are also differentiated into types. It is therefore necessary to use either a polyvalent serum or one of limited valency corresponding to the type of the strain giving rise to the infection to be treated. By combining a few selected strains serum of a potency approximating equaling or possibly exceeding that of monovalent sera can be prepared for the treatment of meningococcal meningitis. It would seem as though the relationship of the different types of meningococci differs in this respect from the pneumococci and streptococci. The results of serum therapy in meningococcal meningitis are very striking but quite variable, depending upon the severity of the infection. The fulminating cases are difficult to treat promptly or effectively. Epidemics vary greatly in virulence and thus in their mortality. Hence the results of the different series reported in the literature are not comparable. Dopter reports the lowest mortality—14.5 per cent—in treated cases. His results have not been obtained by others. Flexner reports 30.9 per cent deaths in his cases 17.8 per cent failed to recover in our series.

There are practical difficulties in preparing sera of the requisite potency and breadth of valency with the different strains of the pneumococci and streptococci. In the treatment of pneumonia it is necessary to determine the type of serum to be used if satisfactory results are to be obtained. Moreover in the treatment of pneumonia we find marked differences in the results obtained with serum therapy among the different types. For example some

the action of which as a vaccine has not yet been determined. Vaccine therapy and serum therapy alike as they relate to streptococcus infection, are complicated by the fact that the toxins and antitoxins vary according to the strain. It is necessary to use a corresponding vaccine for preventive inoculation or a corresponding serum for treatment after infection has developed. The strains bear no specific relationship to any of the characteristic disease processes such as scarlet fever or erysipelas. The different strains are found with about the same frequency in each of these diseases. There is no specific etiological relationship, hence there is no specific vaccine or serum therapy as yet developed. Preventive inoculation with the toxin is therefore limited for the present to those who are constantly exposed, it certainly is not practical for general use with the preparations available. To obtain a combination of toxins that will protect against all hemolytic streptococci is the difficult problem. The time required for immunity to develop is also a practical limitation in epidemics. The number and size of the doses have been repeatedly increased since the procedure was first recommended.

Vaccine therapy may be said to date from Jenner's work on smallpox, which belongs to quite another group of infectious diseases. The vaccine therapy of this group differs fundamentally from that of the bacterial infections. Smallpox, rabies, and epidemic poliomyelitis in man and distemper in the dog are incited by filterable viruses. There is no convincing evidence that the agent of the disease smallpox and the agent of the vaccine are different species. By passage through the cow, the vaccine virus becomes so modified that it gives rise only to a modified infection as compared with the disease smallpox. From time immemorial, protection against smallpox has been dependent upon a "take." This is the result of the development of the living virus in the tissues.

Similarly, in rabies, the vaccine prepared from the cord of infected animals, dried or treated with various chemical reagents, is a modified form of the virus that gives rise to hydrophobia. Its practical value is to be attributed to the long period of incubation in this disease, which permits active immunization of the tissues with the vaccine before the disease has time to develop and thus is preventive in its action. If the administration is delayed, treatment with the vaccine would be considered dangerous were it not for the fact that rabies is invariably fatal. In other words, when this virus finds lodgment and develops to the extent of inducing the disease, the virus survives but not the host.

There is corresponding experience with immunization of the dog against distemper. These vaccines proved of little or no value until it was recognized that the living virus must

be introduced. However, experimental new methods have established the slight but sufficient immunity in the tissues by the introduction of the vaccine and that this must be given in treatment to the inoculation of distemper virus in modified form. For a very valuable one, it seems that the injection of the dead vaccine or living virus. Moreover, in the case of the dog, serum therapy is used to control the disease produced by living vaccine if this should be necessary.

Attempts to develop a vaccine for distemper, and thus control, epidemic distemper have been unsuccessful. Now turned to preparations in the hope of obtaining a vaccine that might be safely given to a subject, and this has not yet been accomplished. These are concrete examples of vaccine therapy in the virus group.

There is still another group of diseases caused by other species of microorganisms, the *Plasmodia* or the *Trypanosomes*. In these we have as yet no vaccine therapy, comparatively little information regarding the problems involved.

Serum therapy is passive immunity in contrast to active immunization by vaccine. Serum therapy is the use of the products of an active infection in a healthy individual. A horse, for example, is infected, that is, receives a long course of vaccine treatment, and then the state of immunity is used. In serum therapy, it can be accomplished in two ways: one with other bacterial products, and the other two before the horse reaches the state of hyperimmunization. In the first, the globulins are used, and in the second, the globulins are used of the homologous type of infection.

These sera may be divided into those that are predominantly toxic in their action, such as tetanus, and botulinus antitoxin, and those that possess passive immunity against, such incitants of infection as pneumococcus or pneumococcus. The bacteria may possess both types. These are all quite familiar with the use of sera in neutralizing the diptheria and botulinus toxemias, but with pneumococcus, pneumococcus, and streptococcus disease is characterized by a bacterial toxin of the tissues that does not occur in tetanus, or botulinus. The problems of therapy are therefore greatly complicated. It is not only necessary to neutralize the products of the bacterial incitant, but the bacteria that have invaded the tissue must be destroyed also.

to us because when a new serum is prepared there is so much newspaper publicity about it that each of us has to decide what he is going to do about it, and whether he is going to use it.

I have had a good deal of experience in the use of pertussis vaccine. We have used the vaccine which has been publicized by Dr. Sauer of Chicago for the past three years. In the cases where we have used it, it is my personal opinion that we have not had more than two slight cases of whooping cough develop and these were so mild that we had to resort to the use of the blood count and blood plates in order to be sure that we had an infection of whooping cough.

I would like to say a word about the use of the erysipelas serum. Before we had that, as described by Dr. Birkhaug, the mortality in the past ran around 60 per cent but since we have used that serum the mortality has dropped to about 9 per cent.

About the use of convalescent serum, that is as limited that it is not a serum that can be used to wipe out an epidemic, but when available we have found that serum very useful.

In regard to the infantile paralytic I would like to say that our Board of Health agrees quite closely with what Dr. Wadsworth has said. They will not help us in using it and will not give their permission for us to use it in the vicinity of Detroit. Dr. Kolmer feels very strongly that his vaccine is a safe vaccine. We had a letter from him within the past two weeks in which he stated his vaccine had been used in 8000 patients each receiving three injections, and he feels very definitely that his vaccine is safe. Of course we agree with most public health authorities. It has been very pleasant to be here and listen to Dr. Wadsworth.

PRESIDENT MARSHALL Perhaps Dr. Dalton will discuss this. It is a subject he is familiar with and interested in.

DR. DALTON I am greatly interested in this subject and also want to assure the members of the Society that we are very fortunate to have Dr. Wadsworth come here and read a paper on this subject. We have now pretty nearly the last word on the subject.

I would like to correct if I may the impression Dr. Howard seems to have about infantile paralysis being endemic in Vermont. To be sure we do have a number of cases each summer but I am sure, in studying reports from other states, that we have no more per cent of the population than many other states and less than some. The reason we are said to have more in Vermont is that we have been studying infantile paralysis intensively since 1914 and have not hesitated to tell about it and it is probable that every diagnosed case is reported.

Returning to Dr. Wadsworth's paper I am frequently impressed with the gullibility of the public, and many of the doctors, in regard to these vaccines and serums. Only within a few days you probably have noticed in one of the southern states, they have been using a serum which is supposed to be potent and specific for infantile paralysis and the Public Health Department of that state has given its approval to the use of this and there have been about 600 persons inoculated and pronounced secure against the disease. I expect this announcement has done a great deal of injury throughout the whole country because people who are afraid of infantile paralysis feel, perhaps that now the subject has been closed and they may be following a false impression. Some of the doctors feel the same way in regard to the use of human immune serum. I appreciate the fact that when a doctor has a case of infantile paralysis

he has to do something and he wants to do the thing which is for the best interest of the patient. When the doctors call me I tell them it is well to use the serum if they want to but not to let the family think they now have a specific cure for infantile paralysis.

While serum may do some good, there are no statistics which show that it will prevent the paralytic stage from developing. In the Massachusetts series, it did appear that there were fewer paralysis cases which had the serum than in those which did not have the serum.

I hope that Dr. Wadsworth's report is printed and that every doctor will read it.

PRESIDENT MARSHALL Dr. Wadsworth will you close the discussion?

DR. WADSWORTH There are some very interesting points in this discussion which I could not bring out in detail in my paper. As Doctor Dalton has mentioned the streptococci in poliomyelitis I might add that I have talked with Doctor Rosenow of the Mayo Clinic who has a broad point of view in regard to the biological adaptability of the streptococci which we appreciate but which as applied to particular infectious processes lacks definite proofs. For example he has been unable to bring forward any convincing evidence that poliomyelitis is a form of streptococcus infection or that vaccination with the streptococcus is an effective preventive measure. On the contrary his work in this field was not confirmed by Doctor Bull then at the Rockefeller Institute. Doctor Gilbert in our laboratories immunized a monkey with the streptococcus which I received from Doctor Rosenow but subsequently induced characteristic poliomyelitis in this animal following inoculation with the filtrable virus of the disease. We have been working intensively for ten years with the streptococci and it is extremely difficult to determine the biologic variation in the different strains. They vary in their toxigenic and antigenic action comparatively few are of practical value in the production of potent antisera. It is largely owing to this fact that the commercial manufacturers of serum were handicapped by attempting to prepare sera with cultures lacking in the requisite potency. It has been only since they have adopted new methods and special strains such as the Dochez N Y 5 which is now almost universally used, that the available sera have improved in quality. In the immunization of horses a year or two are required to obtain sera of high titer.

In regard to the serum from recovered cases of poliomyelitis our experience has brought us to the conclusion that it is not of practical value. In 1931 we spent \$100,000 to provide treatment for cases of poliomyelitis throughout the state. It is extremely difficult to diagnose the cases and treat them with the serum in time to have any recognizable effect on the course of the disease. Thus it comes down to the original feeling that I had during the height of the epidemic and you as practicing physicians may agree with me namely that the important thing in the treatment of poliomyelitis is absolute quiet. Certainly I know of no preventive or other treatment that is effective.

For the past six years we have been studying the preparation of pertussis vaccine. In 1930 I discussed the problem with Doctor Gardner of Oxford who work stressed the selection of certain fresh strains. We have found quite marked differences in the strains but the selection and maintenance of those that are satisfactory antigens for the preparation of a vaccine have not yet been solved satisfactorily. It is important however to secure a strain that will retain its antigenic potency and maintain it under conditions that will preserve these properties.

PRESIDENT MARSHALL We surely appreciate your coming here and giving us this excellent address
We will now adjourn this session until two o'clock this afternoon, and the House of Delegates will meet at one o'clock in this hall

Adjournment to 2 P M

MISCELLANY

VERMONT DEPARTMENT OF PUBLIC HEALTH
NOVEMBER, 1935

The following communicable diseases were reported to the office of the Department of Public Health during the month of November chicken pox 336, diphtheria 4, measles 203, mumps 43, German measles 23, poliomyelitis 3, undulant fever 5, scarlet fever 39, typhoid fever 4, whooping cough 130 and tuberculosis 4

The Laboratory of Hygiene made 1,706 examinations, the details of which are

Examinations for	diphtheria bacilli	133
"	Widal reaction of typhoid fever	36
"	undulant fever	63
"	gonococci in pus	141
"	tubercle bacilli	216
"	syphilis	531
of	water, chemical and bacteriological	109
"	water, bacteriological	248
"	milk, market	146

Examinations of milk, submitted for chemical only	6
" " milk, submitted for microscopical	1
" " foods	2
" " drugs	0
" for courts, autopsies	3
" " courts, miscellaneous	17
" " miscellaneous	53
Autopsies to complete death returns	1

The Director of the Division of Venereal Diseases reports twenty six cases of gonorrhea and thirty seven cases of syphilis made to this Division in November Six hundred and fifty eight Wassermann outfits and 312 slides for gonorrhea were distributed from this Division

The After Care Nurses of the Infantile Paralysis After Care Division made 184 home visits, calling on 179 patients One patient was admitted to the Audubon Hospital and one patient discharged from this hospital Twenty one pieces of apparatus were fitted, ten pieces of apparatus were repaired and forty-three orthopedic corrections made to shoes The Vocational Worker of this Division reports sales made, amounting to \$156 14

Seven towns of the state were visited by the State Advisory Nurse of the Public Health Nursing Division, in the interest of the work of this Division Part of the nurse's time this month was devoted to starting a project under WPA One thousand and ninety seven Notifications of Birth Registration and 700 pamphlets were mailed out in November

THE BIRTH RATE THROUGHOUT THE WORLD

The gratifying rise in the birth rate which was recorded for the United States in 1934 was by no means world wide The long time declining tendency in fact was still in evidence in 20 of the 34 countries whose 1934 birth rates have become available thus far It is true that the drop in 1934 was less than 1 per cent in four countries, namely, The Netherlands, New Zealand, Italy, and Venezuela, and that in five instances—the Irish Free State, Norway, Sweden, Poland and the Union of South Africa—the 1934 birth rate was identical with that for 1933 This may mark the end of the prolonged downward trend in natality in these countries

Clearly, however, the declining birth rate still remains a problem in the social economy of 15 nations, where the decreases in 1934, as compared with 1933, ranged from 1.2 per cent in France and Switzerland, to 5.4 per cent in Spain, 5.6 per cent in Austria and 6.3 per cent in Palestine

Eight countries, in addition to the United States however, recorded rises in their birth rates in 1934, with the increases in most instances ranging between 2 and 3 per cent By far the most notable

instance of an abrupt reversal of the long-time downward trend is Germany, where the astounding rise of 22.4 per cent was registered in a single year Germany, in fact, is the only one of these 33 nations whose 1934 birth rate was actually higher than for any year of the 5 year period 1930 to 1934

The birth rate for the United States for 1934 was 17.1 as compared with 16.6 in 1933, but these figures are below the rate of 18.9 for 1930—*Statistical Bulletin*, Metropolitan Life Insurance Co., November, 1935

MALARIA DEATHS

Officers of the Metropolitan Life Insurance Company are reported to have estimated that there are ninety thousand persons suffering with malaria in the United States

Dr L. L. Williams of the United States Public Health Service, is quoted in *Science* as believing that this estimate is too low Malaria accounted for 4520 deaths in the United States in 1934, which is regarded as indicative of the figures cited

MEDICAL PROGRESS

PROGRESS IN THE STUDY OF CARDIOVASCULAR
DISEASE IN 1934

I INTRODUCTION

OUR knowledge of the cardiovascular system has been increased during the year 1934 by the contributions of a great many investigators. Their observations have done much to solve various problems associated with the circulation, have supplied valuable information to others engaged in research, and have afforded a better understanding to those confronted with complex cardiac situations in clinical practice. There have not been any observations of such great importance or sufficiently substantiated, however, to alter drastically our previous concepts or treatment of diseases of the heart.

Of outstanding importance in 1934 was the work initiated and carried on by a group of Boston physicians, which may ultimately provide the medical profession with a new method of treatment for patients with congestive heart failure and angina pectoris. Great and widespread interest is manifest in the progress being made on this problem of total ablation of the thyroid gland in heart disease.

The value of electrocardiography in the study of heart disease is well recognized. Several groups of investigators have been studying electrocardiograms more closely in the hope that they may give even more accurate information than has generally been expected of them.

There has been an increase in the mortality rate due to heart disease. *Cohn* and *Luagg* have reviewed the mortality statistics of the

registration area of the United States to determine whether the death rate due to diseases of the heart was actually increasing. In the later decades a distinct, although not a great, rise has gradually become more evident in recent years. The apparent rise in the mortality rate of heart disease has largely depended upon the fall of the death rate of infectious diseases, not only of children but of all ages. At the Cook County Hospital at Chicago *Flaxman* has estimated that 17 per cent of the patients admitted had organic heart disease. Because of the great frequency with which heart disease is encountered in the general practice of medicine physicians everywhere have been attracted to and have developed a keen interest in the subject. To facilitate the study of the cardiovascular system it is the purpose of this review to give a summary of the work concerning it done in 1934 by providing a bibliography and abstracts of contributions thought to be representative and of interest.

Two monographs of considerable value for special study have been published in 1934. *Cordry* has edited a book of six hundred and seventeen pages on arteriosclerosis comprising twenty-one chapters written by twenty-three contributors. It is a useful reference book on this disease of the circulatory system. *Pal* has presented a monograph on the subject of vascular tension written with the viewpoint of correlating the physiologic mechanisms with the clinical picture. It is essentially a good review of the author's work and of the German and Austrian literature.

II ANATOMY

Robb, *Easby* and *Hiss* have performed further experiments showing that the heart consists of several muscle bundles arranged spirally each with a specific blood supply and from which they strengthened the impression that impulse conduction of the heart beats is in and runs parallel to the fibers of the ventricular muscle bands. Injury to a muscle band by compression, by ligation of its blood supply or by transverse section, produces a result typical for that muscle bundle, namely various electrocardiographic changes of the coronary type.

Gross has prepared specimens with anatomically open but functionally closed foramina ovale in such a manner that he can regulate the pressure in the right and left auricles. He has observed that an increase of pressure in the right auricle greater than that existing in the

McGinn, Sylvester. — A Resident in Medicine, Massachusetts General Hospital. For record and address of author see "This Week's Issue" page 1219.

left auricle results in the passage of fluid from the right to the left auricle, however, a reversal of this shunt is not possible. It is believed that this probably explains the occurrence of paradoxical embolism in cases having functionally closed foramina ovale although patent to the passage of a probe.

III PHYSIOLOGY

Henderson and his associates believe that a third factor, in addition to the vasomotor nervous control of blood vessels and the pumping action of the heart, is necessary to the circulation. This is the force that sends the blood back to the heart through the venous system. They have found that a muscle in a state of tonus has an internal pressure of 50 to 70 mm of water. If a muscle is in a state of tonus, it takes up through its elasticity some of the force of the incoming arterial blood. The pressure increases the venous outflow from the muscle and facilitates its return to the right heart. In flaccid muscles the force of the arterial pressure is lost and the venous return is impeded.

Robb and *Weiss* have found that the injection of sodium cyanide intravenously gives a reliable index of the velocity of blood flow in the pulmonary and peripheral venous circulations. No strict correlation was found between the clinical manifestations and the aspects of the circulation studied. As a rule, the slowing of the circulation time was proportionate to the severity of the congestive failure.

Determinations of the heart volume and stroke volume during rest in normal and decompensated individuals have been made by *Lyscholtz*, *Nylin*, and *Quarna*. The heart volume was calculated from x-ray measurements. In healthy individuals of different sizes under standard conditions the index of heart to stroke volume is nearly constant, and appears to be a measure of the functional condition of the heart during rest. In cardiac insufficiency the stroke volume falls below normal, whereas the heart volume increases.

Schneider and *Crampton* determined the output of the heart of several subjects in both the reclining and standing positions. There was an increase in the cardiac output after fifteen minutes when the subject changed from the standing to the reclining position. *Starr* et al have made estimations of cardiac output and determinations of metabolism, blood pressures and pulse rates on healthy individuals and on hospital patients for the purpose of seeking relationships by which the condition of the heart muscle might be ascertained. The relationship between heart work per beat and heart size holds more closely than any other studied. It was found to be abnormal almost without exception in cases that had once been decompensated. In patients with neurocirculatory

asthenia the average cardiac output, stroke volume, and heart work per minute and per beat were far below normal.

Harrison and his associates have studied a group of patients with "evening dyspnea," which is described as the increased difficulty in breathing experienced by cardiac patients in the late afternoon and evening and is not to be confused with the paroxysmal type. It was found that the vital capacity was slightly lower and the oxygen consumption was ten per cent higher in the evening than it was in the morning. The respiratory rate was about fifteen per cent greater in the evening. As a result of animal experiments it was shown that the pulmonary afferent fibers of the vagus were very sensitive to pulmonary congestion and by reflex action stimulated the respiratory center. Because of increased bodily activity during the day it is thought that there is greater pulmonary congestion present at evening than in the morning and that this increase more readily irritates the nerve endings.

Gilligan and her associates found that the serum cholesterol value increased after total thyroidectomy and that the basal metabolic rate decreased. The most striking changes occurred by the end of the first postoperative month, although the serum cholesterol continued to rise gradually as hypothyroidism developed. The administration of thyroid resulted in an elevation of the metabolic rate and decrease of the serum cholesterol concentration.

Harrison has found a direct relationship between an increased venous pressure and the cerebrospinal fluid pressure in patients with congestive heart failure. As the patient improves and the venous pressure drops, the spinal fluid pressure also goes down. Removal of cerebrospinal fluid resulted in reducing the venous pressure in many of the cases, and in a majority of the patients there was a temporary decrease in dyspnea.

Interesting observations have been made by *Pickering* on the relationship between cerebrospinal fluid pressures and arterial hypertension. When the spinal fluid pressure was over 250 mm water in hypertensive individuals, the patients were noted to be younger, the kidneys badly damaged, and the prognosis was very poor. Older hypertensive patients had lower spinal fluid pressures, the kidneys were less severely damaged, and the downhill course was less rapid. Albuminuric retinitis was thought due to neuroretinal edema, inasmuch as only the patients with a cerebrospinal pressure of over 250 mm had these eyeground changes. There was no alteration in the pressure of the spinal fluid during headaches or acute attacks of coma. Some relationship is suggested between high diastolic pressures and high cerebrospinal pressures, although the latter seem unaffected by elevated systolic pressures.

IV PATHOLOGY

Before making a comparative study of the diameters of arterioles of patients with and without hypertension, *Morris* determined that there was no artefact due to the fixing process and none due to the physiological state of the vessel after death. The walls of the arterioles appeared to be definitely thicker in persons having persistent hypertension than in a control group without hypertension. However some individuals in the hypertensive group did not have thickened arterioles. This is believed to be evidence supporting the contention that arterioles become thickened after long periods of high blood pressure and that this thickening does not by itself produce hypertension.

By feeding cholesterol to rabbits *Leary* has been able to reproduce lesions very similar to those of human atherosclerosis. Evolution of the lesions through lipoidosis, lipid cell formation and fibrosis is much more rapid in animals than it is in man and consequently is more amenable to study. It is suggested that diets containing a high percentage of cholesterol may favor the atherosclerotic changes in the blood vessels. The paper contains excellent microphotographs illustrating the changes that have taken place in the vessels.

Schur has made an extensive review of the subject of adhesive pericarditis which has included a summary of the literature, the pathology and the pathologic physiology. From seventeen personal cases proved at autopsy he has noted the clinical signs which form a rather complete symptomatology for this condition.

Levine reports finding at the autopsy of a ten months old infant a heart weighing 150 grams associated with diffuse thickening of the endocardium of the left ventricle, calcification of the aorta, and stenosis of a portion of the left descending coronary artery.

An interesting case has been recorded by *Fischer* of a twelve and a half months old child whose heart showed rheumatic valvulitis at postmortem examination. The mother of the child suffered from polyarticular rheumatism at the third month of pregnancy and again at the fifth month postpartum. The case of a seven weeks old infant who died of bacterial endocarditis, the infectious process being superimposed on the mitral valve and in the absence of congenital lesions has been reported by *Tausig*.

Calvin and *Nichamun* have reported two cases of spontaneous rupture of the thoracic aorta in children. Emphasis has been placed on the importance of rheumatic fever in such cases inasmuch as this was the factor responsible in nearly one half of the forty four reported cases of aneurysm of the thoracic aorta in persons under eighteen years of age.

V ETIOLOGY

A Congenital

Muir and *Brown* have studied forty cases having the physical signs of a patent inter-ventricular septum. They encountered neither cases of heart block nor of permanent cyanosis, and believe that if either of these conditions is present, there must be an associated anomaly. The "maladie de Roger" has no characteristic x ray picture.

B Rheumatic Heart Disease

Rothschild and his associates feel that the majority of cases dying with heart failure in the first five decades and having a valvular defect are due to an active rheumatic infection rather than to the mechanical defect of the valve. Their conclusions follow the pathological study of one hundred and sixty-one cases dying with evidence of rheumatic heart disease. In the first decade active infection was present in 100 per cent of the cases, the percentage decreasing gradually to thirty-eight per cent in the fifth decade. Of the total number of cases fifty-five were quiescent, the youngest being found in the second decade.

Swift has directed attention to the varied symptoms indicating the chronic nature of rheumatic fever such as prolonged low grade fever, increased sedimentation rate and white count, and recurring arthritis. The greater susceptibility of individuals having had rheumatic fever to upper respiratory infections with consequent development of joint symptoms when ordinarily normal individuals overcome the infection without sequelae is further evidence of the chronicity of the rheumatic infection.

Perry believes from his study of the sedimentation rates of children with rheumatic heart disease that the condition must be considered active if the sedimentation rate remains elevated and no other cause likely to maintain such an elevated rate is found.

Fraser has presented four cases of acute rheumatism in which endarteritis of the coronary vessels was present, apparently due to the rheumatic infection.

C Subacute Bacterial Endocarditis

Although the protracted course of subacute bacterial endocarditis due to the streptococcus viridans is a common condition, an acute process with fatal termination due to the same organism is infrequent. *Held* and *Goldbloom* have reported four cases of acute and rapidly fatal streptococcus viridans endocarditis.

A review of three hundred and sixty-four cases of subacute bacterial endocarditis by *Weiss*, further confirms the general opinion that this disease most frequently follows infection of the upper respiratory tract.

D Angina Pectoris

To produce attacks of angina pectoris and to evaluate the severity of the attacks, a tol-

erance test has been devised, which consists of determining the number of trips a patient can make over measured steps located in a chamber with controlled temperature. *Riseman* and *Stein* have reported their results in using this exercise test which they found very helpful in judging the status of angina pectoris patients.

Wayne and *Graybiel* found that there was an average reduction of twenty-five per cent in exercise tolerance in six patients with angina pectoris following a heavy meal. Distention of the stomach, however, by the introduction of air had no effect on the exercise tolerance. It was concluded that in angina of effort the exercise tolerance was diminished after food, because of the increased energy expenditure of the heart rather than because of gastric distention. External temperature changes had no effect on exercise tolerance of the six patients. A case is described of angina sine dolore where the symptoms were of substernal pressure rather than pain. Electrocardiographic studies showed that during these periods there was present a rapid ventricular action very closely resembling fibrillation.

White and *Sharber* have compared the frequency with which alcohol and tobacco were used by seven hundred and fifty patients with angina pectoris and by a control group of seven hundred and fifty individuals of the same sex and age incidence but without angina pectoris. An analysis of their observations shows that neither the use of nor the abstinence from alcohol or tobacco has any definite significance in the etiology of angina pectoris.

The occurrence of angina pectoris and intermittent claudication in patients with pernicious anemia has been described by *Pickering* and *Wayne*. Among twenty-five consecutive patients with anemia, the hemoglobin being twenty-five per cent or less, eight had precordial pain brought on by exercise and relieved by rest. Seven of the twenty-five anemic patients had pain in the legs brought on by walking and relieved by rest. After the anemia was cured, only one patient had pain in the legs and two complained of chest pain. It is believed that the leg pain is the result of the accumulation of metabolites in the tissues due to incomplete oxidation and the anginal pain results from an insufficient oxygen supply to the cardiac muscle. The electrocardiograms of ten anemic patients showed only lengthening of the P-R interval in two cases which subsequently became normal when the anemia was corrected.

E Coronary Disease and Coronary Thrombosis

Because of the frequency with which the diagnosis of coronary occlusion is made, *Barkei*, *Wilson* and *Coller* cite four cases of upper

abdominal disease closely simulating coronary thrombosis. Two cases of gallbladder disease were erroneously diagnosed coronary occlusion, a third case of perforated gastric ulcer required intensive study to establish the correct diagnosis, and in the fourth case both cholelithiasis and coronary disease were present.

In a statistical survey *Enklewitz* has found that coronary thrombosis occurred twice as frequently in diabetic as in nondiabetic patients. Of one hundred diabetic patients beyond forty years of age, thirty-four showed coronary thrombosis and forty-five coronary sclerosis. An opinion is expressed that both coronary thrombosis and diabetes in individuals over the age of forty years are manifestations of degenerative vascular disease. In a series of one hundred and fifty cases of coronary occlusion, *Blumer* found the incidence of the use of alcohol and tobacco almost exactly the same as in a control group of one hundred and fifty patients without coronary thrombosis.

F Blood Pressure

Cushing has presented evidence suggesting that the source of eclampsia and essential hypertension may lie in the posterior lobe of the pituitary body. The activity of the posterior pituitary lobe is judged by the extent of basophilic cell invasion from the pars intermedia and an excessive infiltration of these elements represents the histopathological basis of eclampsia and essential hypertension. Further study along these lines may provide valuable information regarding hypertensive states.

Ayman failed to find hypertension associated with any of two hundred and forty cases of active tuberculosis. Investigation of the past and family histories and the postmortem examinations of hypertensive patients showed that the tuberculous infection had been present at some time in life. Tuberculin studies with various dilutions showed reactions in ninety per cent of a group of patients with elevated blood pressures and in ninety-one per cent of a control group with normal blood pressures.

Levine made a gross and microscopical examination of twenty-seven hypertensive hearts. All of the hearts had minute myocardial scars many of which contained varying amounts of elastic tissue. No correlation was found among age, sex, race, heart, weight, degree of blood pressure or the cause of death.

Adson and *Brown* sectioned the anterior spinal nerve roots on both sides from the sixth thoracic to the second lumbar in a twenty-nine year old woman with a blood pressure of 228 mm systolic and 156 mm diastolic. A report was made one month after operation, at which time the pressure was observed to be 168 mm systolic and 128 mm diastolic, when in the upright position. The effect of position was striking, the pressure always being lower in the upright

position than when recumbent. It is suggested that by lowering the blood pressure when the person is walking around, a certain strain is removed from the heart. The renal function apparently was unimpaired by the change in blood pressure.

G Cardiovascular Syphilis

Burnett and Rymer found associated cardiovascular disease to be present clinically in 319 per cent of two hundred and fifteen patients with neurosyphilis. Electrocardiograms were abnormal or questionable in forty-seven per cent of one hundred and sixty-four patients so studied. The authors were impressed by the incidence of coronary changes found in their series.

Four cases of angina pectoris have been reported by Van Muzden and Schoof, the cause of which seemed to be a syphilitic mesoarteritis in which the inflammation of the coronary ostia had produced a stricture. The prognosis of angina pectoris due to this cause is unfavorable.

Keefer and Mallory have reported twenty-two cases of aneurysms of the aorta complicated by pleural or pulmonary changes. These included atelectasis, bronchopneumonia, abscess, and bronchiectasis as the result of tracheal or bronchial compression of the lungs. Pulmonary tuberculosis occasionally accompanies aneurysm of the aorta.

H Thyroid Heart Disease

Lahey and Hurxthal have reported an operative series of three hundred thyrocardiac patients defined as patients with toxic goiter in which the outstanding feature has been cardiac disability. The mortality after operation was 4.25 per cent. Seventy-one per cent of the patients with auricular fibrillation were restored to and maintained in normal rhythm and compensation was restored in ninety-five per cent of the patients after hyperthyroidism was alleviated by a subtotal thyroidectomy. Preoperative therapy consisted in the administration of digitalis, Ling's solution, and diuretics as necessary. Quinidine is used to restore normal rhythm but not until the fifth postoperative day.

Ernstens and Mulvey found that seven per cent of patients with hyperthyroidism had auricular fibrillation before operation and that sixteen per cent developed it after operation. Postoperative auricular fibrillation usually appeared within the first sixty hours after operation without the occurrence of congestive heart failure and normal rhythm was usually re-established in forty-eight hours. The arrhythmia was more common in thyrotoxic patients having an adenomatous goiter than in those with hyperplastic goiter.

Lerman, Clark, and Means have added eighteen new patients to their original series of thirty myxedema patients in whom it was noted

that the size of the heart diminished after starting thyroid medication. Of the eighteen new cases fifteen had enlarged hearts, all of which, with the exception of one decreased in the transverse diameter 1.3 to 4.6 cm. after treatment of the myxedema was instituted.

I Pulmonary Heart Disease

Among anthracite coal miners Dyson found two hundred and thirteen cases of pneumoconiosis of which number eighteen had complicating pulmonary heart disease or chronic cor pulmonale. The condition he points out is not uncommon and can be diagnosed in patients with pneumoconiosis by the presence of a large right ventricle and pulmonary conus, and right axis deviation by electrocardiogram.

Churchill has offered three explanations for the cause of death after pulmonary embolism. First, immediate death may follow complete obstruction of the pulmonary artery due to cerebral anemia and failure of the respiratory center. Secondly, delayed death may be due to a condition resembling shock after partial obstruction of the pulmonary artery and thirdly, delayed death may be due to right heart failure as the result of partial obstruction of the pulmonary artery. Comments were made on the Trendelenburg operation or the surgical procedure for the removal of clots from the pulmonary artery on the basis of ten cases, none of which were successful.

Belt has observed that a high percentage of postoperative fatalities from pulmonary embolism shows evidence of minor degrees of cardiac incompetence.

J Miscellaneous

A review of four hundred and ninety-six cases of myocarditis which developed in four thousand six hundred and seventy-one diphtheria patients has been made by Hoyle and Welford. The death rate of diphtheria myocarditis they found to be sixty-two per cent, death occurring usually in the first fourteen days of the disease. The mortality was highest in cases of nasal diphtheria and of poor prognostic evidence were vomiting, abdominal pain and a falling pulse rate and blood pressure. It was thought that dextrose solution given parenterally definitely helped some of the cases.

An etiological classification of neurocirculatory asthenia has been made by Craig and White and an analysis has been made of one hundred cases of this disorder, fifty with organic heart disease and fifty without evidence of organic heart disease. Palpitation, respiratory discomfort, precordial aches and exhaustion are considered to be the four cardinal symptoms of neurocirculatory asthenia, and when associated with sighing respiration and precordial tenderness the diagnosis is almost

certain Radiation of the precordial discomfort into the left shoulder or arm is possible The diagnosis of neurocirculatory asthenia must frequently be added to that of an organic cardiac condition where symptoms of the former are present

In the opinion of *Warfield* no form of athletics other than college rowing injures a normal heart He cites the studies of *Deutsch* and *Kauf* who found that occasionally a heart would become dilated after some form of sport After rest the heart resumed normal size It was believed that these hearts had previously suffered some muscle damage, probably from childhood infection For this reason, it seems wise to be conservative in deciding when a child may resume activity after an infection Slight systolic murmurs at the apex without cardiac enlargement he considers to be functional Patients with valvular trouble are allowed freedom in activity within the limits of producing symptoms, providing there is no active infection present

Purks has compared the causes of death after operation of sixty cases having organic heart disease with sixty postoperative fatalities having no heart disease The first group of sixty deaths occurred in a series of four hundred and ninety-four operations on four hundred and fourteen cardiac patients and represents a mortality of 12.1 per cent and the second group occurred in sixteen hundred operations or 3.7 per cent Congestive failure was found not to be an important cause of death, but the cardiac group was more susceptible to pulmonary infections and to fatal coronary occlusion

VI SYMPTOMS AND SIGNS

Friedlander and *Levine* have studied thirty-five patients, thirteen of which had paroxysmal or transient, and twenty-two, permanent, auricular fibrillation Four cases of auricular flutter were also reviewed In no case was there evidence of organic cardiac disease, and it was concluded that these arrhythmias were of functional origin They represented six per cent of all of their cases of auricular fibrillation and twenty per cent of all those with auricular flutter The majority of the patients were males, there being only three women in the series, and most of the patients were under fifty years of age Quinidine sulphate is most successful in restoring normal rhythm but daily doses of both digitals and quinidine are helpful in diminishing the frequency of the attacks

McGinn and *White* have reviewed one hundred and twenty-three cases of aortic stenosis proved at autopsy and one hundred and thirteen clinical cases, and have reported their observations This valvular lesion was found almost as commonly as mitral stenosis, and the diagnosis could be made more frequently if it

was considered The majority of the cases had calcareous deposits in the aortic valves, both superimposed on old rheumatic infections and occurring singly It appears justifiable to make the clinical diagnosis of aortic stenosis when a harsh systolic murmur is heard in the region of the second right interspace and in the absence of dilatation of the aorta An aortic systolic thrill, diminished aortic second sound, or a plateau pulse, are helpful confirmatory findings but need not be present to make the diagnosis of aortic stenosis

Following a clinical pathological study, *C E White* has concluded that arcus senilis does not occur in a sufficiently high percentage of older individuals to be considered a sign of senility, and because of the low percentage of occurrence in various forms of arteriosclerosis, it can hardly be indicative of that pathological condition

Further studies in optical recording of heart sounds or phonocardiography have been carried on in South America. *Menéndez* and *Orias* made such records on one hundred healthy medical students and observed third heart sounds in forty-two of the tracings and evidence of vestigial third heart sounds in eighteen others Auricular heart sounds were noted in fifteen cases, and in five, vestigial auricular heart sounds were found Invariably the third heart sound occurs during the last moments of the ventricular inflow phase, and it is thought that they are due to vibrations in the ventricular wall set up by the in-rush of blood from the auricles

Battro, *Menéndez*, and *Orias* studied twenty-two cases with definite audible gallop rhythms by recording the heart sounds simultaneously with the venous pulse The timing of the sounds in the heart cycle was not constant, and varied especially with the heart rate It was thought that gallop rhythm resulted from the pathological exaggeration of phenomena present but inaudible in normal individuals Phonocardiography is in the process of development and may provide us with helpful clinical information that cannot be detected with the most careful use of the stethoscope

Following an analysis of the physical signs present in twenty-three patients with bundle branch block, *Lewis* concluded that the nature of the signs did not permit their use in diagnosing the condition of bundle branch block Records of heart sounds were made in all of the cases Reduplications of the first sound, a presystolic gallop rhythm, and a palpable presystolic impulse were found frequently Inasmuch as some of their patients did not have such signs and since they may occur in people without bundle branch block, their diagnostic value is small

In these times of complicated laboratory procedures and specialized medical centers, *Har-*

rison has made an opportune comment emphasizing the importance of obtaining the patient's history in discussing functional tests of the heart. The best index of the capacity of the heart to do work is the patient's story as to the amount of activity required to bring on dyspnea. The most reliable index as to the condition of the coronary circulation is the amount of work that can be performed without producing angina pectoris. Other signs are helpful in judging whether the capacity of the heart for work is impaired, but of less importance than the subjective symptoms of the patient are the presence of gallop rhythm, an enlarged heart, electrocardiographic changes, and a diminishing vital capacity.

King, Hitzig, and Fishberg observed three cases of left recurrent laryngeal paralysis following failure of the left ventricle. Postmortem examination with careful dissection of the recurrent nerve was made in two cases. They concluded that the left recurrent laryngeal nerve runs through a triangle bounded by the arch of the aorta, the left pulmonary artery, and the ductus arteriosus, and that the nerve can be compressed by a dilated and distended pulmonary artery resulting from failure of the left ventricle.

VII X RAY

Ihro has reported the results obtained in using the Stumpf kymograph in examination of the heart. He found the method useful in that it gave a more detailed study of the movements of different parts of the organ. Baird, Ling, Icy, and Palmer have reported the failure to obtain striking benefits in eight cases of severe essential hypertension treated by x-ray radiation of the pituitary and adrenal glands.

VIII ELECTROCARDIOGRAPHY

Acute distention of the right heart chambers of dogs was produced by Buchbinder and Katz by means of clamping the pulmonary artery and injecting metallic mercury intravenously. Electrocardiograms taken failed to show right axis deviation. When mercury was employed, aberrations in the ventricular complexes were due to short circuits between the intracardiac metal and extracardiac electrodes. Krumhaar reported electrocardiographic changes found after clamping the pulmonary artery of cats. Auricular-ventricular block, ventricular fibrillation, and changes in the P and T waves were observed. It was thought that the changes were due to increased intraventricular pressure.

Katz, Hamburger, and Schutz induced a general anoxemia by rebreathing in seventeen normal subjects and in six patients with angina pectoris. Although electrocardiographic changes took place, only two subjects with angina pectoris complained of pain. The elec-

trocardiographic changes consisted in diminution of the amplitude sometimes with inversion of the T waves and depression of the S-T segment. Because of the electrocardiographic changes in normal individuals as well as in patients with angina pectoris and the variability of the production of pain, induced anoxemia as a test for coronary disease is of questionable value.

McGinn and White have used the Lucas comparator to measure the durations of the QRS complexes of the electrocardiograms of one hundred and fifty normal and three hundred and fifty abnormal subjects. The average duration of the QRS complex in normal adults was 0.0777 seconds. Females and children under twelve years of age had average measurements slightly below 0.0777 seconds. In normal cases with duration times longer than 0.0900 seconds particular variations in the QRS deflections, such as upright Q or S waves accounted for the prolongation. A note was made concerning inconsistencies in naming the QRS deflections with suggestions as to changes in nomenclature.

Edeiken and Wolfert call attention to the poor prognosis of M or W shaped complexes of an amplitude less than 5 mm. found in lead two. Their cases have been divided into two groups, the first of which contained twenty-one cases, and of this number fourteen are dead, six are incapacitated by severe myocardial disease and one is untraced. Only two have lived more than three years after the M or W complex was observed. One tracing showed no other abnormal electrocardiographic finding. The second group contains twenty-five cases, of which number twenty had coronary occlusion, nine having died within two years. None of these electrocardiograms were normal in all other respects, although in eleven the changes were slight or inconclusive.

Koray and Katz injected ninety-five per cent alcohol into various areas of the ventricular myocardium of dogs. They concluded that the standard three leads cannot be used to differentiate injuries to the anterior and posterior walls of the ventricles, the right and left ventricles, and injuries to the basal and apical portion of the ventricles. No constant correlation could be made between the size of the injured area and the magnitude of the electrocardiographic changes.

Results of work done in further localizing areas of myocardial infarction in dogs' hearts by means of the electrocardiogram have been reported by Wilson and his associates. Ligation of the septal branch of the left coronary artery resulted in infarction of a large area of the septum. Electrocardiograms showed at first changes in the RS-T segment, later intraventricular or atrioventricular conduction disturbances, and all showed right bundle branch

block. They believe that the R deflection of the levoecardiogram is not of septal origin and that most of the endocardial surface is active before the first deflection is written.

Additional electrocardiographic evidence of coronary infarction that may occur without changes in the T waves and that remains either definite or regressed has been offered by *Wintemitz*. Necrosis of the anterior heart wall may be present when the R wave in lead one is small with deep S waves in leads two and three, or when the principal deflection of any lead is in the negative direction. Necrosis of both the anterior and posterior walls by two thromboses is suggested by the diminished amplitude of the main waves, although the smaller waves persist unchanged.

Barnes has reviewed eighty-four electrocardiograms of patients who had suffered acute myocardial infarction to determine the frequency of occurrence of the T_1 and T_3 changes described by *Parkinson* and *Bedford*, and the Q_1 and Q_3 changes described by *Wilson* and his associates. The former refers to the high or low origin of the RS-T segment in lead one, depending on whether there is anterior or posterior infarction. The opposite deviation of the RS-T segment is present in lead three. *Wilson's* classification is in reference to the presence or absence of Q waves in leads one and three, depending upon the position of the infarcted cardiac area. Although *Barnes* found the RS-T changes to be more typically developed, he feels most information can be obtained by considering both kinds of changes.

Durant has given the criteria to determine whether Q waves are abnormal. Excepting cases of right axis deviation, the Q wave in lead one is abnormal if it measures at least 1 mm and is at least one-fifth as large as the largest R deflection of any lead. Curves of the Q_3 type are defined as those in which the Q wave in lead three is at least half as large as the largest QRS deflection. Because of the permanent character of these changes, they are thought to be valuable aids in recognizing coronary disease.

Shookhoff and *Douglas* have questioned the significance and evaluation of the so-called Q_3 wave of the electrocardiogram as commonly interpreted. They found that in normal ventriculograms the Q waves of all leads corresponded in time, but that in the tracings with large Q_3 waves they did not correspond in the timing of the ventricular deflections. In fifty cases of this latter type the Q_3 wave was found in most instances to correspond either entirely or in part with the R waves of leads one and two. For this reason it is believed that the presence of a deep Q wave in lead three does not justify the assumption that a particular myocardial area is the site of disease and that it necessarily indicates coronary disease. They consider factors that change the relative posi-

tion of the ventricular musculature, as by rotation of the heart by a high diaphragm, the most important cause of the " Q_3 " wave.

In twenty cases that had come to necropsy after an acute myocardial infarction, *Barnes* found that fairly typical Q_1 and Q_3 changes corresponded respectively with anterior and posterior infarcted portions of the left ventricle and associated interventricular septum. However, not all acute infarctions of the left ventricle were followed by characteristic Q patterns.

Alterations in the T waves and in the S-T segments of the electrocardiograms of three patients with acute rheumatic fever have been observed by *Easby* and *Roesler*. Inversion of the T waves as seen in coronary disease and high or low origins of the S-T segment, both of which findings varied with the course of the disease, were noted. The literature has been extensively reviewed and they have found anatomical studies supporting the suggestion that such electrocardiographic changes are due to myocardial variations consequent to acute infection of the coronary circulation.

Bayley found that seventy of one hundred and seventy-three cases of bundle branch block had the less common type or right bundle branch block. He believes that right bundle branch block is more common than is usually thought and that bundle branch block is more frequently associated with arteriosclerotic heart disease than any other disease.

White has presented electrocardiograms of a patient having a recent coronary thrombosis superimposed on previous coronary disease, as indicated by left bundle branch block. After the more recent coronary occlusion, the T wave in lead three became inverted. Postmortem examination confirmed the suspected changes in the coronary vessels.

Barnes has found in a case of acute coronary occlusion with pericarditis that the RS-T segment is upright in all leads and so varies from uncomplicated cases. This difference should suggest pericardial involvement.

Lead four is thought by *Battio* and *Del Rio* to be helpful in establishing the diagnosis of angina pectoris. In four out of twenty cases of angina pectoris, lead four showed evidence of myocardial infarction, while the three conventional leads were practically normal. *Wood* and *Wolferth* have directed attention to the presence of large T waves in the precordial leads, as the result of observations on seven cases having the symptoms of coronary occlusion. These large T waves are obtained from only a small area of the precordium and disappear at a later date. They suggest that very large upright T waves indicate a lesion in the anterior portion of the left ventricle and very deeply inverted T waves in the precordial leads signify a lesion in the posterior surface of the left ventricle.

IX. PHARMACOLOGY

Scupham has found theochromine sodium acetate useful in the treatment of some early cases of thrombo angustis obliterans and intermittent claudication.

Van Laere and his associates produced cardiac dilatation in twenty-three dogs by diminishing their oxygen supply. The dilatation decreased after digitalis was given and when the dogs were again subjected to atmosphere deficient in oxygen, the hearts failed to dilate as much as prior to the administration of digitalis. It was felt that the drug acted directly on the myocardium and increased the tone of the muscle.

König has attempted to prevent postoperative thrombosis and embolism by the administration of synphrin tartrate a compound similar to and one-fiftieth as strong as epinephrin. The dosage is twenty drops by mouth or 1 cc. hypodermically three times a day for seven days. The patient also is given hot inhalations of carbon dioxide every hour for from four to six days. Comparative observations on four thousand five hundred cases showed satisfactory results. The incidence of postoperative thrombosis and embolism was reduced from 38 per cent to 10½ per cent and the pulmonary complications were reduced from 9.4 per cent to 3.4 per cent.

X. TREATMENT

1. Medical

Barack and Levy have again emphasized the beneficial effect of supplying oxygen to patients suffering from acute coronary occlusion. They used most frequently a concentration of fifty per cent oxygen. In the discussion of their paper, several points of interest were brought out, namely, that with a nasal catheter a concentration of forty-two per cent oxygen can be maintained in the inspired air, sometimes a concentration of oxygen as high as ninety-five per cent is necessary to relieve symptoms and occasionally the administration of oxygen succeeds in relieving the pain of acute coronary thrombosis when morphine has failed.

Marked relief of symptoms has been observed by *Sutton* in eleven cases of rheumatic pericarditis with effusion in which a therapeutic pericardial paracentesis had been done. From two cases of pericardial effusion that came to necropsy, it was learned that the distended pericardium almost reaches the posterior chest wall. This would seem to justify a posterior approach which can be done without penetrating the lungs.

Glickrist increased the ventricular rate by administering ephedrine in four of six cases with complete heart block. The normal dose was one-half grain every eight hours, and it has been given for as long as two and a half

years without harmful effect. He felt that barium chloride did not prevent Stokes-Adams seizures.

Evans and Hoyle have closely observed one hundred and twenty-two patients with angina pectoris to discover which of the many drugs they used was most efficacious in relieving or preventing the pain. Tablets of glyceryl trinitrate dissolved on the tongue were the most successful. When used before expected attacks it was frequently found to prevent them.

B. Surgical

The superior and inferior thyroid arteries have been divided and ligated by *Lyon and Horgan* with beneficial results. By this procedure they were able to lower the basal metabolic rate without producing myxedema, and so diminish the demands on the circulation.

Blumgart and Davis have described the procedure of completely removing the normal thyroid gland in the treatment of chronic heart disease. A hypothyroid state is induced which can be controlled by thyroid medication, so that the patients may be comfortable and still benefit by the reduction in cardiac work. Much relief has been given patients under the conditions of reduced metabolism, the symptoms of which are insignificant in comparison with the benefits derived.

Weinstein and his associates have concluded from their observations of nineteen patients whose chest pain had been relieved immediately after total thyroidectomy that this relief was due to interruption of afferent impulses from the heart. This relief was transient and not until the basal metabolic rate had been lowered was the chest pain permanently affected. The use of local anesthesia was thought unimportant, inasmuch as the immediate relief was also observed after the use of nitrous oxide anesthesia.

The group associated with *Blumgart* interested in totally removing the thyroid gland in cases of congestive heart failure and angina pectoris, has presented its criteria in selecting cases for the operation. Both the preoperative and postoperative treatment of the patients have been outlined. The results have been encouraging thus far, but the final appraisal of this therapeutic procedure awaits the observation of a larger group of patients over a longer period of time.

DeCourcy, DeCourcy, and Thuss believe that a relationship exists between hypertension and hypersuprarenalism. They liken overactivity of the suprarenal glands to overactivity of the thyroid gland in hyperthyroidism. In cases of hypertension they have been removing about two-thirds of each suprarenal gland in a two-stage operation. The beneficial effect on the hypertension is such that they advise this operation in selected cases.

Blalock has reported successfully suturing a wound produced by an icepick in the intrapericardial portion of the ascending aorta

THE INFLUENZA MENACE

Science reports that there is a possibility of an influenza epidemic in the United States this winter which is founded on the information received by the United States Public Health Service, that there are about five thousand cases of this disease in Honolulu. This epidemic started early in November.

The last big influenza epidemic, that of 1933 is reported to have started in Hawaii. It invaded the United States with a record of ninety thousand cases.

THE COMMUNITY FUND CAMPAIGN

The forthcoming Community Fund Campaign serving one hundred hospitals, health and social agencies in the membership of the Community Federation of Boston is receiving generous support from the physicians of Greater Boston. The goal set for the 1936 Campaign is \$3750 000.

This amount will not fully meet the needs of the welfare agencies which are members of the Community Federation, says Ripley L. Dana, general chairman of the Campaign "and these agencies will have to practise economies which to some extent will hamper them."

"But it seems more business-like to fix the goal at a figure which can be reached even though it is less than the agencies require, than to fix a goal at a figure which will meet the requirements of the agencies but which at the moment and under present conditions seems beyond the capacity of the community to provide."

I believe that \$3750 000 can be raised. It must be raised. I hope this amount will be largely oversubscribed.

The dates set for the 1936 Community Fund Campaign are January 26 to February 10. Dr. John F. Monks is Group Chairman and Dr. George C. Shattuck, Vice-Chairman, of the medical group.

DR. M. E. BINET WILL VISIT THE UNITED STATES

Dr. Binet, Vice-President of the Medical Society of Vichy (France) will visit the United States. The purpose of his visit is to extend an invitation to several American physicians to attend the International Congress of Hepatic Deficiency which will be held in Vichy in 1937 presided over by Professor Maurice Loeper, Professor of Clinical Medicine at the Faculty of Paris.

TUBERCULOSIS IN BROOKLINE

As part of the Seal Sale Campaign the Brookline Anti-Tuberculosis Society has made public, through the Health Bulletin of the Board of Health the following statistics:

"40 deaths 1897 population 17 000 8 deaths, 1934 population 50 000 253 possible cases, 1935 to be watched and prevented exposure to 80 children who have gone to summer camps annually for health and happiness. The Anti-Tuberculosis Society to help guard your health planned action to combat the disease."

INDEX

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

VOLUME 21

1935

The date of publication of any case may be determined from the case number. The first two figures of each case number indicate the volume number, 21. The third and fourth figures give the number of the week, dating from January 1. The last figure gives the case number for the week. For example, Case 21362 is the second case for the 36th week of Volume 21.

- Abscess of appendix with perforation 21212
 of kidney 21272
 of lung 21402
 anhidriphragmatic, with perforation into pleural cavity 21182
 Adenocarcinoma of esophagus, 21521
 of gallbladder 21061
 Adrenal amyloidosis of 21332
 Agranulocytic angina, see Blood
 Amebic granuloma of cecum 21312
 Amyloid disease of liver spleen kidney and adrenals 21232
 (See also Nephrosis)
 Anemia, aplastic, see Blood
 Aneurysm dissecting of aorta, 21042
 with rupture 21011 21041 21282
 mycotic, of aorta and heart, with rupture, 21231
 saccular of splenic artery with rupture, 21111
 Aorta, sclerosis of with ulceration and thrombosis 21031
 (See also Aneurysm)
 Appendix abscess of with perforation, 21212
 endometriosis of 21091
 Asthma, bronchial 21192
 Bant's disease, 21341
 Bile duct, carcinoma of 21061
 adenoma 21122
 stones in 21311
 stricture of 21361
 (See also Cholangitis)
 Blood diseases of
 Agranulocytic angina, 21372
 Anemia aplastic (benzol poisoning) 21301
 Leukemia osteomyelitis, 21352
 Myeloma, multiple 21012 21052, 21082 21371
 Polycythemia vera, 21381
 Purpura thrombopenic, 21381
 Brain glioma of (?) 21252
 Carcinoma of bile duct (papilla of Vater) 21061
 of gallbladder probable 21322
 of intestine, 21072 21262, 21391
 of kidney with invasion of ureter 21342
 of pancreas with extension to duodenum and generalized metastases, 21101
 of stomach 21111
 adenoma of bile duct 21122
 of intestine 21061 21061 21342 21371
 of ovary with invasion of the appendix 21092
 of pancreas tail with generalized metastases 21401
 of stomach 21121 21181
 of thyroid recurrent, papillary with metastases to lungs, 21432
 of uterus, 21432
 bronchiogenic, of lung 21181 21132 21222 21261
 21291
 granulosa cell of ovary 21191
 oat cell, of lung, with regional metastases, 21431
 Cholangitis acute nod chronic, 21361
 Cirrhosis see Liver
 Colitis see Intestine
 Diverticulitis acute 21442
 Diverticulum Meckel's ulcer of 21441
 multiple of descending colon and sigmoid, 21442
 Euccephalomyelitis 21421
 Endocarditis see Heart
 Endometriosis of appendix 21001
 of ovary 21091
 of uterus 21492
 Esophagus, adenocarcinoma of 21521
 sarcoma of leiomyoma with extension into and ulceration of mediastinal lymph glands, 21501
 varix of ruptured with hemorrhage 21172
 Fallopian tube leiomyoma of 21511
 Fibroma of ovary 21411
 Gallbladder adenocarcinoma of 21061
 carcinoma of 21332
 Glioma, questionable, 21052
 Granuloma, amebic of cecum 21312
 Gumma of liver 21171
 Heart
 Aneurysm of mycotic, with rupture 21231
 Coronary disease of periarthritis nodosa, 21461
 thrombosis, 21032 21422 21522
 Endocarditis bacterial acute 21451
 subacute 21141 21142 21231
 Hypertensive disease of 21241
 Rheumatic disease of endocarditis chronic
 aortic, with low mitral regurgitation 21152
 with stenosis, 21461
 without stenosis 21392 21451
 mitral with stenosis, 21142 21152 21392
 21461
 without stenosis, 21151 21451
 Stenosis aortic, calcareous 21231
 Hemochromatosis of liver 21251
 Histiocytic regional with perforation 21162
 Infarct of kidney total 21031
 of spleen 21031
 Intestine carcinoma of, 21262 21391
 with diffuse peritoneal metastases 21022
 adenoma 21061 21081 21342 21371
 colitis ulcerative, acute 21072
 chronic, 21071 21332
 diverticulitis, acute 21442
 diverticulum Meckel's ulcer of 21441
 multiple 21442
 Granuloma of amebic, 21312
 Histiocytic regional with perforation 21162
 Lymphosarcoma of 21472
 polyp of, multiple 21061
 tuberculosis of 21161 21311
 ulcer of duodenal acute with hemorrhage 21222
 obstructing 21402
 Kidney abscess of 21272
 amyloidosis of 21232
 carcinoma of with invasion of ureter and generalized metastases, 21242

infarct of, total, 21031
(See also Nephritis, Nephrosis, and Nephrolithiasis)

HOSPITALANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

FOUNDED BY RICHARD C. CABOT M.D.

TRACY B. MALLORY, M.D., Editor

CASE 21521

PRESENTATION OF CASE

First Admission A sixty-one year old white American artist was admitted complaining of pain in the right knee following an injury three days previously.

He had "heart trouble" eleven years before entry attributed by his physician to medication received for an attack of influenza which he suffered at that time. He had a left inguinal hernia for fourteen years. He had a "bad attack" of pleurisy at the age of fourteen. Two and a half years prior to entry he had an attack of sharp pain in the penis followed by hematuria. There had been no similar difficulty since.

His father died at seventy four of cardiac failure, the mother died at eighty-seven with jaundice. One sister had heart trouble.

Physical examination showed a well-developed and nourished man. The chest was emphysematous. There was an occasional squeak audible bilaterally. The heart was not enlarged; the sounds were regular and of fair quality. The blood pressure was 140/80. There were bilateral inguinal herniae, the right being larger than the left. There was tenderness and swelling about the internal condyle of the right knee.

The temperature, pulse and respirations were normal.

He improved with physiotherapy and massage and was discharged on the fifth day.

Second Admission, two years later for repair of the left inguinal hernia.

Third Admission, four months later.

He had been well until twelve days before entry, when while walking up a hill he suddenly developed a sensation of constriction about the thorax at the level of the heart. There was no radiation. He continued to walk became dyspneic, and developed tingling sensations in both arms and forearms. This persisted for twenty minutes and then subsided spontaneously. Three days later he was seized with a similar attack while sleeping. This was more severe and the tingling sensation was more marked in the left arm and hand. His physi-

cian gave him two pearls of amyl nitrite which afforded him considerable relief. He remained in bed for seven days but then arose for an anniversary dinner. At the table, while eating, another attack occurred which continued for four hours and was finally relieved by two hypodermics and six pearls of amyl nitrite. During the attack there was marked fear of death. He had no attacks after this but entered the hospital because of fear of recurrence. His weight which had been 170 pounds seven years before was now 140. There had been no dietary restrictions.

Physical examination showed slight puffiness of the lower lids. The sclerae were injected. There were leukoplakic spots on the tongue. There was a fatty tumor in the left posterior part of the neck. The fundi were negative. The apex impulse was neither seen nor felt. The left border of cardiac dullness was 10 centimeters from the midsternal line 15 centimeters beyond the midclavicular line. The sounds were regular but distant. There was a blowing systolic murmur replacing the first sound at the apex. The second sound was sharp. A_2 was greater than P_2 . The blood pressure was 140/85. The radials were thickened but compressible. A few inspiratory crackles were audible at the bases but disappeared quickly. The abdomen was protuberant. The hernia scar was well healed. The knee jerks were slightly exaggerated.

The temperature, pulse and respirations were normal.

Examination of the urine showed a specific gravity of 1.011 to 1.013. The sediment contained 15 to 25 white blood cells. The blood showed a red cell count of 5,000,000, with a hemoglobin of 80 per cent. The white cell count was 9,000, 67 per cent polymorphonuclears. A Hinton test was negative. An electrocardiogram showed a deeply inverted T_1 and T_2 ; P_1 and P_2 were notched. P_3 was inverted.

The x ray showed no significant change from that previously taken. The transverse diameter of the heart was 14.6 centimeters, that of the chest being 28.7 centimeters.

On the fourth morning directly following breakfast he had an attack similar to the others, with a sensation of congestion in the left arm and in the left posterior part of the neck. This responded quickly following the administration of one-hundredth of a grain of nitroglycerine. He was discharged on the twenty third day.

Fourth Admission, fourteen months later.

The patient had no further attacks of chest discomfort. He remained well until six weeks before reentry, when he became constipated and noticed that his stools were thinner and contained material resembling "shredded tobacco". There were no bloody or tarry stools. He began taking a laxative daily. A short time later he developed dull aching pain across the upper abdomen which occurred directly after

meals and lasted for about an hour. It sometimes recurred during the night but for the most part returned only two or three times a week. There was associated gaseous eructation. The pain was not definitely localized and was not very severe. Occasionally it kept him awake and the fear of initiating it prevented him from eating a regular diet. Gradually he developed a sensation of fullness in the epigastrium after meals and thought food did not pass. After five or ten minutes this was relieved spontaneously. He frequently avoided this sensation by drinking hot broth before meals. There was no nausea or vomiting. His weight decreased about ten pounds during this illness.

Physical examination showed that he had aged considerably and was poorly nourished. The skin was loose and flabby. The abdomen was scaphoid. The heart was slightly enlarged to the left but there were no other changes. The lungs were clear. The abdomen was negative.

The temperature, pulse and respirations were normal.

Examination of the blood showed a red cell count of 4,700,000, with a hemoglobin of 75 per cent. The white cell count was 13,000, 73 per cent polymorphonuclears. Examinations of many stool specimens were negative for blood. An electrocardiogram showed a split P_2 . T_2 and T_3 were inverted. There was slight widening of Q-R-S, a rather low voltage and a slight elevation of S- T_2 and S- T_3 .

X-ray showed a slight delay in the passage of barium through the lower end of the esophagus. There was no dilatation of the esophagus except when the patient drank barium rapidly. The fundus of the stomach protruded through the diaphragm at the esophageal hiatus. There was a diverticulum of the esophagus just below the aortic arch and a definite filling defect and constriction of the lower end of the esophagus due to a lesion 4 centimeters in length which apparently extended downward and involved the fundus of the stomach. The remainder of the stomach, pylorus and duodenum was negative. Three days later another x-ray showed dilatation of the lower third of the esophagus which included the diverticulum. The relief was irregular and there were bandlike areas of decreased density instead of the normal rugae. The entire area was soft and pliable except for the epicardia, which appeared to be rigid. There was a constant fleck about 3 millimeters in diameter in this region.

On the fourth day an esophagoscopy was done which revealed a hemorrhagic surface 11.5 centimeters from the front of the teeth. This bled easily when rubbed with a sponge. A specimen was removed for examination. During the second week the patient received repeated heavy doses of x-ray to the chest. He had little reaction to the irradiation but had considerable symptomatic improvement. The discomfort was relieved and he began to eat

a full diet. He was discharged one month after entry.

Fifth Admission, six weeks later

Since his last admission he felt very well, gained weight and continued to eat a full diet with no discomfort. Two days before entry he again developed a sensation of substernal discomfort while eating. Food appeared to "stick" for ten minutes. He retched considerably with no relief but finally took one-hundredth of a grain of nitroglycerin which gave complete relief.

Physical examination showed a partial compensation of his previous weight loss. The heart and lungs were unchanged. The liver edge descended about 3 centimeters beneath the costal margin with respiration. It was slightly tender but not nodular.

He was given another series of x-ray treatments and discharged without symptoms in three days.

Sixth Admission, ten weeks later

He remained quite well for about two weeks after his discharge but then began to vomit soft foods. Emesis became more frequent and for two days prior to reentry he was unable to retain anything. The vomitus contained food, mucus and a little yellow bitter material. There was rapid loss of weight and strength and the sensation of blocking was now felt higher up behind the sternum. His bowel movements were regular, once daily, with a laxative.

Physical examination showed considerable weight loss since the previous visit. The skin of the chest was browned and scaly. The blood pressure was 110/70. The remainder of the examination was unchanged.

The temperature, pulse and respirations were normal.

Examination of the blood showed a red cell count of 4,100,000, with a hemoglobin of 70 per cent. The white cell count was 9,000, 80 per cent polymorphonuclears. A stool examination was negative.

An x-ray showed a narrowing of the lumen of the esophagus at the site of the lesion. The esophagus remained filled while the patient was prone. In the upright position, however, the barium passed fairly well. The lesion was more sharply defined and appeared to involve the fundus of the stomach.

The patient was given further x-ray therapy. He refused other treatment and returned to his home in three days. He became gradually weaker, was able to eat less food and finally died two months after his final discharge.

DIFFERENTIAL DIAGNOSIS

DR. TRACY B. MALLORY: I have asked Dr. Means to start the presentation of this case and then turn it over when we come to the details of the esophagus to Dr. Mosher, who knows nothing about the case and will give a differential diagnosis from that aspect.

Dr. J. H. MEANS I will try to bring out the things that are important. This was a man I took care of in the Baker Memorial, followed through two diseases, and saw on Cape Cod last summer several times up to the time of his death.

The first admission had nothing to do with the final story so let us pass over it.

The repair of the hernia is of no interest at the present time.

Let us go to the third admission when I first saw him, and consider that briefly.

The weight loss had been very gradual and did not indicate any wasting disease. The story abstracted from the Baker Memorial record is fairly clean, but as I got it verbally I got a still more vivid impression that it was a classical picture of coronary thrombosis of a mild sort. When he came to the hospital there were no symptoms whatever. He was kept in bed for four weeks simply as a precautionary measure because we believed he had coronary thrombosis.

As I recall the cardiologist had thought the electrocardiographic findings were an indication of coronary thrombosis. He had another small attack of coronary pain in the hospital, not an impressive one, but yet a fairly typical attack of angina pectoris apparently. Since then he had no more symptoms of any kind pointing toward his heart, therefore we can set that aside as chapter one. Of course I saw the autopsy and I now know what this man had but I did feel at the time, as anyone would that he had had a small cardiac infarct. Subsequently I inferred that it was a well healed one because of the extraordinarily good result which followed. Chapter two has nothing to do with the coronary picture. When he came in the second time it was for a totally different disease. That is the one that interests us chiefly at present.

The history does not give us an accurate impression of this man's symptom picture. Doubtless this account was abstracted from the Baker Memorial history which the house officer took. I have no doubt that it is correct but it does not give the proper emphasis. The outstanding part of the picture was dysphagia. He had difficulty getting food down the esophagus into the stomach. This became apparent on talking with him. His sensation was of food sticking at the lower end of the sternum and after a time passing on into his stomach.

Am I right in supposing that this electrocardiogram still shows some evidence of coronary disease? Dr. Glendy?

Dr. ROBERT E. GLENDY Yes.

Dr. MEANS So although he had no symptoms pointing to the coronary and had carried on a fairly normal existence he still had electrographic evidence that something had happened to the heart over a year before.

We might let the x-ray men state their findings at this point to make it interesting. They were not in entire agreement.

X-RAY INTERPRETATION

Dr. AUBREY O. HAMPTON This is the lower end of the esophagus and a herniated portion of the fundus of the stomach. Complete filling is not possible in the upright position. He was lying on the table drinking out of a tube as rapidly as possible when this film was taken. The left side of the diaphragm is here, the stomach there, the stomach comes through the diaphragm up to here and thus we think is in the region of the cardiac sphincter. In this area near the cardiac sphincter there is a one centimeter fleck which we thought to be ulceration, and surrounding it is a large area of induration. There is also a diverticulum up here just below the arch of the aorta. I described this lesion as being rather unusual in that the ulceration was smaller than one would expect with a malignant lesion of this type. That is, the ulcer should be dish shaped and its margins should be nearer to the periphery of the filling defect, and for this reason was asked Dr. Schatzki to see this patient.

Dr. RICHARD SCHATZKI The x-ray examination seemed simple until this moment and became complicated as soon as I looked at the patient. The reason was this. There were those changes just described by Dr. Hampton, the small hernia of the stomach through the hiatus, a diverticulum, and just above the cardia was this area of rigidity with a small area of ulceration, or rather this small constant fleck, but there was also pathology higher up in the esophagus above the diverticulum almost to the arch of the aorta. Then the question arose as to what this lesion higher up was. In some of the pictures one saw definite band like areas of decreased density running through this region. It was rather difficult to combine all these facts, pathologic changes extending over at least the lower half of the esophagus with increased rigidity in the lower end of the esophagus.

I finally reported that I had never seen a picture like this. The upper part of the picture looked more like varices than anything else but it was difficult to explain the rigidity of the lower end of the esophagus by this diagnosis. I had never seen a patient with difficulty in swallowing due to varices but if at the time of the examination I was forced to explain all the anatomical changes by one diagnosis I would favor varices though it was impossible to exclude cancer.

DIFFERENTIAL DIAGNOSIS CONTINUED

Dr. HAMPTON He did drink a little alcohol did he not?

Dr. MEANS Yes within reason. He was an artist.

The next event was the esophagoscopy and

Dr Mosher is going to discuss the case at this point. He has had just the information that Dr D Campbell Smyth had when he did the esophagoscopy. The x-ray men were in some doubt as to what the lesion was and the suggestion was made by Dr Schatzki that he had esophageal varices, and the picture, as Dr Schatzki has said, is almost classical of that. There was no reason, however, that we could discover why he should have had esophageal varices. We had no evidence of cirrhosis of the liver.

Will you carry on, Dr Mosher?

DR HARRIS P MOSHER I am glad Dr Means said something about this man's being an artist and mentioned his being human because as Dr Means started out he implied that this was inconsequential from the scientific standpoint.

I was overcome with the elaborate history. It took half the morning to read it. I was very much pleased that the medical house officer missed the chief point, namely, that the man had difficulty in swallowing. This carries me back to my own house officers a little more cheerful than before I came over.

The chief feature in this case is that the man had difficulty in swallowing at his fourth admission, and in this connection he had abdominal pain. The examination by Dr Smyth was practically typical of carcinoma and the report on the biopsy was epidermoid carcinoma. Thus it was a perfectly straight case.

The x-rays as you saw, and as Dr Schatzki said, suggested varices. Dr Schatzki was enthusiastic enough to come over and watch Dr Smyth at the examination. He looked over Dr Smyth's shoulder trembling and said he trembled more when Dr Smyth took a specimen, thinking that Dr Smyth was going to get into trouble from hemorrhage. This did not happen.

The points I wish to speak about are the pouch and hernia of the diaphragm. A pouch at the level of the arch of the aorta is extremely common. It is usually due to a suppurative gland which has become attached to the esophagus and in healing pulls it out into a pouch. It gives few symptoms. They are easily found with the esophagoscope. These pouches usually empty themselves and so, from the clinical standpoint, amount to very little.

Herniation of the stomach through the esophageal opening of the diaphragm was discovered, as the older men know, by Dr Morrison of this city. Dr Jones has operated on quite a few of these cases by mobilizing the lower end of the esophagus, pulling it down and fastening it. These hernias are fairly common, especially after sixty years, and cause very few symptoms, and are no longer operated upon.

The patient was treated by x-ray and swallowed better for a short time. This brings up the question of the treatment of carcinoma of

the esophagus by x-ray. We have had two cases under treatment in this hospital with disappearance of the lesion. X-ray will cause the disappearance of the carcinoma, but the resulting fibrosis is apt to be a condition equally dangerous.

DR A. S. MACMILLAN My part will be limited to the showing of lantern slides on the relative frequency of carcinoma in patients with difficulty in swallowing. This slide was made from a careful study of 1,000 cases of dysphagia. It shows that carcinoma accounts for 40 per cent, and cardiospasm or, as Dr Mosher has correctly labeled the condition, fibrosis of the lower end of the esophagus is second in frequency with 15 per cent. Other lesions that are to be found in the esophagus are webs, pouches, paralysis, burns, and ulcers. Varices of the esophagus while they may account for profuse hemorrhage do not produce obstruction. In the general classification of the causes of death in the United States, according to the government statistics, carcinoma of the esophagus is low in the list, accounting for only 15 per 100,000, while 214 per 100,000 cancers occur in the stomach. Carcinoma of the esophagus occurs, as you would expect, at the same time as carcinoma in other parts of the body, the average age in our three hundred and eighty patients was sixty-seven, with very few in the third or fourth decade.

DR MEANS There is very little more to add. Dr Hampton gave this man a course of heavy radiation, as heavy as he knew how to give.

DR HAMPTON We gave him 8000r, 2000r to each of four fields 10 by 20 centimeters in size directed to the lower half of the esophagus. He had no discomfort from these treatments. As a matter of fact, he ate an elaborate dinner during the treatments and said he had some champagne, too. He felt quite well. Following these treatments the tumor in the esophagus did smooth out and we thought that there was less delay in the passage of barium through the esophagus, although there was not much delay in the first place. At the second entry after the x-ray treatment we thought the lesion looked the same as in the beginning. We gave him another series of treatments equal to the first and, so far as I can tell, without injuring his skin appreciably.

DR MEANS He went downhill rapidly with esophageal cancer and died. Gastrostomy, which was offered to him, he refused, I think quite wisely, and with morphia was made comfortable. He never had pain at all, had gradually increasing dysphagia, and finally got to the point where he was bothered with swallowing mucus, having that collect and being obliged to vomit it up. I talked to Dr Mixter about gastrostomy who said the chief reason for do-

ing it was to relieve the pangs of hunger. If they were troublesome, as they may be, gastrostomy offers relief. This patient did not complain of that and it was not necessary. He gradually became more and more emaciated and finally died of weakness.

CLINICAL DIAGNOSES

Carcinoma of the esophagus
Coronary heart disease

DR. HARRIS P. MOSHER'S DIAGNOSES

Epidermoid carcinoma of the esophagus
Diverticulum of the esophagus

ANATOMIO DIAGNOSES

Adenocarcinoma of the esophagus with metastases to the tracheal and esophageal glands and lungs
Diverticulum of the esophagus
Arteriosclerosis, marked, aortic coronary renal
Bronchopneumonia
Pulmonary congestion
Cholelithiasis
Cachexia

PATHOLOGIC DISCUSSION

DR. MALLORY. When the second phase of this man's illness developed the history was a fairly obvious one of cancer of the esophagus and I do not suppose there would have been any question of diagnosis at all if Dr. Schatzki had not been brought into the case. Dr. Schatzki found this quite extraordinary picture which was inconsistent with anything anyone had seen in cancer of the esophagus. The autopsy specimen shows very clearly why that was the case. We found an extensive tumor in the lower third of the esophagus, close to the cardiac orifice. Then the mucosa of the esophagus for the most of its middle third was elevated by papillary masses of tumor. Looking at it from the surface one would suppose that he was dealing with a papilloma of squamous epithelium, rather similar to what one sees in the bladder. Microscopic examination shows something entirely different, however. The tumor proves to be an adenocarcinoma although in places there is a little bit of cornification and you can call it adenocarcinoma if you want to. It is invading all layers of the esophageal wall, the submucosa, the muscularis, and the serosa. It crops up to the surface from below the various spots but even where these shaggy papillary masses are most marked there is a layer of normal epithelium above the tumor so the situation is exactly analogous to that seen with varices, a hidden mass in the

submucosa pushes the true mucosa upward and it is only reasonable that an x-ray picture identical with varices should have been produced.

With regard to the rest of the autopsy, we found almost complete occlusion of the descending branch of the left coronary evidently quite old and calcified, but we were not able to find any gross evidence of infarction of the myocardium.

DR. HAMPTON. The biopsy was taken eleven inches from the teeth. I think the large lesion that we first found was fourteen inches from the teeth.

DR. MALLORY. Adenocarcinomata are less common than squamous carcinomata and when found are usually at the lower end of the esophagus close to the cardiac orifice. I think there is little question that the tumor started close to the cardia and gradually worked its way upward through the lymphatics and perineural spaces possibly in part through the blood vessels.

DR. GEORGE W. HOLMES. Is this condition of extension by cancer up along the esophagus giving the appearance you describe generally known to pathologists?

DR. MALLORY. It certainly was not known to me. I had never heard of it. Do you know of any cases, Dr. Mosher?

DR. MOSHER. No.

CASE 21522

PRESENTATION OF CASE

First Admission. A sixty-nine year old white American woman was admitted because of an injury to the back following a fall.

Physical examination showed a rather obese elderly woman lying quietly in bed. The heart appeared to be normal. A. was greater than P. The blood pressure was 175/80. A few fine rales were audible at both lung bases. There was a point of tenderness over the eighth dorsal vertebral spine and marked spasm of the erector spinae muscles. No attempt was made to elicit spinal movement. All normal reflexes were present and unaffected. A sensory examination was negative.

An x-ray examination showed a collapsed fracture in the region of the fourth and eighth dorsal vertebrae.

A high back brace was applied and the patient was discharged on the fortieth hospital day still wearing the back brace and suffering no marked discomfort.

Second Admission, two years later.

The patient had been seen in the clinic many times following her discharge. She was treated there palliatively for complaints which concerned themselves for the most part with lower abdominal pain, cramps, constipation and painful stiff joints of long standing. She had been

seen at another hospital five months prior to her reentry where she complained of "chest pain, heart attacks, attacks of cough, and shortness of breath." Hospitalization was advised but the patient returned to her home.

At 3 00 a.m. on the morning of her reentry she was awakened by a severe pain in her epigastrium and lower chest, radiating to the region between her shoulder blades. There was also pain in both upper quadrants. The patient's condition was such that further details could not be elicited. The pain continued unabated until 7 30 a.m., when the patient came to the hospital in a taxicab.

Physical examination showed a poorly nourished elderly woman evidently suffering from considerable pain. She was restless and uncooperative, and her condition precluded further examination. There was no cyanosis. The heart sounds were of poor quality and were slightly accelerated. The blood pressure was 100/60. There was marked tenderness in both upper quadrants. It was particularly exacerbating on the left. The liver edge was thought to be palpable three centimeters beneath the costal margin.

The temperature was 98.6°, the pulse 90. The respirations were 20.

Ten minutes after examination the patient became intensely cyanotic, her neck veins became markedly engorged, and she died within a few minutes.

DIFFERENTIAL DIAGNOSIS

DR SYLVESTER MCGINN. On the first admission there are three points that stand out. One is that we can establish the normal blood pressure as 175/80. The second is that she was having early signs of congestive failure marked by fine râles at both lung bases. The third is an injury to two vertebrae.

"She had been seen at another hospital five months prior to her reentry where she complained of 'chest pain, heart attacks, attacks of cough, and shortness of breath.'" There is an important bit of evidence here. We would like to know what the chest pain was, whether it was precordial discomfort or the chest pain of angina coming on exertion, and what the heart attacks were like. Were they paroxysmal attacks of tachycardia or did they relate again to the anginal syndrome? The fact that hospitalization was suggested and advised makes me think that she had a considerable degree of cardiac involvement at the time. I think we must assume that.

In summary we have an elderly woman who had been definitely having attacks of heart trouble, probably with congestive failure and, I believe, with angina, having an attack at night and dying about five hours later. I think it is fair to assume that the attack she had at three o'clock was the beginning of the final

episode five hours later. There are abdominal symptoms with reference of pain to the mid-scapular region suggesting gallbladder disease. I do not believe that people can die that suddenly of gallbladder disease. A cerebral accident causing sudden death is another possibility. She had five hours to develop some kind of neurological symptoms and I think we would have been told if there were any present. Sudden death can come in aortic stenosis and I believe if she died from aortic stenosis we would have been given more information if murmurs had been present. Sudden death is observed in cardiovascular syphilis, either from involvement of the coronary vessels or rupture of an aneurysm. That is a possibility, but I think the three most likely possibilities are those of coronary thrombosis, pulmonary embolism or dissecting aneurysm. We have a real lead for dissecting aneurysm here, in that the pain is definitely referred to the midscapular region and if there is any one single point we have in looking for dissecting aneurysm of the aorta it is this presence of midscapular pain. Death was marked by venous engorgement. If she had a dissection beginning at three in the morning and rupturing five hours later I believe that she probably would have been bled out rather than have engorgement of the neck veins, unless there was a cardiac tamponade where rupture had taken place into the pericardium. In view of the past history, I do not think that is quite so likely as the two conditions that are left, pulmonary embolism and coronary thrombosis.

At three o'clock something happened to give her a definite drop in blood pressure from 175/80 to 100/60. She was not definitely cyanotic when she came into the hospital but that is not particularly against pulmonary embolism because with the initial embolus patients often go into shock and are seen without venous engorgement and without cyanosis. I do not know whether an embolus could occur so late from the effects of the neck injury, but it must be included. There is another possible location for a thrombus and subsequent embolus. The liver was three fingers down, indicating well-marked congestion and in any such case thrombi in the larger systemic veins are frequent and would provide sources for an embolus.

The final possibility is coronary thrombosis. It is an atypical condition where the pain is especially noticed in the abdomen and yet that can occur. A reference of the pain to the midscapular region would be consistent with a right coronary occlusion. I saw one case of coronary occlusion, occurring in the hospital, where all the symptoms were related to the lower abdomen, in the region of the pelvis, and it was some time later before the pain ever did get up into the chest. Rupture of the heart is strongly suggested by the terminal symptoms though

the time interval seems short. Again it is possible to have a pulmonary embolism after a coronary thrombosis as a result of a mural thrombus and yet five hours seems a short time for a clot to have formed.

I think, in view of the past history and believing that the attacks of chest pain were an aortic, that she had a coronary thrombosis, probably with rupture of the heart into the pericardium.

DR. GERALD BLAKE The contrast between the patient's appearance ten minutes before death and immediately after death particularly the engorgement of veins in the neck, suggest failure of the right heart. It is perhaps better explained by pulmonary embolism. But we have no story of previous infarction of the right heart, and it is too early for this attack to produce an embolus from a mural thrombus. My thought was that this patient had coronary thrombosis, probably in the right coronary.

DR. PAUL D. WHITE May I add a comment about rupture of the heart? It seems to me very unlikely if the coronary thrombosis which is the probable diagnosis here occurred at three a.m. that the heart could have ruptured that same day, the cases of heart wall rupture from coronary thrombosis that I remember generally occurred in the second week or between about five and seventeen days after the acute coronary occlusion.

CLINICAL DIAGNOSIS

Coronary thrombosis

DR. SYLVESTER MCGINN'S DIAGNOSIS

Acute coronary thrombosis, possibly with rupture of the heart into pericardium

ANATOMICAL DIAGNOSES

Coronary thrombosis with occlusion, fresh

Infarct of heart, old

Arteriosclerosis, marked Coronary, aortic, renal

Peritonitis, chronic, generalized.

Hydrothorax, very slight, bilateral

Pulmonary tuberculosis, healed, right apex.
Cholelithiasis

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY I think the earliest case of rupture that I have seen occurred three days after the thrombosis. They are usually later than that. This patient did show a coronary thrombosis but it was in the usual spot, the descending branch of the left coronary artery and not the right. There was no gross evidence of infarct of the heart, as you would expect in a case dying within four or five hours of the time of onset. It takes a definite length of time before degenerative changes become visible even microscopically several hours are required. The patient, like a good many cases of coronary thrombosis, had apparently had one before. We found one small area of healed infarction, an old fibrous scar evidently years old to which there is no lead whatever in her past history.

DR. MCGINN How long does it take for a mural thrombus to form and how long before an embolus can be given off? Can a fat embolus or clot arise from an injury two years old?

DR. MALLORY It seems unlikely without some succeeding, recent trauma. One does of course, from time to time see a sudden pulmonary embolus in a medical patient in whom there is no history whatever of phlebitis, and no lead as to the possible source of emboli. As a matter of fact small emboli, according to Dr. Belt of Toronto, are probably commoner in medical cases than in surgical cases. The very massive embolus that is rapidly fatal, however, seems to be pretty rare in medical as compared with surgical cases.

In regard to the rapidity of formation of a thrombus I do not know of any exact figures. I should guess that it would take forty-eight hours perhaps before the thrombus formed but that is nothing more than a guess and probably some little time after it is formed before it is likely to break loose and give rise to an embolus.

WHO IS INTERESTED IN RAISING THE STANDARDS FOR PRACTICE?

If the question concerning interest in raising standards of qualification for the practice of medicine in Massachusetts is phrased "Who is interested?" one finds signs of concern for or against such raising on the part of a few persons only. The Board of Registration in Medicine regularly puts itself on record by recommending to the General Court each year that the standards be raised. The Massachusetts Medical Society puts itself on record as favoring such raising. The proprietors of low grade medical schools, or their representatives, put themselves on record as opposed to raising standards. The members of the General Court apparently take little interest in the matter and express themselves as satisfied with the status in quo.

The opposition states that the Board is interested in increasing its own power, that the Medical Society is interested in limiting practice to

persons of whom it approves. In other words the "Haves" are trying to keep out the "Have nots." The proprietors of the objecting schools are seeking to preserve their vested interests since they are reported to be making money under present conditions.

But to whose interest is it that the standards of medical practice be raised? To the Board? Yes, because its prime function is to protect the public against incompetent practitioners of medicine, and its members know that mere graduation from a medical school is no guarantee of competence. To the medical profession? Yes, because it is a profession and its prime function is to render a service and not to make money. To the General Court? Yes, because its prime function is to make the laws by the administration of which the people of the Commonwealth are protected against incompetent practitioners of medicine. It seems to be satisfied with the status in quo because the legislators appear to be impressed by the persons who make the most noise, magnitude of noise directs their thinking.

The medical schools reported to be making money? Their answer is equivocal, no, in so far as they are interested in making money, yes, in so far as they are interested in education. The equivocation is due to the fact that medical education is expensive and costs more than students pay. Since actions speak louder than words, the interest in education becomes inconsiderable and the worship of mammon makes the welkin ring.

What is for the interest of the people, who are sick, many of whom, medically speaking, do not know their left hand from their right? Should they not have the best medical care there is? Is not every human being entitled to the best possible medical care? Yes, and the problem is the practical one of making it available.

If raising the statutory standards for admission to the practice of medicine will actually improve medical care in the state, what justification is there for not changing the statute? Should revenue derived from giving an inadequate medical education be allowed to stand in the way of better medical care for the people of Massachusetts?

But who lifts a voice that can be heard all over the state on behalf of the sick of the state? The Board mildly recommends. The Medical Society mildly approves the recommendation. The General Court is complacent since the people do not speak for themselves. Who will be a Moses to this people?

PRACTITIONERS, WAKE UP!

IN June, 1935, upon the recommendation of the Committee on Public Relations of the Massachusetts Medical Society, the Council of

the Society voted to urge the various boards of health and health officers throughout the Commonwealth to refrain from establishing clinics and doing immunization work against diphtheria for people who are able to pay for that work, except in cases of emergency.

At the same time upon recommendation by the same committee the Council voted to urge the practitioners of medicine to organize for immunization work at an appropriate cost to the public.

In making these recommendations, the committee felt that on this program the practitioners would be stimulated to be more of a force in the problems of preventive medicine and the patients would be better served in having this work done by the family physician.

These votes have been spread throughout the Commonwealth and already some misgivings have been voiced by health officers that this immunization work against diphtheria will diminish if the health officers do not continue their clinics for this work. The figures which are obtainable suggest that where at the request of the practitioners the health authorities have not done this work, the immunization work is not done. Another feature of this problem is that there is the need of educating the public in regard to the value of this work and experience indicates that persuading an individual to adopt a new idea is more difficult if there is expense attached to it.

If the health officers are going to give up immunization against diphtheria the practitioners must not simply immunize those who apply but must aid in educating the public in regard to the importance of eliminating diphtheria from the Commonwealth. An aggressive attitude rather than a passive one toward bringing patients into physicians' offices for this work should be organized and pronounced ethical arrangements should also be made so that patients may receive this immunization at a price commensurate with their ability to pay. Unless the practitioners wake up and do this work, the misgivings of health officers will be justified and the work should be turned back to them.

It is of interest to note that the physicians of Boston as represented by the members of the Middlesex South, Norfolk and Suffolk District Societies have already organized to offer opportunities for immunization at a rate much below the usual price of office visits and that the health officers of the City are urging the patients to go to their family physicians for this work.

Let us hope that this experiment will succeed and that throughout the Commonwealth the practitioners and health officers will cooperate in developing similar programs.

PYELITIS AND PREGNANCY

The past two decades have contributed materially to our knowledge concerning, and management of, nontuberculous infections associated with pregnancy. They still remain in two major divisions, namely, infections present during gestation and infections which follow delivery.

Both subdivisions are influenced by the physiological changes in the bladder, ureters and pelves, which are generally admitted to take place to some degree, in all pregnant women. These changes modify the incidence of infection during the pregnancy. They occur in approximately one and a half per cent of all pregnant women, which is well above the incidence of such infections in nonpregnant women. They also modify the character of postdelivery infections if they occur, as they usually do, before the retrogressive changes in these organs, which begin immediately after delivery, have had time for completion.

The changes which occur in the bladder and urethral walls during pregnancy apparently are of little significance. Residual urine is absent except with cystocele or gross urinary pathology. Malformation of the bladder from pressure of the uterus produces nothing worse than a benign form of frequency, which is free from symptoms of stranguria. It is worthy of remark that burning and painful voiding is less common in these bladders, when infection is present, than in the nonpregnant. Absence of this symptom confuses differential diagnosis in many cases of fever.

Changes in the upper urinary tract, due to pregnancy, are of great significance in modifying the symptomatology and management of infections which occur either in the course of pregnancy or immediately after delivery. The characteristic deformity is dilatation of the upper two thirds of the ureters and the pelves. The midportion of the ureter is carried laterally and redundancy of ureteral length is taken up in kinking near the renal pelvis and near the pelvic brim. The pelvis dilates extensively and rounded calyces are often noted which suggest a long-standing condition, but which return to normal in the course of the retrogres-

sion which follows delivery. Deductions made from pyelography, performed during the stage of dilatation, are unsafe findings on which to do radical surgery. These dilatations are accompanied by atony which accounts for the often painless character of the condition and the persistence of dilatability after delivery without the usual pain response to overdistention, so noticeable in the normal kidney. Atony may also be responsible for the severity of postpartum infections of the kidney since edema of the more nearly unchanged lower portions of the ureters may produce retentions in the dilated portion and pelvis above.

While hematuria marks the onset of pyelitis in pregnancy, in a sizable group of cases, and others show only fever and pyuria, dull renal pain, fever, nausea and rapid pulse, with or without bladder symptoms, are the usual symptoms. Acute appendicitis and pelvic peritonitis constitute the common differential diagnosis. Pelvic peritonitis increases in importance in differential diagnosis in the postpartum infections. The white cell count is usually in the neighborhood of 15,000 in urinary infections and higher in the other diseases but is not always reliable.

The state of nutrition and secondary anemia are important considerations both as to incidence of infections and their management. Transfusions are not used in the course of pregnancy as treatment for anemia in most clinics but are freely used in the postpartum stage. Blood-building diet and preparations of iron will suffice in most instances to combat anemia in pregnancy when coupled with proper urologic measures where required.

The treatment of pyelitis in pregnancy should begin with the pregnancy. Where free ingestion of fluid is practiced with all pregnant women, those infections which occur are less toxic in character. Ten to fifteen glasses of water daily are advised. The onset of infection in patients with low fluid intake is quickly marked by severe degrees of toxicity and with sustained nausea. The patient quickly becomes seriously ill and unresponsive to treatment by any means until fluids have been restored in large quantities by other means.

Rest in bed, forced fluids and alkalinization by oral or rectal means are adequate measures for handling the majority of infections in pregnancy. Elevation of the foot of the bed and changing the patient from one side to the other have proved effective in both the pregnant and the nonpregnant in shortening the febrile period. Sixty grains of potassium citrate is adequate alkalinization for the average case. PH determinations on the urine will control the medication.

If conservative measures do not produce evidence of beginning subsidence of pulse and

*A series of short selected articles by members of the Section is being published weekly.
Comments and questions by subscribers are solicited and will be discussed by members of the Section.

temperature by the fourth day, cystoscopic measures should be considered. Of the two signs the pulse is a more reliable indication of the patient's condition than temperature. Beyond the fourth and fifth days patients are more resistant to treatment by cystoscopic measures.

Cystoscopic treatment, early in the infection, is productive of prompt amelioration of symptoms when it consists of nothing more than emptying the pelvis allowing them to drain for fifteen to twenty minutes and washing them clear of pus with a bland solution such as two per cent boric acid solution. If symptoms recur, this can be repeated at three day intervals. Cystoscopic treatment can be expected to fail in the long standing septic case of weeks or months' duration. Injuring ureteral catheters are not required in cases treated early in the disease. They have several disadvantages, they require special and constant care to prevent plugging with pus and mucus they are painful for the patient, and produce edema of the lower ureteral segment by their presence. After removal this edema is in itself obstructive.

There will be found a few intractable cases which are best treated either by interruption of the pregnancy or surgery. Unless there is some unusual reason to the contrary interruption is advised. The insertion of a pezzet tube in the pelvis, which can be worn throughout the remainder of the pregnancy, will preserve the first pregnancy but becomes less attractive for subsequent infected pregnancies should they occur. These sinuses heal promptly after delivery.

Postpartum bladder dysfunction is closely associated with postpartum pyelitis. Perfectly adequate and timely management of the bladder after delivery should theoretically abolish postpartum pyelitis. This is not easy to accomplish. Trauma to the bladder at delivery and probably other factors result in either complete retention of urine or overflow from a residual. In palpation of the abdomen it is not easy to differentiate the bladder and the uterus immediately after delivery. When in doubt catheterize. Frequent voiding of small amounts of urine indicates residual. Bladder management is carried on by one of two adequate measures intermittent catheterization or constant drainage. If infection exists previous to delivery constant drainage with the pezzet type of catheter (not soft winged catheters) is preferable to intermittent catheterization. The onset of retention will often produce symptoms of pyelitis within a few hours in the infected case, but in the uninfected case infection must be introduced and time allowed for its development before a pyelitis is apt to occur. If uninfected catheter relief should be tried for either residual or retention for a period of four or five days. In those cases in which the residual or retention is not allowed to exceed twenty to twenty

five ounces fevers seldom occur. Catheterization must be controlled by the fluid output rather than the clock. Bladders which distend to large urine content between catheterizations have little chance to overcome atony. If constant drainage is placed it should be left undisturbed for five days. This period has been determined empirically. After removal the bladder should be checked for residual. If large the catheter should be replaced for an other five-day period. Two to three ounce residuals are usually handled safely by the patient but should be watched. Constant drainage is preferable for the resistant case because it requires less constant exercise of judgment to insure against inadequate emptying of the infected bladder.

Intravenous pyelography is eminently satisfactory in pregnancy and the puerperium. It should be resorted to early in pregnancy, where there is any suspicion of preëxisting pathology in the urinary tract. It is safer for both mother and child to carry a patient through pregnancy with known handicaps present than to try to rush to a diagnosis as an emergency, after trouble has arisen. Early diagnosis of preëxisting pathology can be made without undue x ray exposure at any time in pregnancy.

In the majority of instances the patient will complete the pregnancy safely. If this is to be accomplished at the cost of destroying one or both kidneys, there must be an accounting of values preferably made as early as possible in the pregnancy. Where the lesion is producing no real damage it can be remedied after delivery. This applies to most stones. Pregnancy cases tolerate any urological operation well if liberally supplied with morphine during convalescence.

Pure cystitis, without renal involvement following intermittent catheterization or constant drainage for bladder atony is usually bacteria and pus free in thirty days. The average renal infection is free in four months. Failure to clear in that time under treatment should lead to cystoscopic investigation. It is assumed that the general condition of the patient, anemia, social aspect of her life and formalin bearing drugs given with a urine having a pH of at most 5 have already been considered and proper relief measures applied.

It is unfortunate that symptomatic recovery so readily follows delivery. Unless the patient is bacteria free, an infected subsequent pregnancy is practically assured.

OUR RESPECTED SENIOR FELLOW

In 1863 Dr Edmund Horace Stevens of Cambridge Massachusetts joined the Massachusetts Medical Society and on January 2 1936 will celebrate his ninetieth birthday.

It is eminently fitting that the members of the

Society should take cognizance of the record and influence of this, our Senior Fellow, and do him the simple honor of a brief reference to his accomplishments

Dr Edmund Horace Stevens was born January 2, 1846, at Stanstead, Quebec, Canada, the son of Dr Horace and Louisa Mann Stevens. Both his father and mother were of old New England stock, their forbears having come to Massachusetts between 1630 and 1640. Dr Horace Stevens had graduated from the Vermont College of Medicine in 1842 and settled in Stanstead shortly after that. In 1848 the family moved to Skowhegan, Maine, and there Dr Edmund H. Stevens lived through his boyhood, attending the local schools and Bloomfield Academy.

In 1861 he entered Dummer Academy in South Byfield, Mass., and remained there until early in 1863 when he was forced to leave school on account of ill health. At that time he, supposedly doomed to an early death from tuberculosis, was put in the care of Dr Henry I. Bowditch. He remained in Boston in Dr Bowditch's care and in the fall of 1863 registered as a student under Dr James Harlow and began to attend lectures at the Harvard Medical School. In May, 1864, he enrolled in the Navy as medical cadet and was assigned to the U. S. S. *Philippi*, attached to Farragut's fleet. In August, 1864, at the Battle of Mobile Bay, while under shell fire from the forts, he sustained a broken leg from a flying splinter and was invalided home.

In September of that year he formally entered the Harvard Medical School. In March 1865 he entered the Army as a contract surgeon and was assigned to duty to the Cavairy Post Hospital at City Point, Virginia, where his father was in command. He was mustered out of the army in July, 1865, and returned to Boston to resume his studies. He graduated from the Harvard Medical School in 1867 and in that same year was appointed Assistant Port Physician of Boston, stationed at Deer Island. He continued in this position until April, 1871, when he settled in Cambridge, where he has remained and practised ever since.

In 1886 when the Cambridge Hospital was opened he was the first Visiting Surgeon to go on duty and he continued to hold the position as Visiting Surgeon in that hospital until 1911, when he resigned and was appointed Consulting Surgeon which position he has since held.

He has been a member of the Massachusetts Medical Society since 1868, and was a Councilor from the Middlesex South District for about fifty years and nominating Councilor for many years. He has been a Fellow of the American College of Surgeons since its organization and one of the original members of the New England Surgical Society. He is also a member of the Boston Obstetrical Society, the New England Obstetrical and Gynecological Society and the Cambridge Medical Improvement Society.

During the World War he was a member of the

Volunteer Medical Service Corps and of the Medical Advisory Board for his district.

Of Dr Stevens' work both the profession and the laity have repeatedly testified. The writer recalls a statement of the late Dr Frederick C. Shattuck, when doctors were under discussion, that he, Dr Shattuck, would feel as safe in Dr Stevens' hands, if obliged to submit to a surgical operation, as he would with any other surgeon. Coming from this eminent teacher and practitioner anything further would be superfluous.

Dr Stevens' interest in the Massachusetts Medical Society is shown particularly in his disinclination to take advantage of the provision for retirement.

The *Journal* tenders its cordial congratulations to Dr Stevens for his long and successful service to humanity with the wish for many more years of active life.

THE DIRECTORY OF THE MASSACHUSETTS MEDICAL SOCIETY

This publication is being compiled with all available information up to January 1, 1936. The material will be in the hands of the printer immediately after the first of the year and the copies will be distributed as soon as possible.

MISCELLANY

CHANGES AT THE MASSACHUSETTS MEMORIAL HOSPITALS AND BOSTON UNIVERSITY SCHOOL OF MEDICINE

The Trustees of the Massachusetts Memorial Hospitals have announced the following important appointments to the Staff:

Reginald Fitz, M.D., to be Director of the Robert Dawson Evans Memorial Department for Clinical Research and Preventive Medicine, and Howard M. Clute, M.D., to be Chief of the Surgical Service. These two appointments, when considered in connection with the completion of the new wing at the Main Hospital, constitute an important accomplishment for the year 1935 and the Trustees and Staff are to be congratulated. These appointments to the Hospital Staff carry with them professorial rank in Boston University School of Medicine and, since the new wing will add materially to the bed capacity of the Hospital, the clinical teaching facilities of the School will be considerably enhanced.

Dr Reginald Fitz was born in Boston, received his A.B. degree from Harvard College, and his M.D. degree from Harvard Medical School in 1909. He served as house officer at the Massachusetts General Hospital and was later a voluntary assistant in the medical clinic of the Johns Hopkins Hospital. Following an appointment at the Peter Bent Brigham Hospital, he was an assistant resident physician at the Rockefeller Institute and later was an associate in medicine at the Massachusetts General Hospital. In 1920 to 1922, following an extensive army service in France, he was in charge of

the clinical section in medicine at the Mayn Clute in Rochester, Minnesota, and after his return to Boston was appointed to the Staff of the Peter Bent Brigham Hospital and was made Associate Professor of Medicine at the Harvard Medical School. He is a member of the Association of American Physicians, the American Society for Clinical Investigation and a Fellow of the Massachusetts Medical Society and the American Medical Association. He is a member of the National Board of Medical Examiners, a member of the Council on Medical Education and Hospitals of the American Medical Association and is Chairman of the Committee on Medical Education and Medical Diplomas of the Massachusetts Medical Society. His wide clinical experience and his interest in medical research and education make his appointment particularly significant at this time.

Dr. Howard M. Clute was born in Maine, received his S.B. degree from Dartmouth College in 1911 and his M.D. degree from Dartmouth Medical School in 1914. He served his internships at the Hitchcock Hospital in Hanover and the Boston City Hospital in Boston. For a number of years he has been associated with the Lahey Clinic of Boston and holds appointments on the Staffs of the New England Deaconess and the New England Baptist Hospitals and more recently has been Chief of the Surgical Staff at the Carney Hospital. He is a member of the American Urological Association, the New England Surgical Society, the Boston Surgical Society, a Fellow of the American College of Surgeons and the American Medical Association. Dr. Clute has been particularly active in the field of general surgery and has written on numerous surgical topics.

The new addition to the Massachusetts Memorial Hospitals completes a thoroughly modern plant with a unique arrangement of operating rooms and an up-to-date x-ray department. The private rooms and the facilities for patients of moderate means are particularly attractive.

TWO ADDRESSES BY DR. PHANEUF IN LOS ANGELES

Dr. Louis E. Phaneuf, professor of gynecology at Tufts College Medical School, addressed the Los Angeles Obstetrical and Gynecological Society on The Low or Cervical Cesarean Section on December 11, and on December 13 gave the annual address before the Los Angeles Surgical Society, his subject being The Surgical Management of Prolapse of the Uterus and Vagina.

AN HONOR TO DR. BARBARA T. RING

As one feature of the exercises during the meeting of the New England Physical Therapy Society at the Ring Sanatorium, an honorary life fellowship was awarded to Dr. Barbara T. Ring as a tribute to the late Dr. Arthur H. Ring and for their contributions to the activities of the Society.

RESUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR NOVEMBER, 1935

Disease	Nov. 1935			Nov. 1934	Average
	1935	1934	Age*		
Anterior Poliomyelitis	58	7	25		
Chickenpox	881	1324	1027		
Dog Bite	654	554	381		
Epidemic Cerebrospinal Meningitis	5	8	7		
German Measles	94	102	57		
Gonorrhea	476	596	553		
Lobar Pneumonia	248	382	291		
Measles	203	326	523		
Mumps	674	183	320		
Scarlet Fever	756	599	732		
Syphilis	464	390	344		
Tuberculosis, Pulmonary	257	281	313		
Tuberculosis, Other Forms	28	38	37		
Typhoid Fever	7	10	15		
Undulant Fever	2	3			
Whooping Cough	274	643	643		

Based on the figures for the preceding 5 years.

RARE DISEASES

Anterior poliomyelitis was reported from Belmont, 1; Beverly, 1; Boston, 9; Brockton, 5; Cambridge, 3; Canton, 1; Chelsea, 1; Concord, 2; Danvers, 1; Fall River, 4; Lawrence, 2; Lynn, 4; Malden, 1; Medway, 1; Melrose, 2; Methuen, 2; Middleton, 1; Montague, 1; Newton, 3; Revere, 1; Salem, 3; Somerville, 1; Swampscott, 1; Wareham, 2; Worcester, 5; total, 58.

Diphtheria was reported from Boston, 8; Canton, 1; Chelsea, 1; Chicopee, 5; Fall River, 2; Lawrence, 2; Lowell, 10; New Bedford, 2; Peabody, 1; Revere, 1; Somerville, 1; Taunton, 1; Weymouth, 1; Total, 36.

Dysentery (amebic) was reported from Cambridge, 1.

Dysentery (bacillary) was reported from Medford, 1.

Encephalitis lethargica was reported from Springfield, 1.

Epidemic cerebrospinal meningitis was reported from Boston, 1; Everett, 1; New Bedford, 1; Revere, 1; Worcester, 1; total, 5.

Malaria was reported from Abington, 1; Brockton, 1; Cambridge, 1; total, 3.

Paratyphoid fever was reported from Haverhill, 1; Tewksbury, 1; total, 2.

Septic sore throat was reported from Boston, 3; Chicopee, 3; Foxboro, 1; Lowell, 1; Shirley, 1; total, 9.

Tetanus was reported from Nantucket, 1; Taunton, 1; total, 2.

Trachoma was reported from Lexington, 1; Medford, 1; total, 2.

Trichinosis was reported from Brockton, 1; East Hampton, 2; total, 3.

Typhoid fever was reported from Chicopee, 1; Fall River, 1; North Andover, 1; Springfield, 1; Woburn, 1; Waltham, 1; Westport, 1; total, 7.

Undulant fever was reported from North Adams, 1, Pittsfield, 1, total, 2

There have been fewer reported diphtheria cases for the year to date than there were in the month of November, 1929

Typhoid fever remains well below last year's record low figure

Infantile paralysis continues to decline after a season of increased prevalence

Lobar pneumonia for the first time since March was reported at a lower level than for the corresponding month of 1934

Epidemic cerebrospinal meningitis occurred to about normal expectancy after a month of somewhat increased prevalence in October

Scarlet fever for the second consecutive month was reported at a higher figure than in 1934

German measles, measles, tuberculosis other forms, and chickenpox were not remarkable

Pulmonary tuberculosis remained below the five-year average for the month

Whooping cough continues to run low, while mumps maintains its increased incidence over last year

CORRESPONDENCE

DIATHERMY IN LOBAR PNEUMONIA

Editor, *New England Journal of Medicine*,

The article by Drs Wetherbee, Foley and Resnik, entitled "*Diathermy in Lobar Pneumonia*", published in the *New England Journal of Medicine*, October 24, 1935, has attracted the attention of men interested in the pneumonia problem. It has, therefore, seemed worth while to make a careful analysis of the data presented. As a result of such a study I should like to make the following points

- 1 The authors' plea for the use of diathermy is based in part on their belief that the specific pneumococcus antiserum has not been shown to be effective. They base this conclusion on the comparison of mortality rates for pneumonia at the Boston City Hospital in 1901 with the mortality rates reported by Dr Stewart in 1934. The City Hospital series comprised 900 pneumonia patients who were reported by Sears and Larrabee to have shown a mortality rate of 29.1 per cent. In 1934 Dr Stewart reported that the pneumonia mortality rate in hospital practice was still 28 per cent. The authors then conclude that "despite the ever-increasing use of serum and the advent of other newer methods of treatment, such as the oxygen tent, the death rate from lobar pneumonia is essentially what it was a generation ago." I do not feel that this is a fair evaluation of serum therapy. The serum is type specific, and can be used only for definite types of pneumococcus in

fection. At the present time its use is limited largely to Type I cases. Therefore, the only accurate measurement of its value is comparison of a group of Type I cases who have received serum with another group of Type I cases who have not received serum. Such figures are now available from the five-year study of the Massachusetts Department of Public Health, and are encouraging. Dr Heffron reports 406 cases treated in the first four days with the serum with a mortality of 10.1 per cent, while in 177 untreated Type I cases the mortality was 27.1 per cent.

- 2 In regard to the physiological changes which may be expected from the use of diathermy in pneumonia, the authors have not taken into account the very careful experimental work done by Drs Binger and Christie at the Rockefeller Institute for Medical Research.* Their experiments on animals and on three human subjects, while perhaps not conclusive, should be given an important place in the consideration of the use of diathermy in pneumonia. After using small thermocouples inserted into the consolidated lung they conclude that the accepted dosage of diathermy does not heat the lung above the temperature prevailing in the rest of the body. This conclusion is at variance with the statement in the article under consideration, which says "That heat causes dilatation of blood vessels with resulting local hyperemia can readily be observed on the surface of the body when any form of heat is applied to it. It is, therefore, not unreasonable to expect similar changes in deep seated tissues which are heated by diathermy, namely, the consolidated portions of the lungs in pneumonia."

- 3 But more important than the question of the value of serum, or the physiological results of diathermy, is an actual analysis of the cases presented in the "control" and the "diathermy" groups. A study of the tables brings out the following points

- A) The present series (36 cases) is so small that one is not justified in drawing any conclusions as to the effect of diathermy on the mortality rate. This point the authors realize.
- B) Although it was originally intended that the candidates for diathermy were to be alternate cases, in the actual series this plan was not carried out. For instance, from January twentieth through March seventh there were *two treated cases as against nine untreated cases*. In most years the mortality from pneumonia is high during this period, and four deaths occurred in the nine untreated cases.

*Binger, C. A. L. and Christie, R. V. J. A. M. A 81: (Aug 11) 67, 1928

From March eighth through May first, the time of year when mortality is not to be lower there were ten treated as against two untreated cases.

- C) The age group of the controls is definitely higher than in the treated group, the average age of the controls being thirty nine years (with only four cases under thirty years of age) whereas the average age in the group treated with diathermy is thirty-two (with ten cases under thirty years of age). Since age is accepted as a significant prognostic factor in pneumonia, this difference would weight the series in favor of the treated group.
- D) In comparing the mortality rate in the treated and untreated groups it should be noted that of the six fatal cases in the control group two had uremia and a third was a chronic alcoholic with delirium tremens and a nonprotein nitrogen of 80 mg. A fourth death was in another chronic alcoholic who had had three previous attacks of pneumonia and since it occurred thirty days after admission could not be considered a primary pneumonia death. It so happens that the diathermy group does not include any case with so grave a prognosis.

Before drawing any conclusions as to the effect of diathermy on the mortality rate in pneumonia, one must then look for a larger and more carefully alternated series. I realize that the authors are interested primarily in symptomatic relief, but their article does stress an apparent lowering of the mortality rate, and therefore must be evaluated partly on an analysis of the data presented on this point.

Sincerely yours,

DONALD S. KING, M.D.

DR. JOSEPH RESNIK EXPLAINS A CONFUSING SITUATION

December 16 1935

Editor *New England Journal of Medicine*

Similarity of names and addresses has caused confusion in the minds of some of my medical colleagues. I therefore wish to state that I am not connected with any gymnasium or health club, nor do I carry any contract medical work.

Respectfully yours,

JOSEPH RESNIK, M.D.

184 Bay State Road Boston.

RECENT DEATH

STRONG—THOMAS MORRIS STRONG, M.D. of 56 Penfield Street, Dorchester died at the Forest Hills Hospital Jamaica Plain December 17 1935. Dr. Strong was born in 1848 in Rosedale, New York and graduated from Rutgers College in 1868 and from the New York Homeopathic Medical College and Flower Hospital in 1871.

His first practice was at Flint, Michigan and he was later located at Ansonia, New York, Allegheny, Pennsylvania and Macon Georgia, before settling in Boston.

For six years he was superintendent of the Massachusetts Memorial Hospitals. His practice was devoted to the eye ear and nose with offices at the Hotel Iikley Huntington Avenue Boston. He was treasurer of the Massachusetts Homeopathic Medical Society for twenty five years and was a member of the American Institute of Homeopathy and the Surgical and Gynecological Society.

He was a Mason and a former member of the Society of Colonial Wars and the Sons of the American Revolution and the Boston City Club.

His widow Mrs. Ada M. (Hodgkins) Strong survives him.

NOTICES

FITCHBURG CANCER CLINIC

There will be a consultation cancer clinic January 8 at the Burbank Hospital 9 A.M. to 12 P.M. The consultants are Dr. Horatio Rogers, visiting surgeon to the Massachusetts General Hospital and the Pondville Hospital and Dr. Laugdon Parsons, visiting surgeon to the Massachusetts General Hospital and the Pondville Hospital.

Hope has been expressed that doctors will take advantage of this opportunity to be present with or refer by note any of their patients having cancer or suspicious of a malignant condition.

FITCHBURG CANCER COMMITTEE,

F. H. THOMPSON, Sr., M.D., *Chairman*

WALTER F. SAWYER, M.D. *Secretary*

HERVEY B. FITCHER, M.D.

CHARLES J. LASKETT, M.D.

BERKLINE R. PROCKWICK, M.D.

APPOINTMENT OF DR. C. R. ABBOTT

Dr. Charles R. Abbott of Clinton has been re-appointed to the position of Associate Medical Examiner of the fourth Worcester District.

FIRST INTERNATIONAL CONFERENCE ON FEVER THERAPY

The first international meeting on fever therapy will be held in New York City September 1936. The use of fever induced by physical and other agencies

as a therapeutic procedure has received universal attention in the past few years. The conference will aim to collect and crystallize available data in this field. Therapeutic, physiological and pathological phases of fever will be discussed.

The suggestion for this conference originated with a group of interested European physicians. Five national conferences have been held in the United States of America. The first three sessions met at Rochester University Medical School in 1931, 1932 and 1933. The fourth assembled at Columbia University College of Physicians and Surgeons in 1934. The fifth was held in 1935 at Miami Valley Hospital, Dayton, Ohio.

It is planned to translate abstracts of all the papers into French, English and German. In order to make the printed copies of the transactions available for the conference, it is necessary that manuscripts and abstracts be submitted not later than June 1, 1936. Those interested in participating are requested to make early application.

Further information concerning the conference may be obtained from the secretary

DR. C. A. NEYMANN

DR. W. M. SIMPSON

DR. S. L. WARREN

THE VAN METER PRIZE

The American Association for the Study of Goiter again offers the Van Meter Prize Award of \$300.00 and two honorable mentions for the best essays submitted on the goiter problem. This award will be made at the discretion of the Society at its next annual meeting to be held in Chicago, Illinois, on June 8, 9 and 10.

The competing manuscripts, which should not exceed 3000 words in length, must be presented in English and a typewritten double-spaced copy sent to the Corresponding Secretary, Dr. W. Blair Mosser, 133 Biddle Street, Kane, Pennsylvania, not later than March 1, 1936. Manuscripts received after this date will be held for competition the next year or returned at the author's request.

The Committee that will review the manuscripts is composed of men well known in the fields of research and clinical investigation of problems related to the thyroid gland.

The Association will publish the manuscript receiving the prize award in their annual Proceedings, and reserve a place on the program of the

annual meeting for presentation of the manuscript by the author, if it is possible for him to attend.

W. BLAIR MOSSER, M.D., *Corresponding Secretary*

REMOVAL

WALTER S. LEVENSON, M.D., announces the removal of his office from 371 Commonwealth Avenue, Boston, to 370 Commonwealth Avenue, Boston.

REPORTS AND NOTICES OF MEETINGS

NORFOLK DISTRICT MEDICAL SOCIETY

REPORT OF THE COMMITTEE ON VACCINATIONS,
IMMUNIZATIONS AND EXAMINATIONS OF WELL BABIES
AND PRESCHOOL CHILDREN

On November 12, 1935, conferences were held with Dr. Francis X. Mahoney, the Health Commissioner of Boston, and Dr. Charles F. Wilinsky, Deputy Commissioner of Health and Director of Child Hygiene and Health Units.

Both were anxious and willing to cooperate in the development of some practical method agreeable to the physicians of Boston which would make possible a greater participation by them in the program of preventive medicine.

They realize fully the economic problems confronting the medical profession and are mindful of the fact that undoubtedly some who come to the clinics of the Health Department can afford to obtain medical services in the offices of the family doctor.

They are mindful, however, that the health of the community is the responsibility of the Health Department and that the expenditures of the city for the maintenance of these services are justifiable and essential and should be continued. They regard these services as educational in their import and serve the doubly useful purpose of not only rendering preventive service but also for the stimulation of the public in a desire for preventive measures.

They are willing to cooperate with the medical profession in an effort to get people who can afford to pay to prefer to obtain the service on an individual basis from their family physician and suggest the development of the following plan:

- 1 That the County Medical Societies cooperate with the Health Department in the furtherance of health education and the stimulation of the public for greater demands for preventive services.

- 2 That the Medical Society circularize its members and advise them to set aside certain hours in so far as this is possible for the maintenance of preventive clinics including vaccination against smallpox and typhoid, immunization against diphtheria, examinations of well babies, preschool children, etc.

- 3 That a reasonable office fee be established not to exceed one dollar per visit for this type of service.

- 4 That acceptable educational literature sponsored by the County Medical Societies and the

Health Department be drawn up to be mailed by the family physician to his patients stressing the importance of this type of service and the willingness of the family doctor to render the same for his patients.

This plan patiently worked out and developed with sufficient time allowed for the laity to appreciate the advantages of this type of service will eventually result in a majority of people who can afford to pay preferring to receive this from the family physician leaving the clinics maintained by the Health Department available to those who cannot afford to pay as well as to those who have not been educated as yet to prefer the service from private sources.

On November 18 1935 a special conference was held at the Beth Israel Hospital. The following were present: Dr. Charles F. Wilinsky, Dr. Chauncy Frothingham, Dr. Robert L. DeNormandie, Dr. Frank S. Cruickshank, and Dr. Henry M. Landesman.

It was decided to have an official combined meeting of the Committees from the Middlesex South Suffolk, and Norfolk District Medical Societies with the Health Department officials in December to complete definite workable plans for those members of these Societies who wish to do vaccinations and immunizations for diphtheria and typhoid examinations of well babies, preschool children, etc.

H. M. LANDESMAN, M.D., *Chairman*

D. L. LIONBERGER, M.D.,

JOHN B. HALL, M.D.

MIDDLESEX EAST DISTRICT MEDICAL SOCIETY

A meeting of the Middlesex East District Medical Society was held at Bear Hill Country Club on November 27 1935 with Dr. F. O. West of Woburn as presiding officer and Dr. A. L. MacLachlan of Melrose as secretary.

At an excellent dinner Dr. Charles E. Mongan, President of the Massachusetts Medical Society was royally welcomed by all the members of the district society who were present in large numbers to greet him as well as the scientific speaker Dr. Howard M. Cline who presented a paper on Thyroid Disease.

Dr. Mongan discussed the medical aspect of the Social Security Act, and its disadvantages to the profession. He also presented the fallacies of unemployment insurance particularly as applied to this State which does not need this legislation, in his opinion. He stated that the proposed act has been sponsored by the social uplift workers without adequately consulting the leaders of the medical profession or getting their advice.

Dr. William R. Morrison, Chairman of the Committee on Arrangements, urged the members to reserve June 8, 9 and 10 for the next Annual Meeting and Dinner in Springfield. He stated that new members of the Society will be particularly welcome and older members are relied on to show their interest in the meetings and clinics.

FAULKNER HOSPITAL CLINICAL MEETING

The next clinical meeting will be held at the Faulkner Hospital on Thursday January 3 at 5 P.M. In addition to the usual clinical pathological conference Dr. Maurice B. Strauss will speak on Anemias in Pregnancy.

All physicians are invited.

WORCESTER DISTRICT MEDICAL SOCIETY

The January meeting of the Worcester District Medical Society will be held in Thayer Hall at the Worcester City Hospital, Worcester, Mass., on the evening of Wednesday, January 8, 1936. The full program is as follows:

6:15 P.M. Buffet supper

7:30 P.M. Business session and scientific program.

(1) Head Injuries—Types and treatment.

Dr. Benjamin T. Burley, Worcester

(2) The Roentgen Diagnosis of Abdominal Aorta. Dr. Philip H. Cook, Worcester

(3) The Treatment of Epileptics and their Relatives. Dr. Foster L. Vibber, Worcester

ERWIN C. MILLER, M.D., *Secretary*

ST. ELIZABETH'S HOSPITAL

INFANTILE PARALYSIS VACCINE MEETING

The next meeting of the Staff of St. Elizabeth's Hospital will take place at the hospital, 736 Cambridge Street (Brighton District), Boston, Friday evening, January 8, 1936, at 8:15 P.M.

PROGRAM

Address by John A. Kolmer, M.D., of Philadelphia, Professor of Medicine, Temple University and Director of the Research Institute of Contagious Medicine.

Subject: Infection, Immunity and Vaccination in Infantile Paralysis

Discussion to be opened by W. Lloyd Aycock, M.D., Director of the Harvard Infantile Paralysis Commission. Hons. Zinsser, M.D., Professor of Bacteriology and Immunology, Harvard University Medical School, and John F. Casey, M.D., Visiting Physician, St. Elizabeth's Hospital.

Physicians and medical students are invited.

NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held at the Peter Bent Brigham Hospital, Boston, Mass., Monday, January 6, 1936, at 8:15 P.M.

PROGRAM

I. Business: Consideration of revision of Constitution and By-Laws

II. Clinical

1. A Method of Determining Blood Volume. Dr. J. G. Gibson, 2nd.

2. Blood Volume Changes in Congestive Heart Failure. Dr. William Evans

- 3 Concerning the Mechanism of Hypertensive Crises Dr Michel Pijouan
 - 4 Hemopericardium as a Cause of Sudden Death Dr Marshall N Fulton
 - 5 The Early Diagnosis of Aortic Stenosis Dr Samuel A Levine
 - 6 Aortic Stenosis, Angina Pectoris, and Syncope Dr A. W. Contratto
 - 7 Is Digitalis Present in Body Fluids in Digitalized Patients? Dr Maurice A Schnitker
- All members and interested physicians are invited to attend

JAMES M FAULKNER, M.D., *Secretary*

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING MONDAY, DECEMBER 30, 1935
